The writer heartily agrees with Mr. Wilson in his preference in designing deep girders in the manner outlined by him, since a web 70 × 5-16 ins. or 90 × ⅜ ins. may be compared with the experimental girders as regards the ratio of depth to thickness of plate, and with a similar distribution of stress it is evident that cover plates in the top flange should be two panels longer than the corresponding ones on the bottom flange, and that rivets should be distributed in a manner calculated to secure the maximum efficiency of the material used instead of in accordance with a theory at variance with the practical conditions of the case.

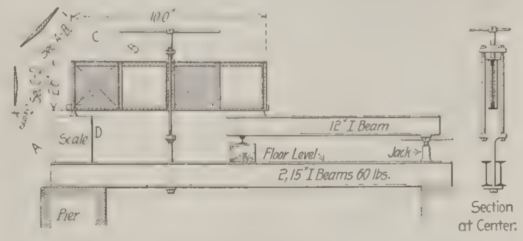

Fig. 1.—Sketch Showing Method of Testing a Plate Girder to Determine Nature of Web Stresses.

The thermo-electric measurement of stress is based on the fact that metal grows cooler on being stretched, and warmer on being compressed, and that the temperature change is proportional to the stress when this stress is well within the elastic limit. The amount of this temperature change may be closely determined by the following formula derived by Lord Kelvin,

$$H = \frac{tpe}{JSW}.$$

Where H is the thermal increase in degree centigrade; t, the temperature centigrade from absolute zero; J, the mechanical equivalent of the thermal unit; p, the pressure applied in pounds, positive if compression and negative if tension; e, the longitudinal expansion per degree centigrade, and W, the weight in pounds per foot of the bar. That the thermo-electric method of measuring stress is fairly reliable may be shown by reference to Fig. 2, the dotted line showing approximately the corrected curve. The readings for this curve were taken last winter by Mr. Frank McIntyre and the writer.

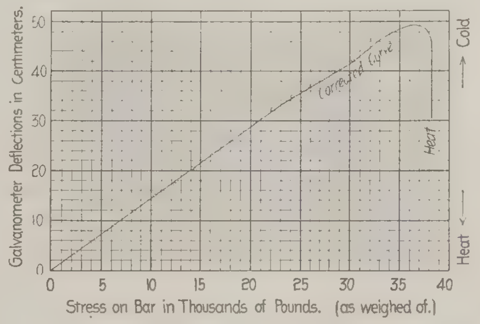

Fig. 2.—Thermal Stress Curve of Boiler Plate Steel Showing Accuracy of Results.

If in the laboratory the temperature change caused by a change in stress of less than half a pound per square inch may be readily noted, it would seem no impossible task to make fairly accurate measurements of stress on some of our railroad structures, and thereby obtain some definite information regarding the effect of the shock and impact of trains at high speed.

Where there are compound stresses, as in the web of a girder, compressive and tensile stresses acting as an angle with each other, the heat evolved by the compressive stress neutralizes an equal amount of cold produced by the tensile stress, and we can only measure the difference which is sufficient to give us a very accurate knowledge as to the exact distribution of stress in this case. Thus, in the girder shown in Fig. 1, a series of measurements were made on the web along the neutral axis of the girder, marked heating effect was found in the plate near all stiffeners, denoting compression, and cooling effect denoting tension in the center of all panels.

This last determination may be regarded as an elegant illustration of the truth of Proposition III., Chapter XV., of "Modern Framed Structures." This proposition is given by Professor Johnson as a fundamental principle of the distribution of stress, and is well stated as follows: "When there are two or more paths over which a load may travel to reach the support, the load divides itself among the several paths strictly in proportion to the rigidities of the paths." Now, in our plate girder the path of greatest rigidity would be the line diagram of a Pratt truss, with the stiffeners for the posts and the flanges as chords, since the plate under and near the stiffener, together with the stiffeners, is better able to resist the compressive web stress than the plate between consecutive stiffeners.

Yours truly,

C. A. P. Turner.

Minneapolis, Minn., Aug. 17, 1898.

(In accordance with our usual custom proofs of the above letter were submitted to Mr. Wilson, and we append his reply below.—Ed.)

Sir: I have read with interest the correspondence on my letter of July 19 (Eng. News, Aug. 11, 1898) in reference to spacing stiffeners in plate girders.

One correspondent claims that "cutting slits in the web entirely changes the conditions, just as would be the case with a Warren girder of two or more systems of web members if one of the systems were cut." Now a Warren girder is a triangular truss, pure and simple, and one of several intersections becomes a lattice (without vertical stiffeners). Each member is a necessity for equilibrium and has its determinate stress. The development of the Warren girder or lattice, by making "n" intersections equal infinity, gives the rolled I-beam or built girder without vertical struts, the web being of sufficient thickness to resist compressive forces effectively and contributing its share in an appreciable degree to the upper and lower flanges. I believe there is no difference of opinion as to the proper method of treating such a girder. The Warren girder, however, is not at all analogous to the case under consideration, of a plate girder with thin web, requiring vertical stiffeners. It appears to be claimed by at least one of my critics that the tension in one diagonal direction on the web, so stiffens it that, no matter how thin the web, it cannot deflect under compression in the other diagonal direction, and actually acts to resist as a short prism independent of its length, and, I presume, the plate is considered as doing double duty, or perhaps even more, resisting diagonally by compression in one direction and by tension in the other, horizontally by compression in connection with the upper flange and by tension with the lower flange, and vertically by compression with the strut. While not going so far as this, there are engineers who include a portion of the web with the upper and lower flanges and with the vertical stiffeners, perhaps even allowing some compressive resistance in the web in the diagonal direction, and the last clause in my letter covers this point; but I do not consider it good practice. What may or may not be allowed is so uncertain, depending on the judgment of the engineer, which is not always reliable, and the economy gained is so little, that, in comparison with the obtaining of a first-class structure, it is not worth consideration, and in my own practice I would not allow a design made under such conditions. Such "finesse" in bridge calculation may do to talk about in high theory, but it will not answer in practical work where simplicity is demanded, even at the expense of a few more pounds of material.

Let us take a girder of, say, 5 ft. depth, with vertical struts at distances of 5 ft., making square panels. The diagonal of this panel is, say, 85 ins., and for a 3-16-in. web the length of the column for compression is 453 times its shortest diameter, or if a ⅜-in. web is used it would be 226 times. How much compression would such a column resist without deflection? and what amount of tension is required, at right angles, to prevent such deflection? It may be theoretically studied out, but what practical man would depend upon the result even if he felt confidence in the theory, knowing, as he does, the imperfections of manufacture. If I read aright, this is what is claimed. Even Rankine, who has been quoted, does not do so. I have before me an old edition, but I presume the latter ones are the same, and he says:

> It is to be considered that the shearing stress at the neutral axis is equivalent to a pull and a thrust of equal intensity inclined opposite ways at 45°, and that the vertical web tends to give way by buckling under the thrust, so that its ultimate resistance in lbs. per square inch is given by the following expression:
>
> $$\frac{36000}{1 + \frac{s^2}{3000t^2}}$$
>
> in which t is the thickness of the plates of the web, and s the distance measured along a line inclined at 45° to the horizon, between two of its vertical stiffening ribs.

In the present case, $s = 85$ ins., and $t = 3\text{-}16$-in., and we find the ultimate resistance to be about 530 lbs., one-sixth of which is, by Rankine, safe, equal to 88 lbs. per sq. in.

It will be noticed that Rankine makes no claim that the tension in the other diagonal allows him to ignore the length of the column. I am familiar with what Stoney says on the subject (p. 155), and his remark that such modes of construction are, however, more or less defective; also, under Internal Braced Pillars (p. 337), when he refers to the lattice bridge and says:

> It is obvious, however, that long compression bars, even though formed of angle or T-iron, have but little stiffness in themselves, and we cannot trust to the tension bars keeping them in line of thrust at right angles to the former direction, for the tension bars may not always be in a sufficient state of strain.

It will easily be seen from the above figures what difficulties I labored under in my early engineering days in endeavoring to reconcile Rankine's method of calculation with the girders I saw in actual use.

It is customary in my own practice, and I presume also in that of others, to run the web through the girder in one piece, if it can be done, for the whole length of the girder; or if it must be spliced, it is done in the middle of a panel. The cast struts of former days were merely bolted through to keep them in place, and with wrought struts it is only necessary to rivet them sufficiently to secure them properly and firmly. The load on a strut is carried to the lower flange and by that distributed, as by a beam, of one panel length, to the web (center to center of panel), being resolved diagonally onto the web and horizontally on the lower flange. The diagonal stress is carried by the web towards the abutment to the upper flange, which also acts as a beam of one panel length, and it is resolved onto the next vertical strut and the upper flange, etc.

I have endeavored to enunciate what I consider a reasonable, practical method of computing thin web plate girders, without involving all the highly theoretical considerations which, while very beautiful, give litttle practical results of importance and may be entirely annulled by defects of manufacture. The short prism theory of resistance of web to compression I consider too uncertain to allow any practical dependence to be placed upon it where the lives of human beings may be placed in jeopardy.

I think if anyone will read that portion of my reply to the discussion on my paper on Bridge Specifications (Trans. Am. Soc. C. E., Vol. XV., p. 484), referring to plate girders, my position in the matter will be very clearly seen. Those specifications were written some years ago, and were among the first so published. Many changes and improvements have been made since then in my own work and specifications, as well as in those of others, but in this matter of plate girders my views remain the same.

Yours very truly,
Joseph M. Wilson,
M. Am. Soc. C. E., M. Inst. C. E.
Philadelphia, Pa., Aug. 31, 1898.

◆

Notes and Queries.

The address is desired of Mr. W. H. Wood, who was at one time a Locating Engineer for the Union Pacific Ry., and was later employed in government survey.

C. S. asks: "Assuming a quantity of air enclosed in a tight tank together with and above a quantity of water; how much of the air will be absorbed by the water at different degrees of high pressure, say 3,000 to 8,000 lbs. per sq. in.?"

The amount of air absorbed would depend on the volume of the water and the time during which it was exposed to the air, perhaps also on the temperature.

◆

THE RAILWAYS OF THE CRIPPLE CREEK, COLO., MINING DISTRICT.

By W. P. Hardesty,* C. E.

(With full-page plate.)

The Cripple Creek mining district is in El Paso county, Colo., the center being (in an air line) less than 20 miles southwest of Colorado Springs, which is on the main lines of railway between Denver and Pueblo. Perhaps no other mining region in the West is naturally so difficult of access as this. The elevation ranges from 9,000 to 10,000 ft. above sea level, and the district is surrounded on all sides but the west by high mountains. The summit of Pike's Peak is but nine miles to the northeast, this being the culmination of the Rampart Range, which separates the district from the plains country further east.

In 1891 attention was first drawn to the gold deposits of Cripple Creek, and within two or three years it was demonstrated that this was one of the greatest high-grade ore-producing districts in the world. The only communication with the outside world at first was by means of stages and freight wagons, the nearest railway point being Divide, on the Colorado Midland, 20 miles distant. The expenses of hauling supplies of all kinds from this station, and hauling out the ore, made it impossible during 1891 and 1892 to market ores that ran less than 2½ oz. in gold or $50 per ton. Nearly all of the product was shipped to the smelting works at Denver and Pueblo, and the cost of mining, transportation and treatment ranged from $30 to $35 per ton. In 1893 the output for the year reached $2,000,000, and it was seen that any railway reaching the district would have a very profitable business. In that year the survey for the first road, the Florence & Cripple Creek Ry., was made.

Florence & Cripple Creek Ry.

The locating engineer for this road was Mr. H. A. Sumner, who has had an extensive experience at such work in the West. The chief engineer is Mr. R. W. Stewart, with office at Florence. The road starts from Florence, on the Denver & Rio Grande Ry., and 32 miles west of Pueblo, and running northerly reaches the district at Victor, a distance of 34.6 miles. It continues on to the city of Cripple Creek, making its total length 40.3 miles. Construction was nearly all done during the first half of 1894, and on July 2 of that year the first train was run through.

The road is narrow gage, with a maximum grade of 4% compensated on curves at the rate of 0.02 ft. per 100 ft., and with a maximum curvature of 30°. There are many curves of this sharpness. It is a typical mountain road, and is one of the most recent examples of the class of mountain railways which were inaugurated by the Denver & Rio Grande Co. in the early '80's, and which so opened the eyes of the world as to the possibilities of railway location in rough country.

About eight miles from Florence the road enters Eight-Mile Canon, a narrow, tortuous channel that requires much skillful work to get through. The road as first built here lay along the bottom of the canon. During the first season an unprecedented flood came down the creek and washed out nine miles of track. The line was afterwards changed so as to run along the side, well above the creek, requiring much heavy construction on account of the difficult country. There are two short tunnels and a number of wooden bridges through this canon. The bridges often burn, so that the longest of them—a high trestle about 160 ft. to 180 ft. long, on the famous "Wilbur Loop"—has been lately replaced with iron to insure safety. This loop is made by the line doubling across the canon and running down the right-hand side of it till the summit of the ridge is reached, when it turns back and continues on its northerly course along the side of a different canon. The summit is reached at Alta Vista, only about three miles from Victor, and at an elevation of over 10,000 ft. The station at Victor has an altitude of 9,734, that at Cripple Creek is 9,396.

The track is laid with 45-lb. rails, which are being gradually replaced with 55-lb. rails. These weights for narrow-gage lines are greater than heretofore used. The engines are 40 tons weight; the passenger rolling stock is all new, but the freight cars were furnished by the D. & R. G. Ry. from its narrow-gage lines.

The Golden Circle R. R.

During the present year a road called the Golden Circle R. R. is being built from Victor to the town of Altman, on Bull Hill, which is said to be the highest town in America. The line goes directly past some of the largest mines in the camp, and the distance to Altman is about five miles, although it is but two miles by air line. Though different in name, the company building the railway is practically the same as the Florence & Cripple Creek Co. For the first mile or two there was much difficulty in securing right of way on account of other railway tracks crossed and in running close to certain mines, there being but little room to swing on account of the work being side-hill, and of the necessity of keeping up the maximum grade. It was necessary to pass through the dumping ground of the Portland mine—the largest producer in the district—and, on account of the enmity of the management of this mine towards the railway company, very stringent conditions were imposed in granting right of way. A covered way (to be gradually converted into a tunnel by the operation of dumping the waste from the mine) was necessary through the dumping ground, and, after considerable study, Mr. Stewart decided to make it of steel.

Steel Arch Tunnel.—The tunnel is of steel posts and arches resting on cast-iron piles. The width is 14 ft. and height 10 ft. to the springing line. The arch is semicircular with a 7-ft. radius. The piles on each side are spaced 8 ft. c. to c., except at each end, where it is 9 ft. The length of the tunnel is 242 ft. The piles are soft cast iron, 12 ins. outside diameter, 1 in. thick, and they were 6, 7, 8 and 10 ft. long, the average being 8 ft. A timber or log core was used in driving, the point of the pile being solid for about half its length. One or two were driven direct, by blows of the hammer on top. The tops were cut off even by a pipe-cutting machine. Cast-iron caps are put on top of the piles to receive the longitudinal I-beams, and the variation in line made in driving the piles is taken up by lead-filling between the flanges of beams and shoulders of caps. The weight on the tunnel is calculated at 14 tons per lin. ft., or 56 tons on each pile. The cost of these pile foundations was $7 per lin. ft. of tunnel. Each of the longitudinal sills for supporting the posts is composed of two 12-in. 31-lb. I-beams, having a bearing surface 12 × 14 ins. on each pile. The posts are spaced 2 ft. c to c., and each is of two 12-in. 31-lb. I-beams. Each half arch is made up of web and angles in three 4-ft. sections, spliced together with ⅜-in. plates; there is also a ½-in. plate on the outside of the angles at the springing line or connection with the post. Some trials were made at the Carnegie works of making the posts of sufficient length and bending them to produce the half arch part, but this produced minute fractures at the outer edges of the flanges, so it was not deemed advisable. The web parts of the sections have straight edges, but the angle iron flanges are bent to circular shape. For lateral bracing, an 8-in. I-beam crosses under the track at each two opposite piles, connecting the longitudinal beams. At the top of the arches is an 8-in. longitudinal beam between each two adjacent ones. At each side of the tunnel and running along at the springing line (on the outside) is an 8-in. channel iron. The roof covering and siding is of 3-in. red spruce. The cost of the steel work and the planking was about $50 per lin. ft. The intention is to brick in between the arches with two rings of brick when the boards shall have rotted out. The arches are set at right angles to the 4% grade, except the portals, which are set vertical. For 18 ft. at the lower end of the tunnel the arches are tilted to correspond to the track elevation for the 18 ft., which is in curve here, one sill being lowered and the other elevated. It is 22 ft. from the top of the arch to the original surface of the dump, and 15,000 cu. yds. of material had to be excavated to make way for the tunnel. The filling on the sides and top will be put on gradually, attention of course being paid to depositing the material so as to secure a fairly even pressure on the sides.

The calculation of the strains in the arches was done on the theory of a surcharged material on the sides and top, no allowance being made for packing. The material was called sand, and Baker's formula for side slopes of 1½ to 1 was used. The waste material from these mines usually packs much less than other material. It was calculated that the center of pressure would be at about the springing line of the arches.

The steel work was supplied by the Missouri Valley Bridge & Iron Works; but the erection was done by the railway company itself. The piles were cast at Pueblo. The railway company had other "tight places" to get through in this same vicinity, and there is a complicated overhead steel trestle crossing the Midland Terminal Ry.

Midland Terminal Ry.

This railway runs south from Divide, a station on the Colorado Midland Ry. and at the summit of the main range here, and reaches Victor in a distance of 25 miles; then turning northwesterly it reaches Cripple Creek in five miles more. The road was completed in December, 1895. The maximum grade is 3%, except for about three miles of 4% grade north of the town of Gillette. The maximum curvature is 16°. Victor Pass, shortly before reaching Victor, is the highest point on the line—elevation, 10,225 ft.

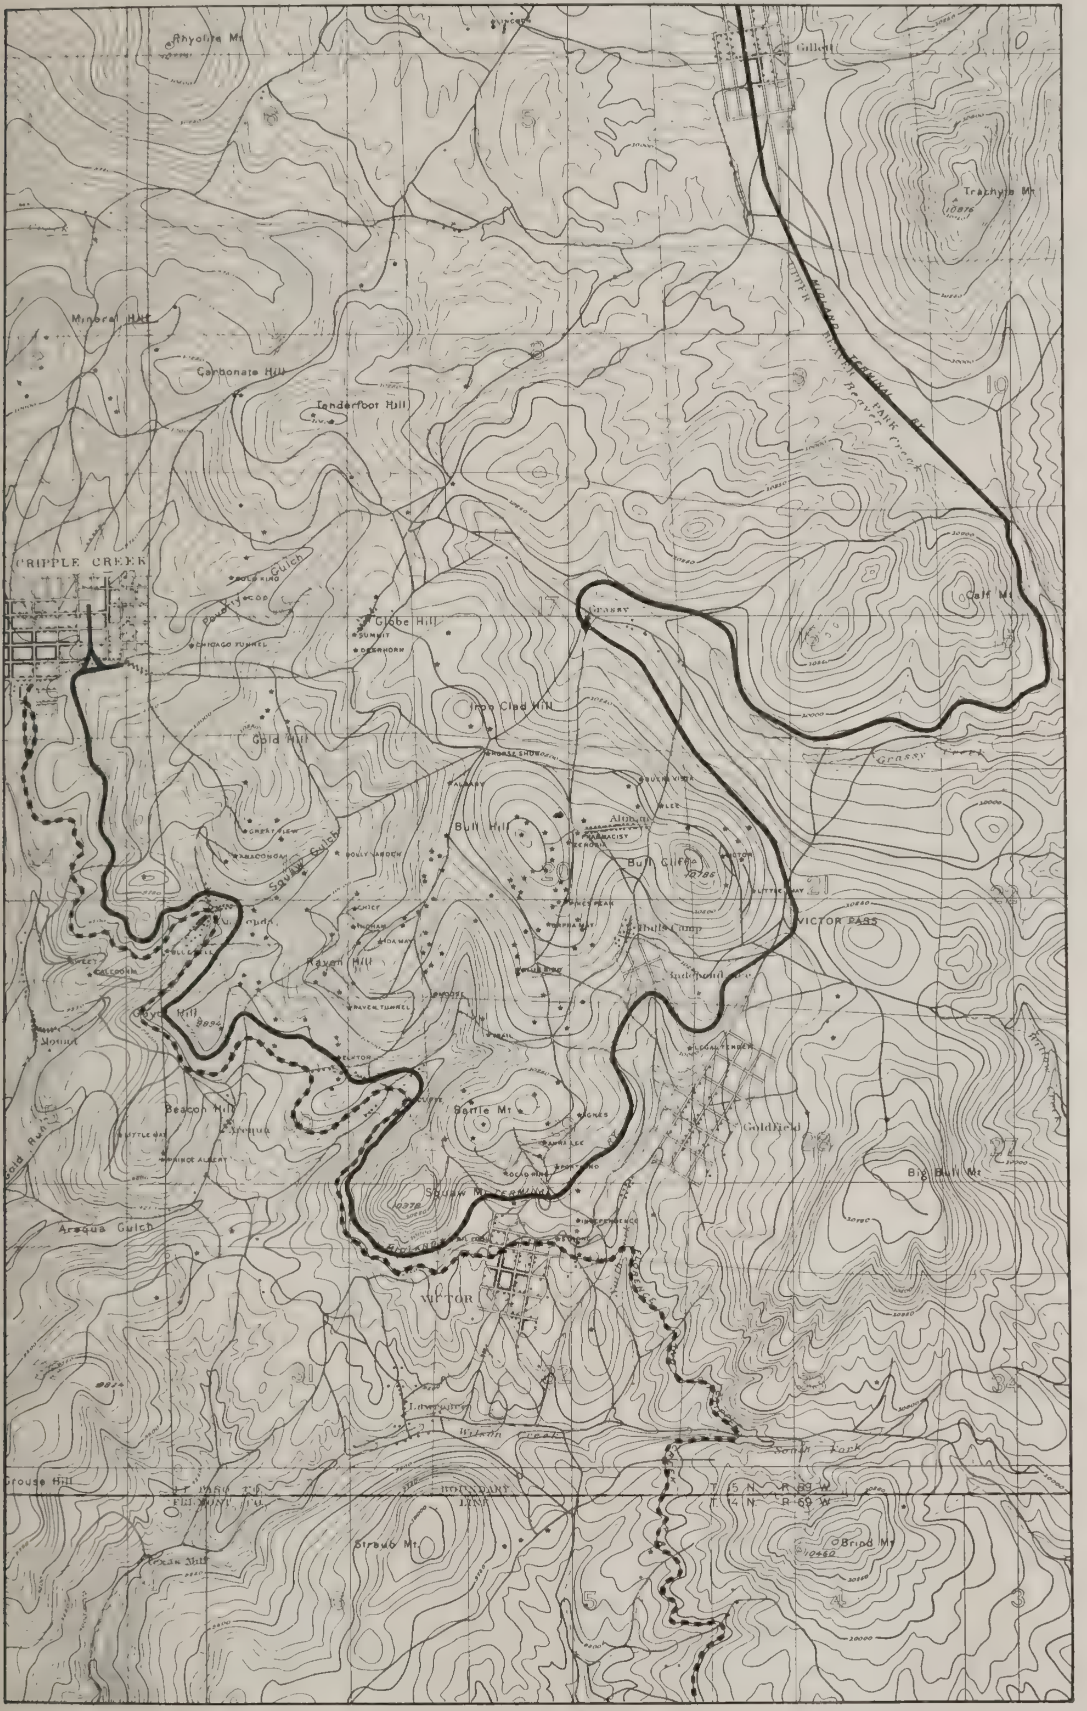
The track is laid with 56-lb. rails furnished by the Colorado Midland Ry., that road having taken them up to lay heavier ones. The rolling stock is as heavy as any used on the main line, notwithstanding which very high speeds are at times reached. This is the only standard-gage road at present reaching the district.

The Cripple Creek District Railroad.

This is the highest electric railway in the world. It connects Cripple Creek and Victor, running directly over the top of the mountains between, instead of running around them on a fairly easy grade line, as do the steam roads. It is a suburban road, and is intended to connect with a through electric line from Cripple Creek to Colorado Springs, when the latter shall have been built.

---

*612 Progress Building, Salt Lake City, Utah.



MAP OF THE CRIPPLE CREEK, COLO., MINING DISTRICT.

Reduced from a Map of the U. S. Geological Survey, published July, 1895, from surveys made in 1894. Datum, mean-sea level; contour interval, 50 ft.

By running over the mountains the District Ry. reaches a part of the camp that the steam roads do not, and thus secures an excellent passenger traffic. The road was completed in December, 1897. The chief engineer was Mr. W. H. Leffingwell, M. Am. Soc. C. E., of Cripple Creek, and the projector and general manager is Mr. L. D. Ross, of Colorado Springs. The road is six miles long, it being three miles each way from the station at Midway on the summit of Horseshoe pass. There is about 1,000 ft. rise from Cripple Creek to Midway, at an altitude of 10,500 ft. On the southeast side the descent to Victor is only about 700 ft., though much development was required on this side the same as on the other.

There is considerable 6½ and 7% grade, and one piece of 7½% grade at the east edge of Cripple Creek. The 7½% was used because the line would have interfered with mining dumps if it had been thrown far enough into the hill to secure an easier grade. As it comes where the rails are made slippery in muddy weather by wagons crossing the track, it is difficult running over it, and much sand is used at such times. Curves as sharp as 60° or about 100 ft. radius are used. The track is elevated ½-in. per degree of curve up to 6 ins. The grade is compensated on curves at the rate of 0.03; 60-lb. rails are used. Three cars comprise the present rolling stock. These are each 40½ ft. long and weigh, with motors, 19 tons. Two 57-HP. motors are used, both at one end. There is but little platform room, one-half of the space for each being taken up by the vestibule for the motorman. In the vestibule is the controller and also the air brake compressor and appliances. The car has two four-wheel trucks, and 3-in. tread wheels are now used, but are to be replaced by 4-in. A second-hand Armington & Sims engine is at present used at the power station at Cripple Creek, and as it can work up to only 175 HP., only one car at a time can be drawn up the hill. Two are run regularly, one always descending. A 6-pole dynamo is used, and the current goes out over the 2-wire feeder line at 550 volts, reducing to 480 and 450 on the line, however. This feeder line runs directly across the country and is tapped where it crosses or comes near the track—about ten times. The trolley wire is No. 00. The bonds for rail joints are No. 0000, No. 00 being found too light.

The cars have a seating capacity of 40, though 100 people are often carried at a load. Immediately on starting down hill the air pump is started going. Straight air is used, the pressure in the cylinder being kept at 70 to 80 lbs., while the average pressure applied is about 30 lbs. The steel brake-shoes used wear out in about three weeks. During the winter, when a snow storm is in progress, a car is kept running all the time to keep the track clear, the track-scraper being used.

The District Ry. is only a connecting link in an electric road that is intended to run from Colorado Springs to Cripple Creek. This line will join the portion already built at Midway on top of the pass. It will be 28 miles long, 14 miles each way to Colorado Springs and to Midway from the divide or summit of the Rampart range. The elevation of this pass is 10,200 ft. The maximum grade will be 7%. The engineer is Mr. H. I. Reed, of Colorado Springs. The preliminary survey from Colorado Springs runs up Bear Creek canon to the divide, where there is now being erected a water-power station. As is well known, the city of Colorado Springs obtains a large part of its water supply from the slopes of Pike's Peak in this vicinity, and the extremely high altitude of the heads of the supply allows of a great fall being used for power purposes, even at this great elevation. By an agreement with the city, the railway company has the right to take water from the former's main supply pipe here, the water to be returned to the city's system further down. A fall of 700 ft. in less than half a mile is secured, sufficient for the development of 600 HP.

From the divide over to Midway the distance by the transmission line is 8 3-10 miles. This line and the transformer station at Midway, with its three step-down transformers and switchboards, are now completed. The transmission is three-phase, three-wire, and the voltage is reduced from 6,300 to 550 volts at the station. There are to be two more power stations built on the west side of the divide, but whether for steam or water power is not yet known, it depending on the developments regarding supplies for the last. Through the inhabited portions of the country traversed by the road, the usual overhead trolley system will be used, but for the remainder of it the third rail system will be used. The cars will be so constructed that they can be attached to any steam railroad train. There are intended to be 30 trains a day, ten passenger and five freight each way—the running time of the former between Cripple Creek and Colorado Springs will be a little over one hour.

At Colorado City (2½ miles west of Colorado Springs) it is proposed to build a number of new reduction works to treat the vast quantities of low grade ore that it will then become possible to ship.

THE SUBSTITUTION OF ELECTRICITY IN PLACE OF STEAM ON A BRANCH OF THE ERIE R. R.

A recent example of the use of electricity as the motive power on a road previously operated by steam locomotives is the railway which runs from Tonawanda to Lockport, N. Y. The road is operated by the Buffalo & Lockport Ry. Co., and serves as a feeder to the Erie R. R. The company was organized in April, 1898, and immediately purchased about 5½ miles of single track running through Lockport, and leased for 99 years the Lockport branch of the Erie R. R., consisting of 13½ miles of single track from Lockport to North Tonawanda. In addition, 7½ miles of single track between Buffalo and North Tonawanda and one mile in the city of Buffalo were purchased. In this way 29 miles of tracks were acquired, all of which were equipped for electric traction.

This work involved the erection of poles, overhead trolley, feeders and the bonding of rails, and was begun May 17, 1898. On Aug. 14, almost exactly three months later, trains were in operation by electricity.

Both passenger and freight service is given, the former by running separate electric cars on half-hour headway. The freight service is handled by two electric locomotives. There are 10 electric motor cars, built by J. G. Brill Co., Philadelphia, Pa. These are mounted upon eight wheels, using two "Perfect" trucks. These are of two kinds, a combination passenger and smoker, 42 ft. long over buffers and 31 ft. long between ends, with 4½-ft. platforms, and a combination passenger and baggage car with a body length of 31 ft. 8 ins. and 4½-ft. platforms. The motor equipment consists of four G. E.-57 motors (208 H.P. per car) and two B 8 series parellel controllers. The total weight of a loaded car is from 20 to 25 tons.

For handling the freight, two 36-ton electric locomotives have been furnished by the General Electric Co. One of these, hauling a train of cars, is shown in the accompanying illustration. In general appearance they resemble the well-known Baltimore & Ohio electric locomotives and the one used on the Hoboken Shore Road, described in Engineering News for July 11, 1895, and Jan. 13, 1898, respectively. The design follows closely that of the locomotives just mentioned, sloping shields being placed on each side of a central cab, and the whole carried on two four-wheel trucks. The cab frame is made of 1¾-in. × 1¾-in. angles, covered with a sheathing of ⅛-in. iron. The main frame is built up of 8-in. channels, running the entire length, and securely riveted to cross plates at the ends directly over the center truck bearings. Heavy oak buffer beams, to which are attached draw-heads and pilots, are secured to the ends of the platform. The trucks have swing bolsters, supported by elliptical springs, and the truck frames are built up of forged and rolled iron securely bolted and riveted together, the pedestals being made of cast steel. The truck proper rests on coil springs, supported by equalizing bars. The wheels are 36 ins. in diameter, with steel rims and iron centers. The locomotives are each equipped with four GE-55 motors. The draw-bar pull at full speed is approximately 3,400 lbs., sufficient to handle a 340-ton train at about 15 miles per hour. The motors are rated at about 160 H.P. each, or a total of about 640 H.P. As the maximum speed required is quite low, two motors are at all times connected in series.

The controller is of the K-24 type, with cut-out wiring, modified to fit the special requirements of the equipment in regard to speed. Outside, the resistance points only two combinations of the motors are possible, the first throwing all four motors in series, and the second, or running position, placing motors No. 1 and No. 3 in series and the pair in multiple with motors No. 2 and No. 4 similarly connected.

The locomotives are equipped with pneumatically controlled trolleys. With this arrangement it is no longer necessary for the engineer or helper to leave the cab and replace the wheel on the wire or reverse the trolley. This is effected by a handle conveniently placed over the engineer's head. The downward motion is obtained by admission of air to a cylinder, the piston of which in moving compresses the spring, holding the pole in place while running. The upward motion is accomplished by the spring and the movement sideways by hand, both pole and handle being on a swivel plate.

The balance of the equipment consists of air-brakes, whistle, bell, air-blast sanding device, air pump, magnetic circuit breaker, magnetic switch, lightning arrester, electric lights, etc.

The following are the principal dimensions of these locomotives:

Length over all	32 ft.
Height of cab over rails	12 ft.
Distance between centers of trucks	13 ft.
Wheel base (one truck)	6 ft.
Gage	4 ft. 8½ ins.
Diameter of wheels	36 "
Complete weight of locomotive	36 tons.

The locomotives have already been subjected to several severe tests. They are specified to be capable of hauling trains of 300 tons weight, exclusive of the locomotive; but they have already proved themselves equal to hauling as many as 28 loaded freight cars at the specified speed of 15 miles an hour.

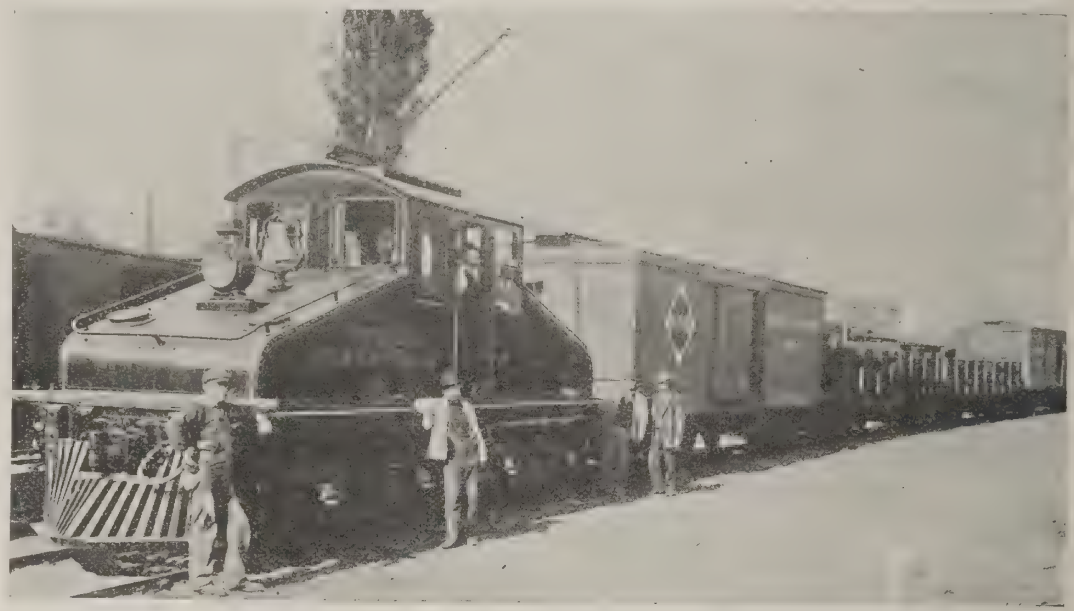
To obtain the necessary current the transmission line of the Niagara Falls Power Co. was tapped between the Niagara Falls power house and Tonawanda. A special transmission line, using cedar poles, triple petticoat insulators and No. 0000 (B. & S.) bare copper wires, carries the current to a rotary converter sub-station at Lockport. This building contains six 150-K-W. air-blast transformers, which drop the voltage from 10,500 to 350 volts, and two General Electric 6-pole 400-K-W. 500-revolution rotary converters, taking alternating current from the transformers, just mentioned, and converting it into direct current at 500 volts.

The switchboard is of the standard panel type, and consists of one panel for the high potential transmission, two panels for the low-tension alternating current side of the rotaries, two "K" direct-current railway panels for the direct-current sides of the rotaries, and two transformer panels. The switches for the high-tension current are of the quick-break type, each blade being separated from its next neighbor by a marble barrier. The blades are pulled open by means of a hooked stick, the hook being inserted in an eyelet into the end of the blade.

Another sub-station, also taking current from the Niagara Falls plant, will soon be built at Tonawanda, the intention being to operate the road in sections. The first of these sections, from the starting point in Buffalo to the city limits, will take current from the Buffalo Railway Co.'s station in Buffalo. From there to Lockport, a distance of seven miles, and half way to Niagara Falls, and half way back to Tonawanda, will be operated by the converters at Niagara Falls. It is also the intention that the Buffalo & Lockport road will either give to or take current from the Buffalo & Niagara Falls Electric Ry., should occasion arise.

The officers of the new company are: Pres., Mr. W. Carl Ely; Manager, Mr. Burt Van Horn; Superintendent, Mr. C. K. Marshall. The operating officers are the same as those of the Buffalo & Niagara Falls Electric Ry.

We are indebted to the General Electric Co. of Schenectady for the illustration and data from which this article has been prepared.



640-HP. ELECTRIC LOCOMOTIVE FOR THE BUFFALO & LOCKPORT R. R.
General Electric Co., Schenectady, N. Y., Builders.

DISCHARGE REGULATOR AND TESTS OF 14-IN REDWOOD WATER MAIN, NEAR LOS ANGELES, CAL.

The West Los Angeles Water Co. recently built a line of 14-in. redwood water main, 37,000 ft. long, to supply the National Home for Disabled Volunteer Soldiers near Santa Monica, Cal. This main is an extension of the Holywood pipe system of the company, and is shown in profile by Fig. 1. In order to avoid as much heavy pressure as possible the line follows the hydraulic gradient as closely as is feasible; and to prevent the full static pressure coming onto the pipe the flow into the same is controlled by a balanced valve operated by a float. Between this structure at Sta. 22 and Sta. 145 water is distributed to many consumers for irrigation and domestic use. From the latter station the line is built exclusively for the supplying of the Soldiers' Home. The contract with the Government authorities for this supply specified that the water should be delivered into a reservoir at the Home at a uniform rate of 348 gallons per min. To accomplish the fulfilment of these conditions from a pipe system subject to constant fluctuation of pressure, without governing the flow at the extreme end of the extension, thereby subjecting the entire pipe to a maximum pressure due to the full static pressure limited only by the elevation of the structure at Sta. 22, was a problem whose solution required something different from any appliance yet devised. To meet this requirement the automatic regulator, Fig. 2, was devised, and may prove of interest to your readers, especially as use has demonstrated its ability to perform perfectly the function required. The device needs little explanation to make its working plain. The telescopic adjuster can be set for any desired head on the weir, when the water will stand just high enough over the lip of the adjuster to admit the passage of such a quantity into the balancing pan, through the hose connection, as will supply the amount passing through the small leak hole in the bottom of the pan, and at the same time retain such an amount in the pan as will constitute an equilibrium when its weight is opposed by the weight of the valve, the movable cast-iron ball and the tension of the spring at the other end of the lever. So long as there is no change in the pressure of the water above the regulator, it is evident that this condition will continue indefinitely. Any disturbing of the equilibrium is only temporary, as the apparatus at once restores it. Thus, if there is a sudden increase of pressure, it at once results in an increase in the height of the water on the weir, a corresponding increase in the rate of flow into the pan, and a consequent partial closing down of the valve until the requisite head on the weir, for which the adjuster is set, is again restored. Should there, on the other hand, be a sudden decrease in the pressure by reason of heavy drafts above, the water fails to run into the balancing pan, that already in, leaks out until the diminished weight is accompanied by an increased opening of the valve through the action of the opposing weight and spring. The weir is not intended to conform to the correct theory for accurate measurement, it being placed for convenience quite near the valve, which results in more or less disturbance of the water. Its error is determined by use of an accurate weir located at the lower end of the line at the point of discharge into the reservoir, and is allowed for in setting the adjuster. There are no new principles in this device, but the general combination is believed to be wholly new.

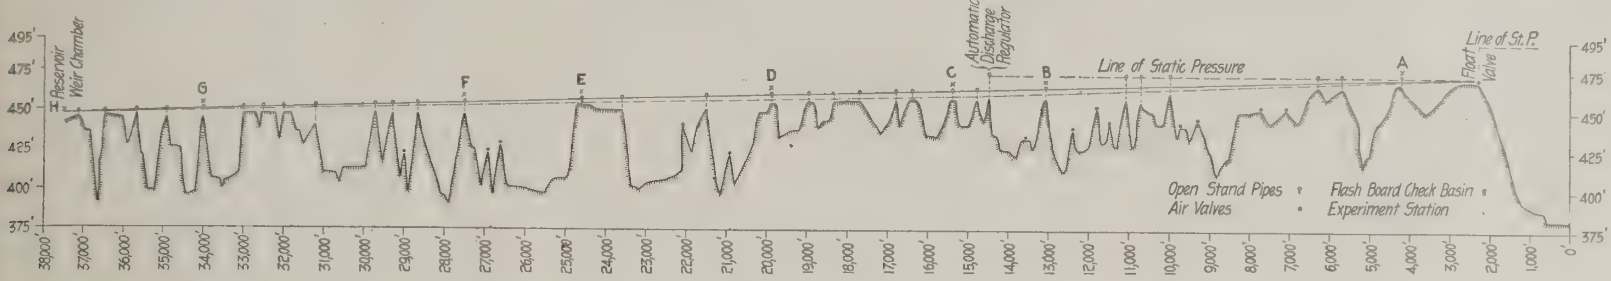


FIG. 1.—PROFILE OF 14-IN. REDWOOD WATER MAIN, NEAR LOS ANGELES, CAL.

The following observations made on the carrying capacity of the line to determine the coefficients of discharge may also be of interest:

Section.	Length, ft.	Average diam., ins.	Loss head in 1000 ft.	Lin. vel., per sec.	Value of C in $V = C\sqrt{RS}$
D to E	4,825	14.05	0.170	0.698	99
G " H	3,436	14,075	0.161	0.695	101
A " B	8,931	14.05	0.178	0.751	104
C " D	4,403	14.11	0.145	0.691	105
F " H	9,912	14.05	0.391	1.167	109
F " B	....	....	0.638	1.531	112
A " B	8,931	14.05	0.375	1.181	113

The losses of head were determined by observations made from the open stand-pipes and other structures on the line; and the volume of discharge by weir measurement at the terminus of the line. The weir itself was checked by volumetric measurement in the reservoir itself. The average diameter of the pipe line was determined by many measurements made during construction. It will be observed that the velocities experimented with are all very low, such as usually give results least concordant. Considering that five different sections were experimented on, the disparity in results secured are not bad for these velocities. The corresponding values for "n" in the Kutter formula are between 0.010 and 0.011, being nearer the latter than the former.

Mr. Arthur L. Adams, M. Am. Soc. C. E., is engineer and manager of the West Los Angeles Water Co. The office of the company is at 405½ Broadway, Los Angeles, Cal.

THE PROPOSED FLOATING DRY-DOCK AT ALGIERS, LOUISIANA.

Proposals are now invited, by Commodore M. T. Endicott, U. S. N., Chief of Bureau of Yards and Docks, for the construction of a combined floating and graving steel dry-dock, to be located at Algiers, La. The bidders are asked to submit full plans and detail specifications, with their proposals, on or before Oct. 31, 1898, and the limit of cost for the entire work is fixed at $850,000.

The Bureau submits a general specification as a basis for the presentation of plans, etc., and from this the following abstract is made: The proposed dry-dock is to be capable of lifting a vessel of 15,000 tons displacement and 27 ft. draft of water, and the cost named is to include the dock, moorings and wharf. The length of the floating steel dock is to be 525 ft. over all, with 28 ft. of water over the keel blocks and a clear width of not less than 100 ft. If the dock is of the balanced type, it must be so designed as to admit of examination and repair in all its parts, with ease and safety; it must lift a 15,000-ton ship above the level of the river, with a freeboard of not less than 2 ft., and the entire structure must be of steel, excepting the keel-blocks, bilge-blocks and shores. If, however, the design calls for any portion of its accessory structure that is entirely beneath the water surface, such portion may be of wood. To operate the dock, steam, electric, hydraulic or pneumatic power may be used.

It is the purpose of the Bureau to give full latitude of design to the bidder; provided, that the design submitted fully meets the requirements of the naval service for the safe docking of the specified size of ship. To this end stress diagrams must be submitted, based upon standard diagrams furnished by the Bureau, and giving the length and distribution of weights in the heaviest U. S. battleship. These diagrams call for a battleship 450 ft. long, weighing 15,000 tons, and having two-thirds of this weight concentrated in the middle half of her length.

If the dock is designed as a single structure, it must be strong and stiff enough, longitudinally, to safely distribute the load over the entire length, if the vessel be docked in one end of this structure; if the design calls for a sectional dock, adequate provision must be made for so connecting the sections that the dock may act as a unit, and the sections be kept level without straining the ship; and if one of the sections should lose its buoyancy, the connections of the sections must be capable of distributing over the remaining sections the weight of the injured sections and all parts of the ship over this section. The dock must not careen more than 3° under the most unfavorable conditions of loading; providing for the vessel landing 2 ft. off the longitudinal center line, and subject to wind pressure of 30 lbs. per sq. ft. The greatest longitudinal deflection permitted will be 1 in. in 3,000, with the most unfavorable load; the greatest transverse deflection must not exceed 1 in 1,800, under similar conditions.

This dry-dock must be completed in 18 calendar months from the date of signing the contract; and proposals must be accompanied by a certified check for $15,000 as a guarantee to commence work within ten days, if contract is awarded; and there will be a bond equal to 20% of the contract price. A penalty of $200 per day will be exacted for delay in fulfilling the contract. The steel specified is acid or basic open-hearth, and the tests of this steel are fully specified.

The specifications give the following data referring to the stages of the Mississippi River at New Orleans, La.:

Zero of gage is 2.53 ft. below mean gulf level.
Zero on the gage is low water of Dec. 30, 1876.
High water of April 16, 1874, reads 16.2 ft.
High water of May, 1897, reads 19.5 ft.

The danger line was changed from 13 to 16 ft. March 15, 1897.

COMPRESSED AIR AND ELECTRICITY AT THE LASSIG BRIDGE & IRON WORKS.

An interesting change is being made in the equipment of the plant of the Lassig Bridge & Iron Works, of Chicago, Ill., by which the use of line shafting will be dispensed with, and all the tools will be operated by compressed air or electricity, according to which power is best adapted for each particular purpose.

The compressed air plant, which is shown in the accompanying illustration, consists of a duplex Corliss air compressor, with two-stage or compound cylinders for the compression. The steam end is composed of two simple Corliss engines of 200 HP., placed side by side, and connected to crank disks on a flywheel shaft, the cranks being set at 90°. Tail rods from the steam cylinders operate the air cylinders. The steam cylinders are 20 × 30 ins., and the air cylinders are 18¼ × 30 ins. and 30¼ × 30 ins.

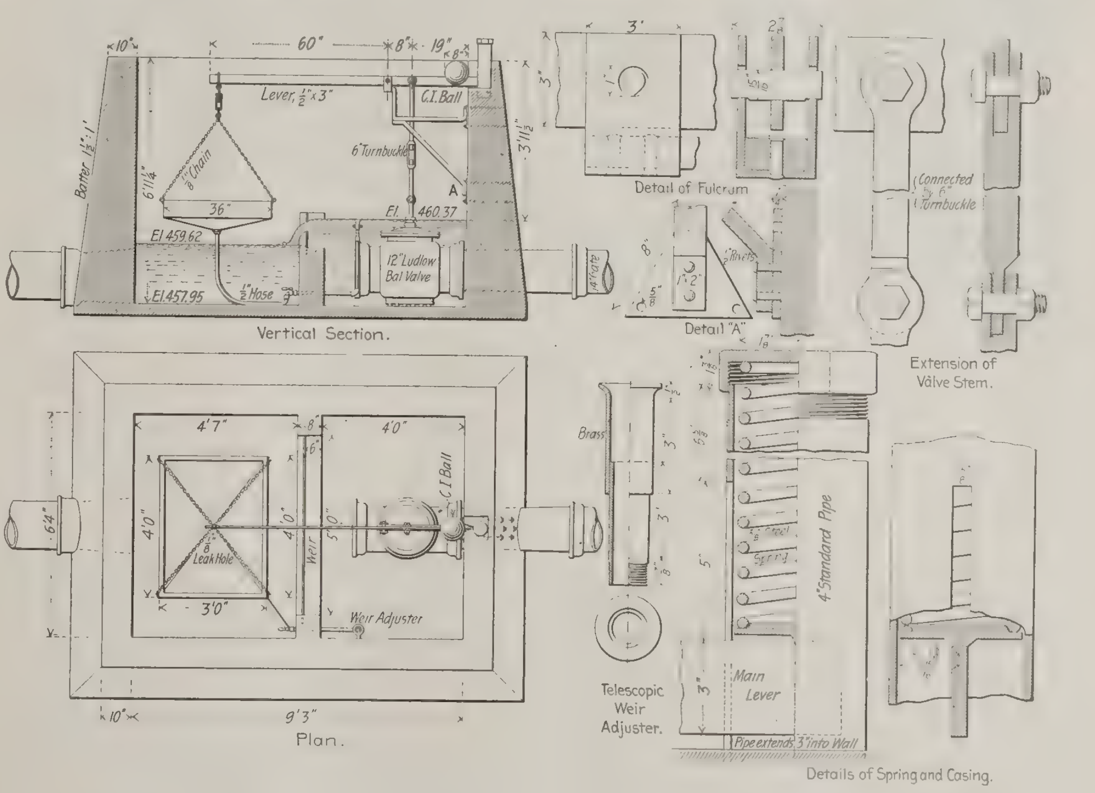

FIG. 2.—AUTOMATIC DISCHARGE REGULATOR ON 14-IN. REDWOOD WATER MAIN.

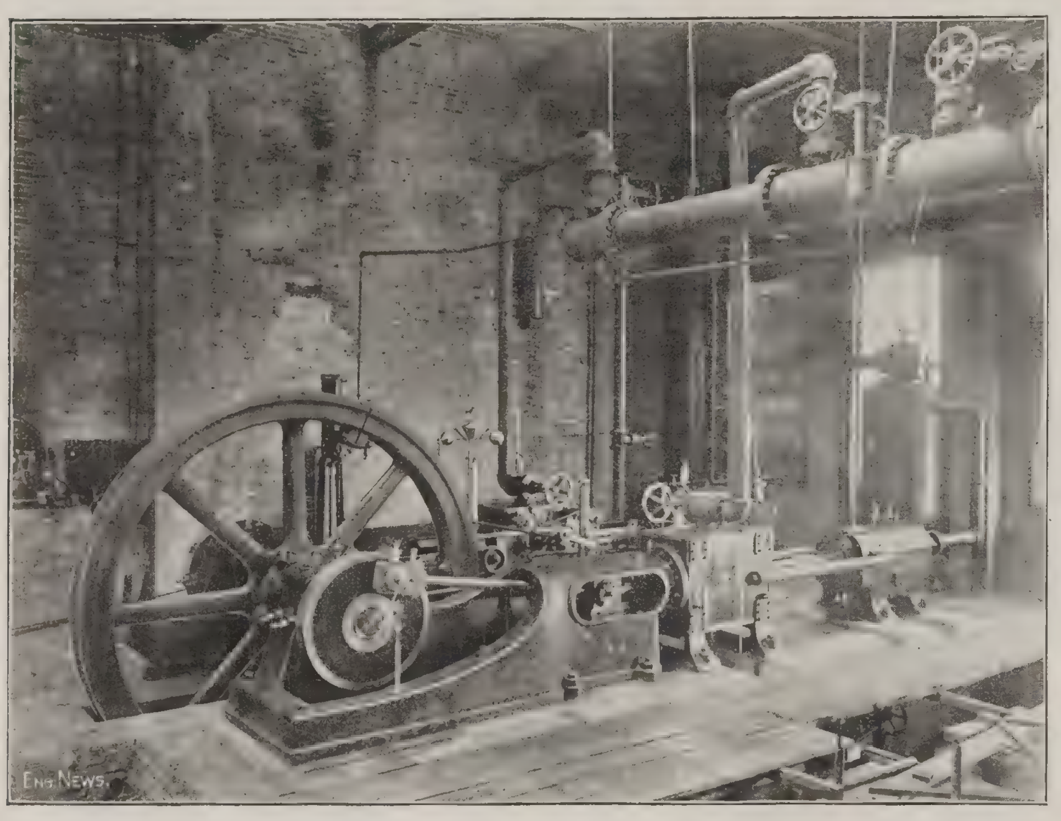
From the low-pressure cylinder the air passes to a vertical intercooler of the receiver type, having sufficient capacity to fill the high-pressure cylinder without any drop in pressure. This intercooler, which may be seen between the windows, is 42 ins. diameter and 11 ft. high. The air enters at the center of the top and passes down through a cylindrical chamber extending about two-thirds the depth of the receiver, and being open at the bottom. In this chamber is a nest of 1-in. vertical tinned brass tubes, through which an upward current of water is maintained. The cooled air passing out at the bottom of the chamber fills the receiver, and is taken out near the top of the receiver by a pipe leading to the high-pressure cylinder of the compressor. In this way the air from the low-pressure cylinder at about 240° is reduced to the temperature of the surrounding atmosphere before it enters the high-pressure cylinder. From this latter cylinder the air passes to the vertical reservoir shown in the corner of the room. The air pressure is 30 lbs. per sq. in. in the intercooler and 80 lbs. in the reservoir, the compressor having a capacity of 2,200 cu. ft. of free air per minute compressed to a pressure of 80 lbs. per sq. in.

To ensure economical working of the engine, it is desirable to maintain a practically constant pressure of 80 lbs. in the reservoir, and this is effected by means of a sensitive regulator of the diaphragm type, whose rod is connected to the governor rod, and changes the cut-off of the valve gear. In this way the economy of the Corliss engine is realized much better than by throttling the steam, and the governor has little to do except to speed up the engine when there is a heavy demand upon the reservoir.



DUPLEX CORLISS TWO-STAGE AIR COMPRESSOR AT LASSIG BRIDGE & IRON WORKS, CHICAGO.
Ingersoll-Sergeant Drill Co., Builders.

In the caps of the main shaft bearings may be seen small stud screws. There are four of these to each cap, tapped through into the pedestals, and their purpose is to take the weight of the cap, and thus relieve the shaft of the weight. The heavy pipe across the engine room is the steam main, supplying the engines of the air compressors and electric dynamos, and it may be explained that as another engine was to be erected side by side with the one shown, it was necessary to take the photograph before the magnesia covering had been applied to the pipes.

This air-compressor plant was put in by the Ingersoll-Sergeant Drill Co., of New York, and we are indebted to the Chicago office of the company for the photograph reproduced herewith. The plant will supply power for the following tools and appliances: 15 air riveters, 11 × 9 ins.; 6 rotary air drills; 6 pneumatic hammers; 4 rivet furnaces, and 36 oil heating furnaces.

The electrical equipment was planned by Mr. F. Sargent, of Sargent & Lundy, Chicago, Ill. The power plant will consist of a dynamo of 200-K-W. capacity, driven by a Corliss engine, and furnishing current to motors driving the following tools and appliances:

26 punch presses,
4 cranes,
1 derrick,
1 plate roll,
1 bending roll,
1 paint mixer,
1 milling machine,
1 link boring machine,
1 radial drill,
1 pair emery wheels,
4 batteries of radial drills, carrying 45 bits, for holes 11-16-in. to 1⅛ ins. diameter.

All the work has been done under the supervision of Mr. Emil Gerber, M. Am. Soc. C. E., Chief Engineer of the Lassig Bridge & Iron Works.

◆

THE SANITARY PROTECTION of the small lake which supplies water to the fashionable resort of Tuxedo, N. Y., contains one feature which is probably without a parallel. This is the provision that any person falling overboard from a boat on the lake is arrested and fined $25. Bathing in the lake was first prohibited, but its limpid waters were so tempting to the boys of the vicinity that in order to enjoy a dip they would contrive to fall overboard when out on the lake. The ordinance in question was therefore adopted to meet this practice, and it is said to be entirely successful.

◆

MUNICIPAL OWNERSHIP OF WATER-WORKS in Des Moines, Ia., was defeated in a popular vote taken on Aug. 28. The vote was light, only 7,500 out of 25,000 voters, and the proposition to purchase the works of the Des Moines Water Co. was defeated by about 150 votes. One reason for the defeat is said to have been that taxpayers considered the price asked by the company exorbitant, and objection was also made to the quality of the supply.

◆

A WATER POWER PLANT IS TO BE CONSTRUCTED at Wrightsville, Pa., by the Martic Water & Power Co., Mr. James H. Harlow, Chief Engineer. The work will include about 22,000 cu. yds. of excavation, 10,000 cu. yds. of masonry, 830,000 ft. B. M. of timber, and the furnishing and installation of 24 turbines with shafting and all other appurtenances complete. Plans, specifications and blank forms for bids can be obtained from the engineer after Sept. 15, as stated in our advertising columns.

◆

THE CONTRACT FOR WATER METERS required by the city of Chicago, from June 17, 1898, to May 1, 1899, is held by the Pittsburg Meter Co., of Pittsburg, Pa. The life is guaranteed for 10 years for meters up to 2 ins. in size; and two years for larger sizes. The accuracy must be within a limit of 3% for five years, during which time the contractor is to keep them in repair. They are to withstand a pressure of 200 lbs. per sq. inch. The number, sizes and prices are as follows:

Diameter, ins.	Number.	Price per meter.	Total price.
⅝	200	$6.95	$1,390
¾	200	10.00	2,000
1	200	13.00	2,600
1½	200	25.00	5,000
2	100	40.00	4,000
3	100	80.00	8,000
4	20	160.00	3,200
6	20	325.00	6,500
Total	1,040	....	$32,690

◆

THE BROOKLYN BRIDGE TROLLEY ACCOMMODATIONS will be increased by the addition of two new loop tracks at the New York terminal. These two new loops, according to the plans, will be situated about 100 ft. distant from the present loops towards Brooklyn, and will necessitate the removal of one stairway and a part of one gallery, as well as the present electric lighting plant of the bridge. The engineers of the bridge and those of the railway companies are also considering plans for improving the terminal facilities at the Brooklyn end of the bridge, but as yet have not reached any very definite conclusions.

◆

THE RESURVEY OF CHESAPEAKE BAY by the U. S. Court and Geodetic Survey has been nearly completed during the present season. This resurvey had been contemplated for several years, as the shore line and bottom of the bay had undergone many changes since the original survey, 50 years ago, but its immediate accomplishment was due to the fact that the work of harbor defence compelled the concentration of this coast survey work in some locality where there would be no fear of interruption, and Chesapeake Bay was the locality selected. The work of the resurvey has been in charge of Capt. Herbert G. Ogden, who has had eight parties, comprising altogether 24 officers and 100 men, employed throughout the season.

◆

AN AMERICAN PACIFIC CABLE from America to the Hawaiian Islands, the Ladrone Islands, Manila and Japan is just now being much talked about in the daily press. The Pacific Cable Co., which already has a license from the Hawaiian government for a cable between those islands and America, has, it is stated, sent its representatives to Japan to make the final contracts with that country if possible. This same company is also stated to have ordered surveys to be made for a duplicate or reserve cable to run from Sitka, Alaska, by the Aleutian Islands, to Japan. The estimated cost of the two cables is between $22,000,000 and $25,000,000.

◆

THE COLLECTION AND DISPOSAL OF THE GARBAGE of New York city has recently been made the subject of investigation and report by a special committee of the Board of Health, consisting of Dr. G. W. Martin and Dr. James B. Taylor. The investigation was made upon complaint that the disposal of garbage as carried out at Barren Island was becoming a nuisance and the committee reported that the nuisance had in fact become as bad as it was last year, when a strong protest was made against it. It recommended that the Sanitary Code be amended so as to compel the removal of garbage from the city every twelve hours to the place of disposal, to prevent any boat or barge used in the removal of garbage from being tied up at any city pier longer than twelve hours at a time, to have these boats covered so as to prevent the escape of bad smells, and to provide that garbage must be deodorized. The committee also recommended that the windows, doors and skylights in the buildings on Barren Island be kept closed at all times, and the air necessary be forced in by fans and drawn out by pumps, duplicate sets of the latter being required, so that the breaking of any would not require the opening of the windows. The Board adopted the report unanimously and directed the Corporation Counsel to amend the Sanitary Code to cover these recommendations. President Murphy was also empowered to revoke the permits of companies on Barren Island who do not immediately comply with the new rules.

◆

A NATIONAL ASTRONOMICAL SOCIETY is about to be organized in this country. Heretofore the astronomers have been in the habit of meeting together once a year at the annual meetings of the American Association for the Advancement of Science, they constituting a large part of the membership of Section A, Mathematics and Astronomy. The number of observatories and the number of men now devoting themselves to astronomical research make the formation of a separate astronomical society advisable. It is probable that the new society will be one of the "affiliated societies" of the American Association for the Advancement of Science, which hold their annual meetings at the same time and place. The present tendency of the old society seems to be toward disintegration into "affiliated societies," but this tendency is no doubt a benefit to the "Advancement of Science."

  "Practical Man" vs. Engineer.

A SYSTEM OF ELECTRIC SUBWAYS is at once to be built by the city of Baltimore, Md., in accordance with a city ordinance adopted by the council last June and approved by the Mayor on Sept. 4. The ordinance creates an Electrical Commission made up of the Mayor, the City Register and the President of the Board of Fire Commissioners who are to appoint a Chief Engineer, who shall be a civil engineer, and also an electrical expert, to prepare plans and specifications and superintend the construction of the work. His salary is to be not more than $4,000 per annum. The subways are to accommodate all the overhead wires in the city except the trolley wires; they are to be built by day labor or by contract, as the commission shall determine, and $1,000,000 is appropriated for their construction.

A 4-FT. SUBWAY UNDER THE MILWAUKEE RIVER has just been completed by the Milwaukee Electric Ry. & Light Co. The subway is 226 ft. long and is made up of lengths of cast-iron pipe 4 ft. in diameter, 12 ft. long and 1½ ins. thick. The subway extends between two manholes on either side of the river, each 8 ft. in diameter and about 30 ft. deep. In laying the pipe four lengths were joined together, making a section 48 ft. in length, and this was lowered from scows and the tapered end was guided by divers to enter the section already in place. The joint at the junction was then bolted up. The river at the crossing is 18 ft. deep, and a trench 12 ft. deep was dredged in the bottom in which the pipe was laid, and was afterward covered with lake sand. After the pipe line was completed and connected with the manholes, it was pumped out and all leaks were made tight. The entire subway was then filled with 3-in. ducts, of which there was room for 110. The manhole shafts were then lined with brick, and the ducts leading to the subway were put in place. The work was done under direction of Mr. Otto M. Rau, Chief Electrician of the company. Two more subways are to be built by the company at an early date.

A CHANGE FROM CABLE TO ELECTRIC TRACTION is to be made on the Broadway cable road in New York city, and work began on Sept 9. The present cable conduit will, of course, be used, and the principal work necessary is the placing in it of the insulated supports for the wires. The cable railway will, of course, continue in operation while the change is going on, and the work will therefore occupy a long time.

THE NEW EAST RIVER BRIDGE is progressing to the point of metal tower erection. Three of the four pier foundations are under way, and the two on the New York side are completed, with 23 ft. above high-water mark. On the Brooklyn side one foundation is within 14 ft. of the required height, or 23 ft, above tide, while the other caisson has not yet reached its final footing, 86 ft. below high-water mark; it is expected that this foundation will be finished in November. The contracts for the steel towers have not yet been let, owing to the financial condition of Greater New York. The $2,000,000 bonds lately authorized by Controller Coler will barely cover existing contracts.

THE QUEBEC BRIDGE CO., at its annual meeting, held in Quebec, has decided to at once call for tenders for a bridge to cost from $3,000,000 to $4,000,000. The capital subscribed amounts to $286,000, and the Dominion government has given assurance that a subsidy of 33⅓% on the cost of the structure would be voted at the next session of Parliament. The Province and the City of Quebec are both expected to grant subsidies. The site of the proposed bridge is opposite the Chaudiere, where the river is 2,595 ft. wide, at high water, and the water is 43 ft. deep. The length of bridge required is 3,100 ft., and the distance from the bed of the river to the lower chord will be 193 ft.

FIVE NEW PIERS ON THE NORTH RIVER, New York, are nearing completion, and are to be finished by the end of the year. These piers are intended for the use of the White Star, Cunard and the Wilson Steamship lines. The total cost to the city of these five piers is $6,000,000, and the shedding over them will cost about $1,250,000 more. The contract for erecting the sheds on all five piers has been awarded to R. P. & J. H. Staats. The two White Star piers are 760 ft. and 732 ft. long; the Wilson Line pier is 732 ft. long, and the two Cunard piers are 718 and 704 ft.; and each pier is 125 ft. wide, except the upper one of the Cunard piers, which is about half that width. The sheds will be one or two-story steel structures, with a continuous two-story bulkhead shed, 1,750 ft. long and 50 ft. wide, connecting all the piers. This bulkhead pier will contain the power, lighting and pumping plant. The annual rental basis for a term of ten years is as follows for the several lines: White Star, $168,750 per annum; Cunard Line, $117,088; Wilson Line, $84,375.

THE DECLINE OF NEW YORK'S FOREIGN TRADE is being investigated by a commission appointed by Gov. Black. The commission is made up of Hon. Chas. A. Schieren, Chairman; Alexander Smith, Secretary; Hon. Andrew H. Green, C. C. Shayne and Hugh Kelly. The subjects to be investigated by the commission are as follows: 1—Deepening of the channel. 2—Dock rentals. 3—Port charges. 4—Pilot fees. 5.—Matter of the availability for commerce of the water front above Hell Gate and beyond Fort Hamilton. 6—Warehouse facilities. 7—Grain elevator charges. 8—Differential railroad rates. 9—New York's lighterage system. 10—Bearing of the Erie Canal upon the commerce of New York. 11—Status of Canadian Canal competition upon New York's commerce. 12—Western demarkation line of territory contributory to New York. 13—Comparative charges at New York and other ports. 14—The establishment of a complete statistical department by the city of New York. The commission will hold its public sessions in the New York City Hall.

AMERICAN HARDWARE, says the "Hardware Record," of London, is rapidly entering the English market, and "American competition is going to be far more severe than it is at present." The export line includes bright drawn steel and all the cheaper grades of steel, brass rods, files, small malleable castings, automatic machinery for all purposes, rubber steam hose, etc. These goods, says the "Record," are now from 25% to 50% cheaper than the prices quoted on English goods in the same line. As to quality, the English workmen are said to prefer the American raw steel and brass, as being more uniform in quality and more easily worked into shapes.

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred Sept. 12 on the Texas & Pacific Ry., between Jefferson and Texarkana, Tex. At this point a bridge across a branch of the Sulphur River had been weakened by the high water following a cloudburst and an east bound four-car passenger train went through into the river, killing one passenger, mortally injuring a porter and seriously injuring five other persons.

A SERIOUS DISASTER to the German torpedo flotilla, which has been participating in the naval manoeuvers in the Baltic and North seas, is reported to have occurred on Sept. 10. It is stated that one torpedo boat was sunk, two 150-ton boats completely disabled, and 12 others seriously damaged. Seven lives were lost.

A BREAK IN A PUMPING ENGINE at the Grand Rapids, Mich., water-works on Sept. 1, put the city on a short supply for two days, and left a part of the hill section without any water. The pumps was on the Holly direct system, of 7,000,000 gallons capacity, and had been running without a stop for four months. The plunger rod of one of the plungers, which was 5 ins. in diameter, and turned down to 4¼ ins. at the screwed end, stripped its screw threads, drawing itself out of the nut, which was 4½ ins. thick. The engine then began to race, but it was stopped before any further damage was done. The calculated pressure exerted by the plunger, which is 25 ins. diameter, working against a pressure of 90 lbs. per sq. in., is 4,488 lbs. The metal to be sheared by stripping the threads could not have been much less than 50 sq. ins. even if the threads were of the weakest form, or square threads, giving a very large factor of safety against ordinary stresses. It is probable that the nut had worked loose, and that this occasioned a hammer blow upon the threads, which in time would cause them to break.

DRY-DOCK NO. 3, at the Brooklyn Navy Yard, shows no signs of weakness in use, and the slight seepage of fresh water at the southern end gives no concern. The battleship "Oregon" has just been taken out of this dock, and the battleship "Massachusetts" is the next vessel to be docked in it. This is the dock which gave so much trouble, and which has been repaired under the charge of Naval Constructor Bowles.

THE BATTLESHIP "OREGON" has had her four breech-loading 6-in. guns replaced by four 6-in. rapid-fire guns, and her smoke-pipes have been lengthened 10 ft., so as to secure better draft when the blowers are not running. The battleship "Massachusetts" is also having her old 6-in. guns replaced by 6-in. rapid-fire, and her smokestacks lengthened in a similar manner. Both the "Oregon" and the "Iowa" are ready for sea again. The cruiser "Atlanta" is having her engines changed from compound to triple-expansion. It is expected to gain three to four knots in speed by this change, with little, if any, more coal consumed.

SMOKELESS POWDER FOR THE U. S. NAVY, to the amount of 1,000,000 lbs., is to be provided by contracts now made with the California Powder Co. and the Dupont Powder Co.; each is to furnish half the above amount at 80 cts. per lb., the government furnishing the alcohol used in the production of the powder.

THE WEIGHT OF SHELL CHARGES used in the United States Naval service—that is, the weight of powder with which explosive shells are charged—are as follows, black gunpowder being used in all cases:

1 pounder,	200 grains.	6 in., about	4½ lbs.
3 "	900 "	8 " "	11 "
6 "	1,400 "	10 " "	20 "
4 in., about	2 lbs.	12 " "	40 "
5 " "	3 "	13 " "	50 "

THE THREE BATTLESHIPS, lately bid for, are to be built upon the plan submitted by the Cramps, according to the decision of the Navy Department. The Newport News Co., the Cramps and the Union Iron Works, all submitted plans for fast ships, but those submitted by the Cramps were found to be the only ones entirely satisfactory to the Department. The Board of Naval Bureau Chiefs has now invited the Newport News Co. and the Union Iron Works to amend their plans so as to make their ships identical with that proposed by the Cramps. Both companies have practically agreed to do this, and it is understood that each of the three companies will receive a contract for one ship.

THE PROPOSED OTTAWA AND GEORGIAN BAY ship canal is still attracting attention in Canada. McLeod Stewart, of Ottawa, has made the following proposition to the Canadian government on behalf of the Montreal, Ottawa & Georgian Bay Canal Co. The company will build a canal with locks of 14 ft. depth, so that steamers of that draft can pass from Montreal to the Great Lakes via the Ottawa River. It will employ only Canadian labor and Canadian sub-contractors, and will use plant and machinery made in Canada, so far as procurable. It will complete surveys within ten weeks from the time the concession is approved. The guarantee required of the government by the company is $340,000 a year for 20 years, or 2% on $17,000,000, which the company gives as a provisional estimated cost of the work. No part of the guarantee need be paid till one year or more after the entire completion of the canal. The annual payment shall be diminished by the amount of the net earnings of the company. Thus, if the company makes net earnings of $140,000 the first year, the government would only have to pay $200,000. Finally, the company will agree to repay any expenditures of the government on account of the guarantee fund from its future earnings, and the government will hold a first lien on all property and franchises belonging to the company. The offer has been approved, it is said, by the well-known contracting firm, E. Pearson & Son, of London, who are the financial backers of the enterprise.

THE LARGEST CARGO EVER CARRIED on the lakes was taken last week by the schooner "Roebling," of the new iron ore fleet, from the docks at Duluth. It consisted of 7,865 net tons of ore. The vessel was towed by the steamer "Stevenson," of the same fleet, which also towed the schooner "Nasmyth," the combined cargo of the three vessels being 19,761 net tons, the largest tonnage ever drawn by one engine on the lakes. By the plan of having one large steamer take in tow two large schooners, all laden with ore, the cost of transportation is greatly reduced, a matter of the utmost importance in the cheapening of the cost of iron and steel production.

PORTABLE PLANT FOR MANUFACTURING ASPHALT PAVING.

The use of asphalt paving has in the past been practically limited to the larger towns and cities, owing to the fact that the asphalt has to be prepared in a special plant, the cost of establishing which precludes its introduction in places where only a limited amount of work can be expected. In order to overcome this difficulty there has been devised and patented a special portable plant, which is complete in itself and can be transported by rail from place to place on its own cars in regular freight trains. With such a plant, supplemented by a steam roller and the special street tools required, a contractor can undertake small pieces of work, as there is no expense for the erection of permanent plants, and when the working season is over the plant can be closed up and stored on a side track or in a shed.

The design of the Hetherington portable asphalt plant, which is described in the present article, was not an easy matter. It was necessary to combine a large number of bulky appliances and special machinery for a complete factory within small compass, upon cars suitable for transportation on railways. It was also necessary to provide a housing and working platforms, and to so arrange the plant that it could be operated conveniently and economically. Furthermore, it was necessary to provide such joints and sectional parts that the entire plant could be packed and enclosed within cars whose dimensions should not exceed the limitations of tunnels, bridges, etc., while at the same time all parts had to be made strong enough to stand the shocks and vibration due to railway service without requiring undue expense for repairs.

Fig. 1 shows in operation a large Hetherington plant recently built for the Assyrian Asphalt Co., of Chicago. Fig. 2 shows a similar plant closed and ready for transportation, but it must be noted that the front car in Fig. 1 is the rear car in Fig. 2.

The plant is all contained upon two cars. One of these, termed the drier car, is 42 ft. long; the other, or melter car, is 36 ft. long. Both are 9 ft. wide. Each car has an underframe of six steel longitudinal sills, composed of 12-in. I-beams and 12-in. channels, and stiffened by eight truss rods. Steel body bolsters are built into the framing, and the diamond trucks have also steel holsters. All castings are of steel and the only wood used is for the deadwoods, which are of oak. The floor is of ¼-in. steel plates, riveted to the steel sills. The cars are fitted with automatic couplers and air brakes, and are built with due regard to the M. C. B. standards.

The equipment of the drier car includes a 50-HP. steam boiler of special design, a 35-HP. steam engine, a boiler feed pump, a sand elevator and conveyor of the link belt type, two drums for heating sand, an air compressor and a double rotary air exhauster to create the necessary artificial draft for the fires of the heating drums. The equipment of the melting car consists mainly of a steel cylinder or agitator, and three or four melting kettles or tanks, each having a capacity of about seven tons of asphalt. These kettles are enclosed in a housing of steel plates, and between them are partitions of hollow fireproof tiles of special design. Similar tiles are used to line the housing, an air space 1 in. wide being left between the tiles and the steel plates. These tiles form an effective insulator against loss of heat and are much lighter in weight than ordinary firebrick. All the tiling and furnace masonry is so built as to be proof against damage by the vibration and jarring of the cars when traveling. The furnaces are above the car floor, the grates being let into the floor, so that there is no projection below the framing.

The cars are run upon a side track at a convenient site for the work, and are placed about 7 ft. apart, the wheels being blocked, and the corners of the cars supported by screw jacks. The sides of the drier car (the leading car in Fig. 1 and the rear car in Fig. 2) are then opened, the lower part falling down to form a working platform, and the upper part forming a roof or shelter, all supported by tubular posts which form part of the equipment. On the melter car, the inclined roof, hinged at the eaves, is folded back and forms an upper working platform above the kettles, supported by inclined braces. A light steel framing supports an awning over this platform. Between the cars is built an elevated tower, spanning the space between their ends, and having its four columns supported on the corners of the cars. This tower is built of light tubing and steel beams. Upon it, about 9 ft. above the ground, is a platform carrying the mixer, in which are mixed the necessary proportions of asphalt, carbonate of lime and hot sand to form the paving material. Suspended just above this is the sand measuring box, which contains the amount of sand required for one charge of the mixer, and is supplied from the hot sand storage bin, at the top of the tower. The latter is a large rectangular steel bin, containing a revolving screen to take out the gravel and coarser particles from the sand. Underneath the tower, and between the cars, is a roadway for the asphalt wagons.

In operation, asphalt is placed in the melting kettles, and sand is shoveled into the buckets of the cold sand elevator, seen at the side of the front car in Fig. 1. This delivers the sand into the heating drums, from which it passes into the boot of the enclosed vertical hot sand elevator, by which it is carried up to the screen, and thence falls into the storage bin. It might seem to be a better arrangement, however, to screen the sand first and not waste fuel in heating gravel, etc., which is not needed, but we are informed that there is so very little gravel in the sand as to have practically no effect on the fuel consumption, and that by using the overhead screen the refuse can be carried away by a chute without having to be rehandled. While the sand is being heated the asphalt is being melted in the kettles and thoroughly stirred in the cylindrical agitator.

When the materials are ready, the operator on the melting car opens a valve in the spout of the agitator and allows a certain amount of asphalt to flow into a steel bucket, in which it is automatically weighed. As the operator at the mixer allows the hot sand and the carbonate of lime to fall into the mixer, the bucket of asphalt is run to the mixer on a short trolley track and poured into the box. The mass is mixed violently for a short time, and the operator then pulls a lever which opens a door at the bottom of the mixer, allowing the charge to fall into a wagon standing between the cars.

The capacity, as demonstrated by actual work this season, is said to be from 1,800 to 2,400 sq. yds. of paving per day. The plant was invented four years ago, but was not fully developed until last year. The latest and largest plant is one recently completed for the Western Paving & Supply Co., of Chicago. Several plants have been built and have been operated successfully at Oswego, N. Y.; Lima, O.; Toledo, O.; Houston, Tex.; Bluffton, Ind., and Grand Rapids, Mich., where a considerable amount of work has been done. The inventor is Mr. Frederick A. Hetherington, to whom we are indebted for photographs and information, and the plants are built by Hetherington & Berner, of Indianapolis, Ind. The same firm also builds stationary asphalt plants.

EQUIPMENT AND MAINTENANCE OF ELECTRIC CARS.*

By M. S. Hopkins.

Car Bodies.—For years car builders have attempted to devise a car body which would be equally durable in both summer and winter, but judging from the character of equipment now in use on the majority of roads, such a car has not yet been produced. The combination car with movable parts is not satisfactory for winter use. It is troublesome, noisy and cold, and is lacking in many of the essential features of the open car for summer service. The open cross seat car of the barge type, with running boards on the side, seems by far the most desirable type of car for summer service, offering the largest seating capacity and the best facilities for receiving and discharging passengers, which is a great advantage in city service. Considering all features, the box car, with side seats, large windows, wide end doors to the side of a roomy platform and vestibules closed on one side, seems best adapted to the average conditions of winter service. While the vestibule type closed on one side is not so convenient for the handling of large crowds, yet the additional safety afforded on double track roads should receive full consideration, even at the expense of convenience. In localities where winters are accompanied with snow fall and freezing weather, the vestibule affords protection to passengers, and motormen, and conductors are able to render very much more efficient service.

---

*Condensed from a paper read at the annual meeting of the American Street Railway Association.

The long car body seems to be growing in favor with the railway manager, due to the comparatively small increase in operating expense, in comparison to increased carrying capacity, and its allowing of the increase of headway or decrease in number of cars run, resulting in a large decrease in operating expense per passenger carried.

In the construction of box-car bodies, the trusses should be as deep as possible, and great care taken to secure a perfectly rigid fastening at end of sill, as the slightest deflection throws an undue strain on the joints and framing of car body. Where side sills are plated on the outside with steel plates, all season cracks should be thoroughly filled with a thick mixture of lead and oil, and the entire surface given a heavy coat of oil paint before the plate is put on. It is hardly necessary to say that all joints should be well leaded and protected from moisture. A heavy steel roof rafter in one piece should be put in at every post, and a saving in maintenance will be made by having platform floors of oak or maple. The trolley stand should be mounted on a trussed support, which will distribute the strain to the ends of the car as much as possible.

Ash seems to be almost universally used in post and light framing of cars. This is probably due to the difficulty in securing the grade of oak necessary, the lighter weight of the ash and the greater ease with which it is worked. Yet, in spite of these difficulties, oak is far preferable, being stronger and more elastic, and a material that will give a far longer life.

Trucks.—Under the average conditions, a 22-ft. closed car or an 8 reversible seat open car body should be the limit for a single truck. Although there are single trucks which will carry a longer body fairly well, yet the increase in maintenance will in most cases warrant the use of double trucks. The local conditions should govern the type of double truck used, the bolster type in most cases being preferable for long cars on high speed, suburban service, while for city service, where heavy grades and quick starts demand maximum traction, and short curves make it necessary for the wheel to turn under sill, the bicycle or maximum traction type must necessarily be used. This type of truck is no longer an experiment, and while they possibly require more careful inspection and adjustment, very efficient service can be secured by their use.

Trucks should be made up of a small number of parts; cast and malleable pieces should be the lightest consistent with strength. Springs should be so arranged as to prevent oscillation, and give an easy riding car under all conditions from no load to full load, and when the truck is of such design as to prevent the use of an under truss, the spring base must be exceptionally long and end springs arranged to relieve strains on the car sills.

Electrical Equipment.—In the selection of electrical equipment the main point is to secure equipment of ample capacity and proper design for the service required. The bearings should be large and lubricated by oil from below and cup grease from above, and so designed that drip from bearings will fall outside of the frame. The armature should be so constructed as to permit the shaft being pushed out without disturbing the commutator and winding.

I am glad to note that the importance of light-weight and slow peripheral speed of armature has been recognized in recent designs of railway motors. The inertia or flywheel capacity of armature should be the smallest possible consistent with the work required. Engineers differ as to the best method of suspension. From a theoretical standpoint, the cradle or side-bar suspension has the lead. The dead weight is largely removed from axle, thereby eliminating to some extent the hammer blow on rail-joints, decreasing the wear on axle brasses and securing the better alinement of gears; yet, in practice, the nose suspension is still preferred by the writer, as the car starts more smoothly—the weight of the motor on the spring supports overcoming the jerk and quiver so common in other methods of support. The specifications for railway motors, as drawn up by leading manufacturers to-day, amount to practically nothing, and I would suggest that the purchaser of motors in his specifications clearly define the rating, heat limit and efficiency.

The series-parallel controller is in most respects a satisfactory device, the chief objection being the narrow range of speed on running notches. Specifications for resistance should provide that the last two points of resistance be of sufficient capacity to allow of their continued use as running notches, especially where cars are operated in city service.

There are several types of magazine fuse boxes or cutouts and single cutouts using a special fuse which possess a number of points of merit. Without going into detail, it is the opinion of the writer that, under average conditions, the standard magnetic blow-out fuse box, using a link fuse, is preferable.

Each car should be equipped with a thoroughly reliable lightning arrester. Points to be noted in selecting this device are as follows: The kicking coil, which should always be installed; the air gap, as small as possible; a positive and quick device for interrupting the current after discharge, and one which will not be injured by the discharge; a non-inductive resistance in the circuit which will limit the flow of current and thereby prevent the opening of the circuit breaker at station when several arresters operate at the same time.

Care of Equipment in Car Houses.—Generally one of the following three methods is used for daily inspection of equipment: Inspection of cars each trip; inspection of equipment at night by motor inspectors; and inspection of equipment during the day by motor inspectors and repair men.

In regard to trip inspection, I would say that in the present degree of perfection attained by manufacturers of railway equipment, trip inspection should not be necessary, except on interurban lines operating at high speed over long runs, and is of doubtful value, besides it is expensive. The period of time for making this inspection is necessarily very short, and the entire time is taken up in mere inspection—little or no opportunity being afforded in which to make repairs.

In regard to night inspection, the experience of the writer has been such as to absolutely condemn the method as expensive, slovenly and unsatisfactory. It is impossible to make a thorough inspection of cars at night, no matter how well lighted the car house may be, and the efficiency of the work done by the men is very far below that of the work during the day. Therefore, when local conditions will admit, inspection of cars during the day seems by for the most advantageous.

We will assume a car house station from which 25 cars or more are operated. There is usually one general foreman in charge of this station. His duties are chiefly those of the transportation department, but he should be a man thoroughly conversant with the usual troubles which may occur in the operation of the equipment, and know how to direct minor repairs. It would, of course, be better if he were able to personally superintend the actual work of repairs, but it is usually very difficult to find men who are good mechanics and likewise efficient in the transportation department.

For making inspection and running repairs such as should be made in car houses, it is a safe rule to have one man to seven cars. It is, however, important to have a man in all car stations, known as chief inspector of that division, who is thoroughly conversant with practical electrical and mechanical matters. This chief inspector should have under his care for inspection and repairs seven cars, and also have direction and supervision of the other two repair men who care for the remaining 18 cars.

The duties of these men should be to make a daily inspection of every car assigned to them, starting first with their motors, examining the grease in the cups, the brushes, cleaning the motors, examining connections, etc. They should remove the covers from their controllers about once in three days, and oil the same very lightly with vaseline or grease, remove any blisters which may have appeared on the contact points, and carefully examine the adjustment of contact fingers. Too much emphasis cannot be given to the inspection of all brake rigging, and very thorough inspection should be made daily from the brake-handle to the brake-shoe, and the brakes tried by inspectors before car is placed in service. A broken brake-chain or worn out shoe, a broken brake-clutch or a broken brake-pin are things that should never occur through neglect, and if an accident of this kind does occur, the cause should be immediately traced and the responsibility located. Economy in maintenance should never be exercised at the expense of absolute safety, and brake-chains, pins and shoes should be discarded long before the danger point is reached.

The actual repair work done by these inspectors should be all work possible to be done without the use of machine tools, or which, if done by them, will not require the loss of car from service for a period of more than two hours.

The question as to how often car equipment should be taken to the shops for a general inspection and overhauling, and to what tests the electric equipment should be subjected at the time of inspection, are subjects on which electrical engineers widely differ. Considering the average conditions, and assuming that equipment is in good condition, it is the opinion of the writer that the taking of cars to shops every six months should maintain the equipment in good condition and assure its efficient operation.

Motor Bearings.—Bearings should be run "close" at all times; the time of their renewal being determined by the effect of the wear on the gear and pinion, as the wear on these parts is largely affected by the wear of the bearings.

After a series of tests, covering quite a period of time, as to the wear of various materials used in motor bearings, the writer feels warranted in making the statement that either the best grade of Babbitt or brass bearings should, under the ordinary conditions, give a longer life than six months, and when a bronze bearing of the proper mixture is used and properly lubricated, a life of twelve months can safely be expected. The method of lubrication largely influences the life of brasses. The writer has, after long tests with various lubricants, discontinued the use of grease entirely on armature brasses, and in most cases on axle brasses, a good grade of engine oil, supplied through wicks, being more satisfactory and economical. In order to reduce the maintenance of brasses to a minimum, the use of phosphor bronze is strongly recommended. Street railways operating 25 or more cars will find it economical to cast and machine their own brasses.

Rough and burnt commutators are too frequently the cause of expensive motor repairs, and usually indicate imperfect motor design or inexcusable neglect. Well designed motors in good condition, even under the hardest service, provided, of course, the average work is within the rated capacity of the motor, should not require turning oftener than once in eight months. There is nothing that so well indicates to the practical man the conditions of the motor as the condition of the commutator. Whenever the commutator shows signs of burning or blackening, steps should be at once taken to prevent it. It is not advisable to try to prevent this by the continual sanding of the commutator by motor inspectors, though the occasional cleaning up of the commutator with sandpaper is necessary with all motors. The causes of trouble of this character are so numerous that mention is made of only a few of the more important.

Brushes should be soft, close-grained carbon, treated with a good lubricating compound—one which does not flow too freely from the heat from the motor, and which will not burn and carbonize on the commutator. The tension on the brushes is, as a rule, too light on railway motors. It is a common belief that heavy tension causes wear of commutator, but experience has shown that the actual wear of commutator due to friction of the brush is very small, and that increased tension will, in some cases, materially decrease the sparking, which causes the greatest wear. Improper alinement of brush-holders frequently causes sparking. In recent practice the use of side contact springs on brushes has been generally abandoned. On motors carrying heavy currents this spring is quite essential, as excessive heating of brush is caused by limited contact in the holder.

Commutator insulation should be made of what is known as the built-up mica, segments of the very softest grade of amber mica. A hard, clear mica should never be used in commutator, as this mica will not wear away as fast as the copper, and there is nothing so disastrous to the life of the commutator as high mica insulation.

The Electrical Testing of Railway Equipment.—Elaborate systems for the periodical testing of insulation on railway equipment seems to be growing in favor with some electrical engineers, but the practical value of these elaborate tests is not fully demonstrated. Experience has shown that tests of this kind are very misleading, and frequently cause the dismantling of equipment which, under ordinary conditions, had no tests been made, would have continued in service for a long time.

Judging from my own experience, it is neither necessary nor advisable to periodically test the insulation on the equipment, but to make such tests only in cases where motors are not working properly. The proper training of motor inspectors as to the little points about railway equipment which clearly indicate trouble with motor will in nearly all cases locate trouble due to weak insulation so that it can be remedied before any serious damage has resulted to any other part of the equipment.

All armature and field coils repaired should be carefully tested as to resistance and insulation to ground, and on all armatures having coils repaired, new commutator put on or commutator turned, resistance between commutator bars should be very carefully measured; using, preferably, a portable Wheatstone bridge testing-set, capable of showing clearly a variation in resistance of 1-1,000-ohm. This is one of the most important tests to be made in the care of railway equipment, as more burn-outs of armatures are caused by the slight short circuiting coils, due to solder, acids or copper turnings bridging over insulation between bars under leads than from any other cause, which can only be located by a test of this kind. Any mistake in connecting up the leads or a bad joint will at once be detected before any damage has been done.

Car Wheels.—Much has been written of late on the subject of car wheels, their wear and alinement, and still street railway managers are careless about their wheels. Too much care cannot be given to the sizing and alinement of wheels, and the pressure with which they are forced in the axle. At least 50% of the wheels removed from the cars throughout the country are caused by broken or sharp flanges or a broken wheel. The use of sand largely influences the life of wheels; but the conditions vary so widely I would not be justified in saying that a sandbox should in no instance be placed upon a car. Where it is possible to successfully operate without them, however, sand boxes should be discarded and other means used for sanding the track. It is in most cases far more economical to fit up a special car, capable of carrying a large amount of sand, and sand the track for say 100 ft. before each point where a stop is likely to be made, and on grades and in places where the track is exceptionally slippery than to sand the rail for its entire length.

Repainting of Cars.—The experience of the writer has clearly demonstrated that it is satisfactory to repaint cars without removing all of the old paint. Patent varnish removers, scalers, etc., are a snare and a delusion. The writer has found the following system of repainting cars to be quite satisfactory: First, remove all old paint by softening it with a blow-pot just enough to allow it to be scraped off with a broad putty knife, not allowing flame from the blow-torch to at any time strike the bare wood. Sand surface off well with block and sand paper. Where any new work has been put in, it should be first primed with a coat of boiled oil and a little lead and allow it to stand for not less than four days. Dashes and all iron work should be thoroughly cleaned with a strong alkali and primed with a coat of linseed oil put on boiling hot and allowed to thoroughly harden; giving one coat of oil and lead before color. If surface is rough, plaster with lead on this coat. Allow it to thoroughly harden, and sand with block; then lay on two coats of flat lead, two coats of color, varnish, stripe and ornament, finish with one coat of rubbing varnish and one coat of finishing varnish. The main object in the painting of cars should be to secure a hard, smooth surface which will hold out the varnish with the very smallest amount of material; the thinner this surface is the better. Care should always be taken where plaster is used to make it as thin as possible, and lead coats, color and varnish should all be carefully tempered, so as to set alike, as most cases of cracking of paint are due to the want of proper tempering and of lead and color coats.

A car painted in this manner should not require repainting for from 6 to 7 years, if properly cleaned and varnished. Cars should come into the paint shop, even where the best grades of varnish are used, once every eight or ten months, and be thoroughly washed down with pumice and strong soap and given a coat of finishing varnish.

After a number of trials of various floor paints and paints mixed especially for the purpose, the conclusion has been reached that there is nothing equal to pure white lead and linseed oil and suitable color for the floors of all cars. The majority of car floors are stripped, and it has been found impossible to find any material hard enough to stand on the top of the strips of a car floor, while almost any material will stand the wear, but not the moisture, between the slats. It is therefore very evident that the best paint for this purpose would be one which would best preserve the wood in the floor of the car from the constant moisture to which it is subjected.

As to the car roofs, the main object is to put as little material as possible on the canvas of car roofs, and that material should be elastic and yet withstand the action of the weather. No paint is too good for the car roof—the best white lead and oil giving the best results.

METAL TRUCKS FOR FREIGHT CARS.

(With two-page plate.)

The great success which has attended the use of metal trucks for freight cars, and the extent to which such trucks are now being introduced, has led a number of designers and manufacturers to enter this field of competition, which is already sufficient to support a practically new industry. Some railway companies also have their own special designs of metal trucks. In an article on our editorial page, we have discussed the general questions incident to the use of metal trucks, and in the present article we describe a number of examples of different types of these trucks. These examples do not include all the metal trucks on the market, but they are sufficiently numerous to illustrate all the different types.

In this article we have divided the trucks into two classes: First, trucks having springs over the axle boxes, in which the whole weight of the car (except that of the wheels, axles and boxes) is carried upon the springs; second, trucks having springs under the ends of the bolsters, in which the weight of the body and the bolsters rests on the springs, leaving the weight of the truck frame to be carried rigidly upon the axle boxes.

In the Fox truck, which was about the first steel truck to come into general use, the springs were placed directly over the boxes, instead of under the ends of the bolsters, as was the usual plan, and this practically new arrangement was widely denounced as being objectionable, particularly on the ground that the short stiff springs would make the trucks ride very hard. From the fact that this truck has steadily grown in favor since its introduction, in 1891, it would seem that this is not of such great importance, or that it has been avoided, and it is particularly to be noted that many of the later forms of metal trucks have the springs arranged in the same way. Where the springs are over the boxes, there are usually two concentric springs to each box, placed in openings in the side frames, the center of the springs being coincident with the center line of the frames. In the Cloud truck, however, a nest of four springs is used, two on each side of the frame, resting on brackets in the boxes and bearing against top seats from the frames, the webs of the frames passing between the springs. In some of the Fox trucks, built for foreign railways, plate springs are used, placed outside the frames and over the boxes, and a somewhat similar plan has been devised for the Cloud truck, but in the latter case two sets of elliptic springs are used over each box, one set on each side of the frames.

Metal Trucks with Springs Over the Axle Boxes.

The Ajax Truck.—This is a cast steel truck, composed of but three members (two side frames and one transom), each of which is a single casting of open hearth steel. The springs are over the boxes, and trucks of this type have no bolster. The construction is shown in Fig. 1. The side frames have the top horizontal from end to end, and are of I-beam section at the middle, made deeper and wider at the ends to form the pedestals, the flanges extending the full depth of the pedestals. Over the axle boxes the frame is enlarged and has the web made circular, to form a seat for the coiled springs. In some of the trucks the frames are lightened by apertures in the deeper parts of the webs. The transom is of rectangular section, with the top and bottom webs partly cut away between the center plate and side bearings to ensure lightness. The ends of the transom have flanges which fit between vertical ribs on the side frames, the transoms thus fitting snugly against the webs of the frames, to which they are secured by bolts. This arrangement prevents shearing strains upon the bolts. The truck weighs about 1,700 lbs., exclusive of wheels, axles, boxes and springs. It was designed by the Shickle, Harrison & Howard Iron Co., of St. Louis, Mo., and is manufactured by that company.

The Black Diamond Truck.—The side frames of this truck are built-up trusses, each formed of two 5-in. T bars. These are horizontal and 12 ins. apart for 15⅜ ins. at the middle, where they are riveted to the transoms. They then incline together and are riveted to cast steel fillers. Beyond these, the ends of the lower bar are curved down to fit against the inner side of the pedestals, while the ends of the upper bars are curved up to fit the top of the pedestals and then turned down vertically to form the outer legs. A double coiled spring is placed over each box. The transoms are 12-in. I-beams or channels, extending through the side frames and riveted to top and bottom gusset plates. Horizontal I-beam spacing pieces are riveted between the webs of the 12-in. I-beams. The truck weighs 1,200 lbs., exclusive of wheels, axles, boxes and springs. The manufacture has only recently been commenced, but some experimental sets are in use, and the specifications for 100 steel frame gondola cars of 70,000 lbs. capacity, for a foreign railway, contain the following clause:

> The diamond type of truck will not be permitted, and preference will be given to the "Black Diamond" or equivalent design, which insures strength, easy repairs, and arrangements to keep the truck square to its work.

One of these trucks was tested by Mr. Robert McKenna, Master Car Builder of the Delaware, Lackawanna & Western R. R., who loaded the truck with 60,000 lbs. of pig iron. This load caused a deflection of ¼-in., but there was no permanent set. The Black Diamond truck was designed by Mr. R. W. Oswald, and is manufactured by the Jackson & Woodin Mfg. Co., of Berwick, Pa.

The Cloud Truck.—This is built up of pressed steel members, and is shown in Fig. 2. It has flanged steel side frames, flanged inward on top and bottom and forming both legs of the pedestals. These frames are horizontal on top and bottom, but are made deeper at the pedestals than in the middle, while the flanges are wider at the middle and serve as gusset plates for the transom connections. The transoms are flanged steel channels, placed back to back. The center bearing is riveted to the transoms, and the side bearings are riveted to the top gussets of the side frames. The ends of the transoms are riveted to the side frames, and also to the top and bottom gussets of these frames. One of the special features of this truck is the arrangement of the springs, which, though placed over the boxes, are clear of the side frames. The webs of the frames come closer down to the boxes than in the Fox, Schoen and other trucks, where the springs occupy the openings in the webs of the frames directly over the boxes. To effect this, heavy malleable iron pedestals are used, with legs of T section, forming wearing surfaces 6 ins. wide for the boxes. These pedestals are riveted to the outside of the frame plate, and their width is sufficient to form a top seat for a nest of four coil springs, 4 ins. diameter, two on each side of the frame plate, with the web of the plate between them. This allows for the use of springs less rigid than where only two concentric springs are used, thus making an easy riding truck. A horizontal bolt, with spacing sleeve, is passed through the bottom of each pedestal. For tenders and cattle cars, two pairs of elliptic springs are placed over each axle box, instead of four coil springs; the pedestals being of special type to receive the elliptic springs. This arraangement is also shown in Fig. 2. There is no difference in the cost of the truck frames, whether coil or elliptic springs are used. The truck frame for a 60,000-lb. car weighs 1,350 lbs., and that for a 100,000-lb. car weighs 2,100 lbs., both exclusive of wheels, axles, boxes and springs. There are now about 2,600 of these trucks in service, including those under 30 steel cars of 100,000 lbs. capacity on the Pittsburg, Bessemer & Lake Erie R. R. The truck is the invention of Mr. John W. Cloud, and is owned by the Cloud Steel Truck Co., Old Colony Building, Chicago, of which Mr. Willard A. Smith is President.

The Fox Truck.—This was the pioneer of steel truck frames, and of pressed steel frames in particular, and was first manufactured in England, at the works of the Leeds Foundry. Each side frame is one plate of pressed steel, flanged inward at the top and ends, and slotted for the axle boxes, the pedestal legs being reinforced by pressed steel pieces of horseshoe shape, riveted to the frame, and a bolt with spacing sleeve holding the lower ends of the legs together. The frames are higher at the ends, over the axle boxes; and at the middle the top flanges are widened out to form gusset plates for the attachment of the transoms, which are pressed steel channels set back to back. The placing of the springs above the axle boxes was a decided innovation at the time when the truck was introduced (about 1891), and this feature was for a time the cause of much opposition. In spite of this, however, the truck has steadily grown in favor and is now in very extensive use, there being a very large number of freight cars in this country equipped with Fox trucks, while the arrangement of the springs has been copied in several other forms of steel trucks. In special cases semi-elliptic plate springs are used, placed outside of the frame plates. The weight of one truck, as used on the New York Central R. R., is 1,382 lbs. The trucks are manufactured by the Fox Pressed Steel Equipment Co., of Pittsburg, Pa.

The Hewitt Truck.—In this truck the side frames are formed of a special rolled steel shape, the section of which resembles an I-beam with the web extended through the flanges, forming a top and bottom T section, as shown in Fig. 3. The frame is 17 ins. deep over all and 12 ins. deep over the flanges. At the ends, the web is cut away and the T-shaped flanges thus left are spread apart vertically, forming top and bottom jaws to receive malleable iron pedestals. Each pedestal has its inner face slotted to receive the edge of the web of the frame, and is secured by one pedestal bolt on the outside, the bolt passing through the pedestal and the ends of the frame flanges. By removing these bolts, and thus releasing the pedestals, the wheels and axles can be removed without taking the truck from under the car. The transoms are 12-in. channels (though Z-bars are shown in the drawing). The channels are set with their flanges outward and are attached to the side frames by vertical angle iron connections and horizontal gusset plates on top and bottom. A double coiled spring is placed over each axle box, the top of the spring being covered by a hood or cap forming part of the pedestal. The truck is designed to have inside hung brakes. Rolled steel is used for all the parts except the center plate, saddle and pedestals, which are of malleable iron. The truck weighs (without axles, wheels, boxes or springs) about 1,400 lbs. It was designed by Mr. H. H. Hewitt, (General Manager of the Union Car Co.), who is President of the Hewitt Steel Truck Co., of Buffalo, N. Y. Its manufacture has not yet been commenced commercially, owing to delays in getting the special section rolled and in procuring the heavier forging machinery which experience has shown to be necessary, but the company already has orders for over 500 pairs of these trucks.

The Joughins Truck.—This was one of the first freight car trucks made up from structural shapes, and was designed with the idea of abandoning the use of the more expensive pressed steel shapes on that style of truck which has the springs placed on top of the journal boxes. Each side frame is made up of an I-beam, and the transom is formed by two I-beams, which are connected to the side frames by vertical angle irons and horizontal gusset plates. A special feature of the truck is the open-ended pedestal, which allows the wheels and axles to be removed after jacking up the car only just enough to ease the spring, instead of having to jack it up the entire height of the pedestal legs.

This pedestal has its outer leg formed by a hinged or removable piece. In one form of truck the ends of the side-frame I-beams are split horizontally and opened out, the superfluous metal in the web being cut away, leaving the top and bottom flanges. A bent steel T-bar riveted to the web forms the top and inner leg of the pedestal, the outer leg being an L-shaped piece of cast steel hinged to the outer end of the top of the pedestal and bolted to the bottom of the inner leg. In another form of the truck the fixed part of the pedestal is a cast steel piece in the form of an inverted L, riveted to the end of the side frame, while another L-shaped piece, secured by a bolt at each end, completes the pedestal. By removing the bottom bolt in either form of truck the loose outer piece of the pedestal can be swung up, clear of the axle box, and the wheels can then be run out.

The weight of the truck is about 1,200 lbs. (exclusive of wheels, axles, boxes and springs). Some of the trucks are now in experimental use under tenders on the Norfolk & Southern R. R., and have been in service for more than two years. They were designed by Mr. G. R. Joughins, who was until recently Superintendent of Motive Power of that road, and were built to his order by the Baldwin Locomotive Works.

The Kindl Truck.—This is another truck built of standard rolled shapes riveted together, but each side frame is a truss (as in the Black-Diamond truck), instead of being formed in one piece. Each frame has one tension member, one compression member and a single tie member, the arrangement resembling somewhat that of a diamond frame. The construction is clearly shown in Fig. 4, which represents a truck for 60,000-lb. cars. Two steel angles, placed back to back and riveted together, form the outer legs and tops of the pedestals. They diverge vertically between the pedestals, the top or compression member curving down 4½ ins. to meet the top of the transom, while the tension member is dropped to meet the bottom of the transom and horizontal tie angle. The inner legs of the pedestals are formed by angle irons (which serve as the guides to the axle boxes) and web plates. Over each axle box is a double coiled spring. The transom is built of two 15-in. channels, 12 ins. apart and toed out. Between them, at each end, is placed a channel end-cover with its flanges vertical and its back outward. To these end pieces the side frames are secured at top and bottom. A ¼-in. horizontal gusset plate extending between the center lines of the axles is riveted to the top angle of each side frame and to the top of the transom. This plate is 7 ins. wide at the ends, and 12 ins. at the middle, and is bent to conform to the curve of the top member of the side frame.

The truck frame for cars of 60,000 lbs. capacity weighs about 1,390 lbs.; that for 80,000-lb. cars, 1,510 lbs., and that for 100,000-lb. cars, 1,900 lbs. These trucks are now in use on 50 new steel hopper cars of 100,000 lbs. capacity on the Pittsburg, Bessemer & Lake Erie R. R., and six coal cars of 60,000 lbs. capacity on the Illinois Central R. R., while orders are being filled for 200 additional cars for the latter road. The truck frame was designed by F. H. Kindl, Chief Engineer of the Carnegie Steel Co., and is manufactured for the Kindl Car Truck Co., Old Colony Bldg., Chicago, by Wm. B. Scaife & Sons, of Pittsburg, Pa.

The Schoen Truck.—While this truck is built up of pressed steel shapes, and appears at first sight to be similar to the Cloud and Fox trucks, it is composed of a greater number of parts than most trucks of this material, the claim being made that in case of accident the truck can be repaired at the railway shops, instead of having to be sent to the maker for new frames or parts. In most metal trucks, however, one of the principal objects of the design is to keep the number of parts as small as possible, and this reduction in parts is very generally held by railway men to be a specially important feature of such trucks.

In the Schoen truck, shown in Fig. 5, each side frame consists of three main parts: (1) A horizontal top member of channel section, with the flanges upward, the ends of this member being turned down vertically to form the outer leg of the pedestals. (2) A horizontal flat bar for the bottom member, the ends being turned up to form the inner legs of the pedestals. (3) A web plate flanged inward on top, bottom and both ends, the flanges being riveted to the top and bottom members and inner pedestal legs. The legs of each pedestal are connected by a horizontal bolt at the bottom, with a spacing sleeve between the legs, and the inner legs are further strengthened by gussets or knee brackets riveted to the legs and the bottom members of the side frames. Wearing plates, which are adjustable, are interposed between the boxes and pedestal legs, and double coiled springs are placed above the boxes. The transoms are pressed steel channels, set face to face, connected by the pressed steel center-plate and side-bearings, which are riveted to them, and having steel distance pieces on the inside. The webs of the channels are bent outwards at right angles at the ends and riveted to the webs of the side frames, while the top member of each side frame is made wide, flat and dished at the middle to form a gusset plate connecting the transom with the frame.

These trucks are manufactured by the Schoen Pressed Steel Co., of Pitsburg, Pa., and are in use on a number of railways. They have been applied to many of the all-steel, hopper-bottom cars of 100,000 lbs. capacity, built by this company for the Pittsburg, Bessemer & Lake Erie R. R. It is one of these latter trucks which is shown in Fig. 5, its weight being about 1,785 lbs., exclusive of wheels, axles, journal boxes and springs. The number of parts is as follows:

	Thick.		Thick.
2 top members	½-in.	1 center plate	½-in.
2 bottom members....	½-in.	2 side bearings......	⅜-in.
2 side frame webs.....	5/16-in.	4 spring caps.......	⅜-in.
4 pedestal brackets....	⅜-in.	8 wearing shoes......	¼-in.
2 transom channels ..	7/16-in.	4 pedestal ties.......	..
2 tr'ns'm center braces	⅜-in.	4 pedestal bolts with nuts, washers & keys	
1 distance plate.......	⅜-in.		

Another form of truck is manufactured by this company, having side frames of the diamond type, but built up of pressed steel shapes. This is described later on. The builders state that their truck frames are in use under 5,000 cars. This is exclusive of metal trucks equipped with the Schoen bolster and small pressed steel parts, more than 100,000 cars being equipped with these.

Trucks with Springs Under the Bolsters.

The American Truck.—This is an adaptation of a cast steel bolster to side frames of the diamond pattern. The bolster is a single casting of soft open hearth basic steel, in shape like an inverted trough, with vertical sides, deeper at the middle than at the ends. The center bearing, side bearings, column guides and top seats for the coiled springs are all formed in this casting. The ends of the bolster project through the side frames, under the top arch bars, and rest upon coiled springs. At the middle of each side frame is a steel casting which forms the bolster columns and lower spring seat. The side frames are connected to each other at the bottom by two flat wrought-iron braces, extending diagonally across between the columns. The ends of these diagonal bars lie between the lower arch bars and the tie bars, and are secured by the column bolts passing through them, while at their intersection they are riveted together.

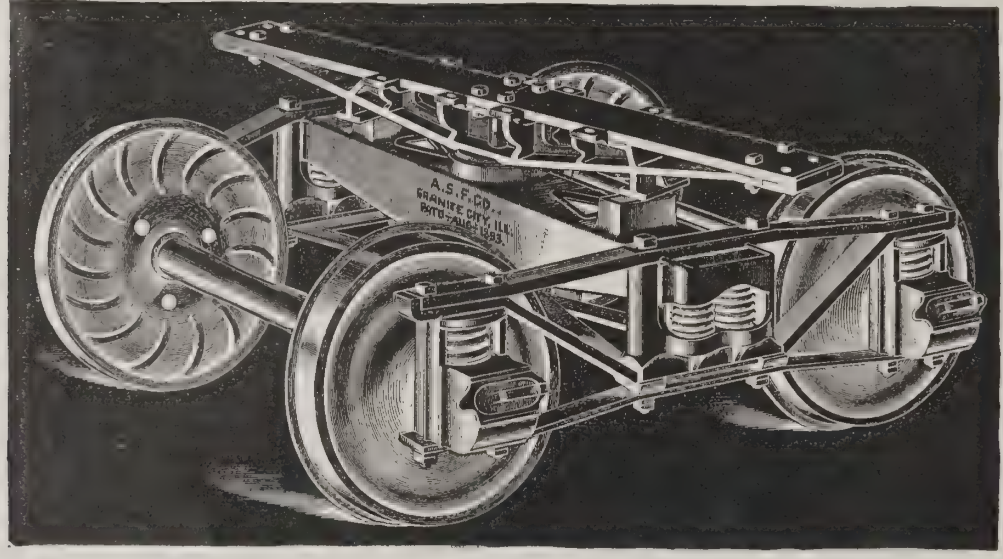
The bolsters for cars of 60,000 lbs. and 80,000 lbs. capacity, and for tenders, are 13 ins. wide, 4 ins. deep at the ends, and 9 ins. deep at the middle. For 100,000-lb. cars they are 11 ins. deep at the middle. They are also made in smaller sizes for swing motion trucks and for narrow-gage trucks. Each bolster is tested by hydraulic pressure to several times the load it is to carry, and the date of the test is stamped upon it.

The trucks are adapted for either inside or outside hung brakes and the spring seats on the bolsters and column castings are made to reecive any size or shape of helical or elliptic springs. The principal advantages claimed for these trucks are simplicity of construction, small number of parts, flexibility and lightness combined with strength to resist shocks and twisting strains. The trucks for 60,000-lb. cars weigh 1,574 lbs., exclusive of wheels, axles, boxes and springs. There are over 35,000 now in use on 130 different railways in this and other countries. They are manufactured by the American Steel Foundry Co., of St. Louis, Mo., whose works have a capacity of 200 trucks per day.

The Haskell & Barker Truck.—This is another application of a metal bolster to side frames of the ordinary diamond pattern. The bolster, however, is not in one piece, but is built up of top and bottom plates riveted to a cast-steel center piece or filler which is not solid, but is made in truss form. This truck is used on the 80,000-lb. coal cars of the Illinois Central R. R. (Eng. News, June 16, 1898). On these cars the bolster is 12 11-16 ins. deep at the middle and 7⅜ ins. deep at the ends, having a top plate ⅞ × 11 ins., and a bottom plate ⅝ × 11 ins. The ends of the bolster pass through the frames and have cast upon them the column guides for the malleable iron columns. Each end of the bolster is supported by a nest of coiled springs seated upon the spring plank, which is a 13-in. steel channel resting upon the lower arch bars of the side frames. The Illinois Central R. R. has 500 coal cars equipped with these trucks, which are manufactured by the Haskell & Barker Car Co., of Michigan City, Ind.

Northern Pacific Ry. Truck.—This railway is using an all-metal truck which was designed by Mr. E. B. Thompson, Mechanical Engineer of the road, and is manufactured at the company's shops. As shown in Fig. 6, it has side frames of the diamond pattern, with the American cast-steel bolster, described further on, the bolster extending through the side frames. A special feature of this truck is the use of the Barber roller, bearing under each end of the bolster. A broad saddle resting on the lower arch bar supports the end of the two angle irons ½ × 4 × 6 ins., 7 ft. 2 ins. long, which form the transoms, and on this are seated four coiled springs carrying a cap with two concave recesses on top to receive the two 2-in. rollers, which lie parallel with the track. On the rollers rests a similar cap attached to a wooden block or filler which is inserted into the end of the bolster. Mr. E. M. Herr, Superintendent of Motive Power, informs us that this truck operates very successfully and that it takes the curves more easily than the ordinary diamond truck without the roller-bearings. The top arch bar is only cambered 1 in. The bolster is of inverted trough section, with vertical fish-bellied sides, having heavy ribs on the inside of the lower edges. The center plate and side bearings are formed on the casting. Inside hung brakes are used on this truck.

The Player Truck.—This is still a third combination of side frames of the ordinary diamond pattern, with a cast-steel transom and bolster, but differs in many important respects from the other trucks described. The transom is a single trough-shaped casting, in which fits a cast-steel bolster of rectangular section. As shown in Fig. 7, the ends of the transom embrace the top and bottom arch bars of the side frames and are further secured by two column bolts at each end. The strain of the load is divided between the transom and the bolster. That upon the former is light on account of the points of support being immediately adjacent to the bearing points, while that upon the bolster is light on account of the use of a short bolster. The transom holds the truck in alinement, leaving the bolster merely the duty of easing the load upon the springs, which insures at all times the full benefit of the springs. In the ordinary diamond frame truck the bolster has this double service to perform, which results in producing a binding at the columns, causing great strain and wear with consequent shaking and loosening of the frame. The truck is adapted to the use of either coil or elliptic springs under the bolster, the latter being especially suitable for tenders. As the bolster does not extend into the side frames, the springs are consequently inside the frames, instead of being between the upper and lower arch bars as in ordinary practice. The transom is open at the ends, and the springs can be replaced through these openings after jacking up the bolster just enough to relieve the load.



A.S.F.CO.
GRANITE CITY, ILL.
PATD-AUG. 1893.

FIG. 9.—AMERICAN BOLSTER AND TRUCK.

The truck frame weighs complete about 1,500 lbs., the bolster weighing approximately 400 lbs. and the transom 650 lbs. It was designed by Mr. John Player, Superintendent of Machinery of the Atchison, Topeka & Santa Fe Ry., and is manufactured by the Shickle, Harrison & Howard Iron Co., of St. Louis, Mo., who are also the makers of the Ajax truck, already described. There are a number of these trucks in service on the Atchison, Topeka & Santa Fe Ry., the Kansas City, Pittsburg & Gulf Ry., and other railways.

The Schoen Truck.—The Schoen web-frame truck, with springs over the axle boxes, has already been described, but the same company also makes a truck with diamond frames built up of pressed steel shapes. In this form of truck, shown in Fig. 8, each arch bar is of channel section, inverted, and is flared out at the middle to form a gusset plate for the transom connections. Over the axle boxes the lower bar fits inside the upper arch bar, and the two are riveted together. The upper bar is 7-16 × 6⅞ × 2 7-16 ins., and the lower arch bar is ½ × 5⅞ × 2 ins. A flat bar, ⅝ × 5½ ins., with its ends turned up, forms the tie bar, but this is 4 ins. below the lower arch bar, to which it is connected by a double channel piece at the middle. The transoms are pressed steel channels, set with the flanges outward, the channels being 15 11-16 ins. apart, back to back. While the springs are placed in the transverse center line of the truck, as in ordinary diamond trucks, they are not in the longitudinal center lines of the frames, but are set well inside the frames, the center lines of the springs and frames being 11¼ ins. apart. The springs are supported in a rather novel manner. A stirrup or U-shaped piece is attached near each end between the transoms, its sides being clear of the transom channels, while its top horizontal flanges rest upon and are riveted to the top flanges of these channels. The loop of each stirrup supports a saddle or seat for the coiled springs upon which rests the end of the bolster.

The bolster is built up of pressed steel parts riveted together, and is fish-bellied in shape, 12 ins. deep at the middle and 7¼ ins. at the ends. It is formed of two channels, with the flanges set inward, connected by the center plate, end plates and distance pieces. It is only 5 ft. 6 ins. long, being entirely clear of the side frames. The transoms have a great part of the vertical web removed from that part which lies between the spring hangers. The part that remains is sufficient for strength, but the makers state that by the removal of the web the torsional resistance of the transoms is so much reduced that the truck frame has great flexibility in a horizontal plane. This flexibility, they claim, enables the truck to readily adapt itself to inequalities of as much as 3 ins. in the track, without straining the riveted structure. The wheels, axles and boxes can be removed as readily as in the ordinary diamond truck. The truck frame is made accurately square in construction, as the bolt holes for the journal boxes are all drilled at once, after the truck frame has been completed in all other respects. The following is a list of the parts used to make up this truck:

Frames.	Thickness.
2 top arch bars	3/16-n.
2 bottom arch bars	½-in.
2 transoms	½-in.
2 stirrups	1-in.
2 tie bar separators	⅝-in.
4 arch bar fillers*	..
4 brake hanger carriers*	..
1 dead lever fulcrum*	..
2 suspension spring hangers*	..
2 suspension spring hanger clips*	..
Bolster.	
2 channels	½-in.
1 center plate	⅝-in.
2 side bearings	½-in.
1 center brace	½-in.
1 k.-pin supp'rt stirr'p	½-in.
2 spring plates	1-in.
2 end tie plates	½-in.

*Malleable iron.

This truck, for cars of 100,000 lbs. capacity, as illustrated in Fig. 8, weighs 1,615 lbs., including the bolster. It is made by the Schoen Pressed Steel Co., of Pittsburg, Pa., and the makers state that it is in extensive use.

Metal Bolsters.

Besides the various all-metal trucks now being introduced there are numerous designs of metal bolsters, which can be adapted to present forms of trucks, either in new construction or to replace wooden bolsters in trucks now in service. Such bolsters are in very extensive use, some of them being manufactured by makers of metal trucks and other railway supplies, while many railways are using metal truck and body bolsters designed by their own mechanical officers. Several metal body bolsters were illustrated in our issue of July 2, 1896, in connection with an abstract of a report on metal underframes for freight cars, made by a committee of the Master Car Builders' Association, and we note below a few examples of the numerous designs of truck and body bolsters now in use:

The American Bolster.—This bolster, shown in Fig. 9, is a single casting of soft open hearth steel. It is an inverted trough, with fish-bellied sides and closed ends, openings being left in the top table to reduce the weight and the corners being strengthened by ribs. On the top table are formed the center plate and side bearings, while on the outer face of each side are formed the lugs or ribs which serve as the column guides. With the truck bolster is used a cast-steel body bolster with inclined lower flanges, forming a truss shape, and having a horizontal top plate riveted to it. On the lower flange are cast lugs of inverted T section, forming the shoes of the side bearings. The truck and body bolsters are both shown in Fig. 9, which also shows the American all-metal truck already described, and all three are manufactured by the American Steel Foundry Co., of St. Louis, Mo.

The Bettendorf Bolster.—This is built up of I-beams which are subjected to an interesting process of manufacture. At each end of the web a portion is cut out, and the lower part of the beam is then pressed up by special machinery, forming a buckled rib, with a dovetailed joint at the end of the bolster. Malleable iron end plates, center braces, side bearings and center plates are then riveted on or secured by hollow lugs on the castings which pass through the holes and are beaded over, thus eliminating rivets. The Bettendorf bolsters for the Cudahy company's beef cars, shown in Fig. 10, have the truck bolster formed of two 10-in. I-beams, and the body bolster of two 8-in. I-beams, the weight of the bolsters being about 450 lbs. and 350 lbs., respectively. These are made by the Bettendorf Axle Co., of Davenport, Ia., and are among the specialties of the Cloud Steel Truck Co., Old Colony Building, Chicago.

The Marshall Bolster.—These truck and body bolsters are built-up trusses. The truck bolster consists of a cambered 12-in. steel channel, 35 lbs. per ft., with flanges downward, forming the compression member, and a plate ⅝ × 10 ins., passing under a king post at the middle of the bolster, and having the ends turned up over the ends of the channel and riveted to them. This plate forms the tension member. The truss depth is 12¾ ins. At each end is riveted a malleable casting on which are the column guides, and the center plate, side bearings and king post are also of malleable iron. The weight of the bolster, complete, is about 565 lbs. The body bolster has a horizontal top plate, with the ends bent over around the ends of the inclined bottom plate, a malleable iron filler being riveted between the plates, and the malleable center plate and side bearings being riveted to the bottom plate. The bolsters were designed by Mr. W. H. Marshall, Assistant Superintendent of Motive Power of the Chicago & Northwestern Ry., and have been applied to a large number of cars. They are being introduced by the Simplex Railway Appliance Co., of Chicago.

The Shickle, Harrison & Howard Bolster.—Cast steel is used for this truck bolster, which is a single casting, of rectangular section, but deeper at the middle than at the ends, and having openings left in the top and bottom tables to reduce the weight. The ends pass under the arch bars of the truck frame, and have cast upon them the ribs which form the column guides, but the center plate and side bearings are separate parts, riveted to the bolster. This bolster is shown in Fig. 11, and is manufactured by the Shickle, Harrison & Howard Iron Co., of St. Louis, Mo., who have already equipped 50 cars with it.

◆

INSPECTION AND TESTING OF MOTORS AND CAR EQUIPMENTS.*

By Frederick B. Perkins.†

I have thought it expedient for the purpose of setting forth my views on inspection to describe the work as being carried on in a modern car house containing 50 equipments. In dealing with the inspection of cars in this car house, we believe better results can be obtained by giving to each man some particular branch of the work rather than assigning to him a certain number of cars and expecting him to do all the work required thereon.

In this modern car house five repair men will be required, besides the foreman of the car house, whose duties in connection with handling of motormen and conductors, sending out cars and similar work, would require so much of his time that he could only have a general knowledge of the work of inspection in the car house. Two of this number would be required to grease and inspect the motors; one to keep the controllers in repair; one to take care of the trolleys and to assist in the care of trucks and car bodies; one to have charge of the trucks and car bodies.

---

*Condensed from a paper read at the annual meeting of the American Street Railway Association.

†Electrical Engineer, Toledo Traction Co., Toledo, Ohio.

The most vital parts of the equipments are the different parts of the motor, viz., armatures, fields, bearings, brushes and brush-holders. The care of this part of the equipments should come under the head of greasing; and on the manner in which this part of the work is done depends, to a large extent, the frequency with which the cars will break down while in service; and also the amount of repair necessary to keep them in operation. Oftentimes the most ignorant and cheapest men are given the place of greasers. On the contrary, it is a position where intelligence and thoroughness are imperative.

The car should pass into the greaser's hands the first day after it is on the road and every second day thereafter. He should examine thoroughly brushes, brush-holders, gears, pinions, bearings and commutator. Of these parts, the care of the bearings and commutator is the most important, and should therefore receive the greatest amount of attention. The manner of caring for the bearings is very simple. They must be well supplied with grease or oil, and care must be taken that they are kept free from dust and grit, and also that the grease feeds properly.

In the matter of the care of commutators, electricians seem divided in their opinion as to whether they should be sandpapered or not; personally, I am not in favor of it. Instead of temporizing the commutator by sandpapering it, and thereby simply putting it in shape for one more day's work, I would get at the bottom of the trouble, and either make a commutator by some preparation of mica and copper which will not spark, or if the trouble lies deeper, remedy it by remodelling the entire motor.

I think, however, that usually the trouble is not in the commutator, nor with the motor, but in either the brushes or brush-holder, or both; and it is probable that with proper adjustment, and with proper care and treatment, we should find the trouble obviated, and sandpapering of commutators unnecessary.

The writer has personal knowledge of a large road where common brushes were used without any treatment or care except to replace as needed, and it seemed as if the man who used the most brushes was given the credit of taking the best care of his motor. The average life of brushes on this road and the above conditions, with the commutator sandpapered every day, was six days. Subsequently the sandpapering was stopped entirely, and the brushes were removed every six days and properly treated in oil. The life of brushes under this treatment was increased from six days to from forty to sixty days. The trouble with commutators, which had before been great, was reduced to a minimum; in fact, almost entirely averted.

Not less than every fourth day every controller and switch comes under the notice of the man who has charge of those parts. The main point is to clean thoroughly, using a little vaseline on the contacts. The parts that are worn should be touched up with a file or should be sandpapered, and if badly worn, should be replaced, so that at least every fourth day the controllers will be sent out in first-class condition. This man can also examine the car wiring, lamp fixtures, headlight, and all similar parts.

The fourth man will have the care of the trolley poles and wheels. These should be carefully looked over each night and oiled if necessary. The man who attends to this part of the equipment will also have considerable time to devote to general inspection of the car bodies and trucks under the direction of the general inspector. Under the scrutiny of these two men should come all the details of a car body, such as grab-handles, window-catchers, curtain fixtures and similar parts.

Concerning outside inspection, it may be a good plan to have it, but I do not believe it is desirable to have a large force. Very little of the time devoted to this line of inspection is really used in looking over the equipments, but must necessarily be consumed in getting from one car to another and in waiting for opportunities, and most of the troubles located by these inspectors are not of such a nature as to require immediate attention; and if they were the inspector could not make the necessary repairs without taking the car to the car house. Troubles of a serious nature, such as would require immediate attention and taking the car out of service, should be easily detected by the motorman or conductor, and reported at once to the proper official.

Taking up next the matter of testing, all materials purchased, such as tape, mica, etc., should be tested to keep it up to the standard. The testing room should be a separate department, and preferably should be partitioned off from the rest of the repair shop. For testing instruments I would advise the following:

A high and low reading direct current volt-meter; one having a double scale reading from 1 to 750, and from 1 to 15.

A direct current ammeter reading from 1 to 100.

A low reading ammeter would be very convenient many times, but is not absolutely necessary.

A 50,000-ohm magneto bell, an alternating current volt-meter and some handy testing set will make an outfit of instruments with which we can do all the testing required.

If the alternating current is not within reach of the car house, we must procure a small dynamo and produce it ourselves. A very small machine, say 2 HP., would be sufficient for all the needs of the testing department. If this machine is designed for about 100 volts, it would be most convenient for our use. With a few small transformers wound for 2,000 volts primary and for either 50 or 100 volts secondary, we are prepared to furnish any voltage within a range of from 5 volts to 10,000 volts.

The man who has this part of the work in charge can very easily and cheaply arrange the detail of installation of the wiring, etc. He can also make some resistance coils and many other pieces of apparatus which will greatly facilitate the quick testing of whatever may be sent to this department.

The testing room should examine and pass upon all supplies for car house or repair shop, and should issue instructions for the treating of brushes, adjustment of trolley poles and many similar questions. Enough samples of finished material should be tested to make sure that the standard of workmanship is being maintained, and armatures, fields, controllers, etc., should be tested to determine their ability to stand the electrical strains which will be placed upon them.

PRODUCTIONS AND TRADE OF PORTO RICO.

The U. S. Bureau of Statistics has just issued a brief general description of the Island of Porto Rico that possesses interest to many capitalists and engineers looking in that direction for investment or employment. As summed up by the Chief of the Bureau, Porto Rico is a delightful winter resort, a valuable tropical garden and an important strategic point. But it has an area smaller than that of the State of Connecticut, or about 3,760 sq. miles.

Under the conditions of long settlement and dense population, most of the available soil is now under cultivation, and the prospects are not flattering for any material increase in its productiveness. The valleys and coast lands are now well occupied by sugar estates; the adjoining inland area is devoted to tobacco, and the mountain sides, to the very peaks, are covered by large coffee plantations. Only one-fifth of the population live in cities and villages; and the large rural population is of extremely simple habits and wants little that we can send them in way of food, clothing, furniture, etc. The small earning capacity of the people, in a depreciated currency, limits the consumption of imported goods.

From the standpoint of the engineer, it should be said that there are only 150 miles of railway and 250 miles of good roads on the island; and these are generally along the coast line; the military road across the island, between Ponce and San Juan, being the exception. Most of the interior is reached by bridle paths over which transportation is effected by packs on small ponies. In the cities and towns traffic is carried on with bullocks and primitive two-wheeled carts. While the towns generally lack water-works, lighting plants, drainage, etc., the conditions are not such as to demand such modern conveniences, and, as a rule, the people are too poor to pay for them. Only about one-fifth of the population is able to read and write, and though a kind of public school system prevails in some cities and towns, it is not of a high order. There are about 400 miles of telegraph lines, and several of the leading towns have some telephones.

According to the latest statistics available, the exports of Porto Rico amount to about $15,000,000 per year at gold value, and the imports to $16,000,000. Coffee forms 60% of the value of the exports; sugar, 20%, and tobacco, 5%; the remainder is made up of cocoa, rum, hides, sponges, cabinet woods, etc. All of the coffee practically goes to Europe, as the growers assert that they can obtain higher prices there than in the United States; and the reduced duties to Spain encouraged export to Spanish ports. About 50% of the imports are manufactured articles, largely cotton cloth, shoes, fancy goods and household articles; rice accounts for 15% of the imports; fish, 10%; meats and lard, 10%, and flour 7%. Naturally, most of these articles come from Spain, as the duties collected were only one-tenth of those charged imports from other countries.

As to prospects for investment, the Bureau of Statistics states that coffee plantations are now held at high prices; or $75 to $200 per acre, in Porto Rican money, according to location, quality of coffee and age of trees. Sugar plantations are relatively still higher in price, because of the more expensive machinery required; and many plantations have lately been abandoned and turned into cattle ranges. Tobacco has been lately very profitable owing to the shortage in Cuban tobacco; but the continuance of this profit is thus uncertain. Tropical fruits have received little attention from either local exporters or American investors, but they might prove more profitable than the other interests discussed, as they would be ready for shipment before the Florida or California fruits come upon the market in the United States.

Any increase in the production and consumption of the island will largely depend upon improvements made in harbors, roads and transportation facilities generally; and here is the opportunity for a combination of engineering with capital in this development. But it should also be remembered that no useful coal deposits have yet been found upon the island; fuel is, consequently, high in price, and the water-power is not to be relied upon, though streams are abundant.

A PLAN FOR THE SAFE MOVEMENT OF ELECTRIC CARS ACROSS A WEAK BRIDGE.

For several years past an attempt has been made to run a trolley line across the Navy Yard bridge, in Washington, D. C. This structure was built in 1876 by Clark, Reeves & Co., of Phoenixville, Pa., and it is made up of twelve through Pratt trusses, each 100 ft. long, with a plate-girder bascule draw-span of 32 ft. Each truss has seven panels, with Phoenix columns and cast-iron boxes at panel points. Superficially the iron-work is still in fair condition. On Sept. 3, 1897, Mr. C. B. Hunt, M. Am. Soc. C. E., Engineer of Bridges of the District of Columbia, made a careful examination of this bridge, and declared it to be of insufficient strength for heavy electric cars.

In investigating the members he assumed a permissible unit stress 25% higher than that used in the original design. The weight of the motor-car was assumed at 30,000 lbs., on a wheel base of 7 ft. 6 ins.; the unloaded motor-car weighs 15,000 lbs., and it was assumed that 100 passengers, weighing 150 lbs. each, could be crowded upon it. The following results, for some of the main members and floor-beams, were obtained under the condition of two of these cars meeting each other on the bridge:

Member.	Unit stress, lbs. per sq. in.	
	Actual.	Permissible.
Trusses: Stirrup (shear) main floor beams	4,640	6,250
Flange ⅙-web added	20,000	15,000
Web (shear)	5,680	6,250
First truss vertical	12,100	11,250
Draw-span: 6-in. I-cross beams, flange	27,000	15,000
Flange, main girder, ⅙-web added	19,900	15,000
Web (shear)	2,400	6,250

It should be noted that all flange unit strains are for tension on the net section, deducting rivet holes; and that, owing to the very shallow tram rail used on the draw, no assumption was justified that a wheel-load would be distributed to more than one of the 6-ft. cross-beams, which are spaced 2 ft. apart. The only live load assumed was that of the loaded car; and as the members considered were all details, limited to one panel of load, it was thought that the motor-car would practically represent the maximum loaded condition of the bridge.

After the investigation by Mr. Hunt the Capitol Railway Co. employed an engineer to examine and report upon the bridge. This engineer declared the structure to be safe, but he recommended some slight change in details. As a final result the Capitol Railway Co. has now obtained a permit to construct a double track trolley line over this bridge. But it is provided that a single overhead inverted wooden trough shall be built on the center line, and in this two wires will be strung. A small carriage will run upon these wires and a flexible cable from it will convey the current to the motors on the car. This arrangement, it will be seen, absolutely prevents more than one motor car crossing the bridge at a time.

As the cars on one side of the bridge are operated by an electric conduit system, while those on the other side have the overhead trolley, the change of current collecting system to cross the bridge will not be so serious a matter as might be supposed at first sight.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; 6 *months,* $2.50; 2 *months,* $1.00. *To all other countries in the Postal Union: Regular Edition, One Year,* $7 60 (31 *shillings*); *Thin Paper Edition, One Year,* $6.31 (26 *shillings*). *SINGLE COPIES of any number in current year,* 15 *cents.*

In ordering changes of mailing addresses, state BOTH old and new addresses; notice of change should reach us by Tuesday to be effective for the issue of the current week. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number 328 *means that subscription is paid to the 32d week (that is the issue of Aug.* 11) *of the year* 1898; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line. Want notices, special rates, see page* 18. *Rates for standing advertisements sent on request. Changes in standing advertisements must be received by Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

The four elevated electric railways of Chicago, or at least the three now in operation, are generally conceded to be well built and efficiently operated, and they perform an excellent service in affording rapid transit to the remote borders of Chicago. But as business ventures they do not pay. The Metropolitan West-Side Elevated Railway is in the hands of a receiver; the Alley Elevated company has been reorganized, but is not paying dividends, and it is doubtful whether it ever will; the Lake Street road has fallen into the hands of Mr. Yerkes, the chief owner of the surface railways of Chicago; and the Northwestern Elevated is not yet completed and work upon it is at a standstill. The chief reason for this failure of four well-conceived business ventures is interesting outside of Chicago; and it is to be found in the recent rapid evolution of surface railways, from horse-cars to cable and overhead and underground trolleys, with a great increase in speed and a more convenient service to the average traveler. When the Chicago elevated roads were first projected, the greater portion of the outlying districts of that city was still dependent upon the horse-car service, and the prospects seemed very bright for any system of transit which would reduce the time of travel between the business center of the city and these outlying districts. Under these conditions the elevated companies were organized, the lines were built, electric traction was adopted, and large dividends were confidently looked for. But the projectors were unfortunate enough to strike a transition period in the development of surface traffic. The rapid introduction of the trolley system in place of horse cars on the surface roads in all the outlying sections of the city completely wrecked their well-laid plans. There is no question as to the speed and excellence of service on the elevated roads, and they seem to be efficiently managed. But the point to be made, and one that must be carefully considered everywhere by the projectors of elevated or underground systems of rapid transit, is that the mass of the traveling public will prefer surface roads whenever these even approach modern standards of speed and quick service. With this system there are no stairs to be climbed and the traveler can stop nearer to his destination; in fact, it is the nearest and most accessible route of travel from one point to another, and though the surface line may be somewhat slower, this fact of proximity will settle the question of choice of route with the great majority of people using city railway lines. In our older cities, where narrow streets prevail and surface travel is liable to congestion; or in cities where the natural conformation is such that the line of travel is largely in one direction, there is doubtless room for profitable elevated or underground roads. But even under these conditions the surface lines are serious competitors. It is no longer, as it was when the New York elevated roads were built, a question of steam or horse flesh. It is a question of competition between trains on a costly elevated or depressed structure and electrically-propelled surface cars, with almost equal speed possibilities and a much less costly and much more accessible roadway.

Including stops, the elevated railways are now able to make only 11 to 15 miles per hour, and the electric surface roads, in the outlying sections, where stops are not frequent and streets are not crowded, often do nearly as well. Under these conditions it is clear that we have about seen the end of elevated railway construction, except in some cases where peculiar local conditions occur, as, for example, the crowded streets of Boston, or the long-distance traffic up and down Manhattan Island.

The death of Hon. Thos. M. Cooley takes away a man to whom the country owes a debt of gratitude for faithful public service in a position of the greatest responsibility, but where few understood or appreciated the value of his work. When in 1887 Congress enacted the Interstate Commerce law and provided for a permanent commission to undertake its administration, every one conversant with public affairs realized that a most critical period had arrived in the relations between the railways and the public. The Interstate Commerce law was a necessary measure; but it contained some unwise provisions. A narrow-minded adminstration of the law might have inflicted serious injury upon railway companies and have made the law itself so unpopular as to open the door for its repeal, and thus postpone indefinitely the progress toward better relations between the railways and the people. When President Cleveland appointed Judge Cooley as the first Chairman of the Interstate Commerce Commission, he probably selected the one man in the whole country who was the best fitted to fill that post. He was not only an eminent jurist, and a man with a broad knowledge of business methods and public affairs; but more important still, he was one of the soundest and ablest living students of railway economics and of the relations of the railways to the public. The good which he accomplished, in educating the public, on the one hand, to appreciate the rights of the railway corporations, and railway officers on the other, to understand the necessity and rightfulness of Government control and supervision of railway operations, can hardly be overestimated. The Commission of which he was a member had herculean tasks to perform. It was expected to accomplish the impossible, and was criticised because it did not do it. For four years Judge Cooley labored at the head of the Commission, and then his health gave way from overwork, and was never afterward restored. He sacrificed himself for his country's welfare as truly as any soldier who meets death on the battlefield; but the great and patriotic service which he rendered during those four years of toil can hardly be overestimated.

In the discussion upon the status of the engineer corps in the Navy, it has been sometimes urged by line officers that there is no need of placing men of technical education in charge of the engines; but good practical machinists would meet every requirement. Experience in our recent naval operations furnishes good proof of the fallacy in this view. A recent press dispatch quotes the Russian naval attache at Santiago as expressing the opinion that, aside from gunnery, one of the greatest weaknesses of the Spanish ships was in the engine rooms. The Spanish navy, like the French navy, has no commissioned engineer officers, and the engines are run by machinists. The condition of the machinery of the Spanish vessels, and especially the torpedo boats and destroyers, is testimony of the defects of this system, in the stress of war. The Russian attache is said to ascribe the remarkably few breakdowns on the American vessels to the care and supervision exercised by the commissioned engineer officers in charge.

We congratulate the city of Baltimore upon the final outcome of the long controversy which has been waged there over the proposition to construct a system of municipal electrical subways. As announced on the first page of this issue, the ordinance for the construction of this system has finally been approved. In our issue of Jan. 28, 1897, we discussed editorially the reasons why the municipal ownership of subways for electric wires is desirable, and we shall not renew the discussion now. We may remark, however, that the happy outcome of the long agitation in Baltimore is due, in a considerable degree, we believe, to the work of one young engineer; and it is a remarkable illustration of what an able and conscientious engineer can sometimes accomplish in leading and guiding public opinion. Some years ago the city of Baltimore took the first step in the direction of municipal subway construction by building a system of subways for its police telegraph and electric fire alarm wires. The Chief Engineer of the Commission which performed this work was Mr. Nicholas S. Hill, Jr., M. Am. Inst. Elec. E. After this work was completed, Mr. Hill was made engineer of a Commission charged with the duty of investigating the problem of putting all the wires in the city underground, and he prepared for that commission a report in which the economic as well as the technical aspects of the subject were exhaustively discussed, and strong ground was taken in favor of municipal construction and ownership. We think it entirely probable that the final outcome in Baltimore is to be ascribed in no small degree to the able and convincing arguments which Mr. Hill presented in his report, and which we doubt not he has followed up in verbal discussions with those responsible for determining the city's policy.

It is one of the compensations which a conscientious engineer occasionally finds that though his work may be hard and his pay for it inadequate, it is often his privilege to play a large part in molding public affairs, and to wield a strong influence toward securing "the greatest good for the largest number."

METAL TRUCKS FOR FREIGHT CARS.

The introduction of steel as a substitute for wood has been a very notable feature in railway freight car construction within the past few years, but the greatest advance in this direction is being made in the trucks rather than in the car bodies. The construction of cars with steel underframes and steel bodies has been the subject of much consideration by railway mechanical officers, and has been the subject of reports by committees of technical associations and of many articles in the technical press. While steel frames and steel bodies are in use to some extent and are likely to become even more general, for reasons which we have previously discussed, yet the process of introduction is but slow in comparison with the increase in the number of cars with ordinary wooden frames and bodies. On the other hand, there is now evident a very strong tendency towards the elimination of wood in truck construction, and all-metal trucks are now being used and introduced to a greater extent than is probably realized, even by railway officers, unless they have paid particular attention to the matter. The general experience with the ordinary style of truck is that wooden bolsters, even if trussed, are not strong enough for modern cars, and that wooden bolsters and wooden spring planks have to be constantly renewed. Mr. A. M. Waitt, of the Lake Shore & Michigan Southern Ry., informs us that while in his experience this is sometimes on account of decay, in most cases it is on account of these parts being too weak to stand the strains put upon them. In metal trucks, however, he has found that it is very rare that any

parts have to be renewed, if the trucks are carefully designed.

The metal truck dates back about 35 years, but its general introduction on a commercial scale only began about six or seven years ago. The Boston & Albany R. R. introduced a metal truck about 35 years ago, and this proved very satisfactory and economical, but after some years it was abandoned, for the reason that under the conditions of car interchange the road did not get the benefit of its own trucks. The cars would go to foreign roads and then be sent from one road to another, making most of their mileage on foreign roads, which reaped the advantages from the small cost for repairs of trucks. In the meantime, the Boston & Albany R. R. was operating on its line the cars of other lines, fitted with the common form of truck, and after paying the extra cost for a more economical truck it still had about the same expenses for truck repairs. While the abandonment of this metal truck was unfortunate from a technical point of view, and also probably from an economical point of view, as metal trucks soon afterwards began to come into general use on other roads, yet it was no doubt warranted by the apparent financial results. The cost of a pair of these trucks (inclusive of wheels), was about $300, or considerably more than that for ordinary trucks, but, as already noted, the economical advantages due to the good construction were not reaped by the owners.

In 1891, the Fox pressed steel truck, which was an English invention, began to be introduced in this country, and it speedily attained great success. For some years it had the field practically to itself, but competition soon began. As the metal truck grew in favor, the number of designs of metal trucks rapidly increased. At the Master Car Builders' convention of 1895, it was stated by Mr. Higgins, of the Lehigh Valley R. R., that there was then about 90,000 pressed steel trucks in use under freight and coal cars, usually of 60,000 lbs. capacity. Since that time, however, the introduction of steel trucks has been very rapid.

The principal advantages of the metal truck may be given as follows: (1) Decreased weight, with corresponding increase in proportion of paying load of the car; (2) Less cost for repairs and maintenance; (3) Kept in square permanently; (4) Easier riding; (5) Fewer parts. The first of these is not embodied in all trucks, and in others the difference is too small as to be of much practical value. In still others, however, the difference amounts to 1,800 lbs. per car, which is certainly a very important saving. The second advantage is probably the most important as far as direct and evident economy is concerned, and on this point there is very little dispute. As long ago as 1893, a Committee on Freight Car Trucks of the Master Car Builders' Association reported that of 39 replies to a question as to the cost of maintenance of wooden and metal trucks, 29 stated that the cost was less with metal trucks. The committee considered that with a good design of metal truck the cost of maintenance would be 18% less than that of the best design of wooden truck. It we compare these costs for the repairs of the frames alone, the metal truck will probably show even more favorably.

In this connection it may be stated that we learn from Mr. B. A. Hegeman, Jr., General Manager of the Lackawanna Live Stock Transportation Co., that one of the company's stock cars is mounted on two Baines trucks, built entirely of iron, which have been in service since May, 1893, or for about five years, and are now in perfect condition. The expense for repairs has been remarkably small, and during 1897 the only expense (exclusive of wheels) was $1.88 for one journal box. This company has the Baines truck under 251 cars, and they have been running since September, 1888, making an average mileage of 3,000 miles per month. Mr. Hegeman states that if it were not for the higher first cost he would have the new trucks built entirely of metal, but that wood is even now only used for the sand planks. As to the fifth point, the reduction in number of parts, this is very generally held to be of great importance, and in 1895, Mr. G. W. Rhodes, of the Chicago, Burlington & Quincy R. R., called the attention of the M. C. B. Association to the fact that some metal trucks were being designed without regard to the principal reasons which led to the introduction of the metal truck; namely, decrease in weight and decrease in number of parts. Of course this view is not universally held, and it is to be noted that at least one type of metal truck—that of the Schoen Pressed Steel Co.—is purposely built up of a large number of parts. For this system of construction the claim is made that it will facilitate repairs at railway shops, as damaged or bent parts can be cut off, straightened or repaired, and again riveted on (or replaced with new parts), instead of sending to the manufacturer for an entire new frame or to have the frame repaired.

When we consider the character of the equipment of modern railway shops, however, and the small percentage of trucks that are damaged, this particular advantage claimed for the use of a great number of parts appears to be open to very grave doubt. This view was expressed very emphatically at the December meeting of the New York Railroad Club by Mr. A. E. Mitchell, of the Erie R. R. Since the spring of 1891 this road has used the Fox trucks on all new freight cars, and by the end of 1897 it had them under 6,815 cars. Of these 13,630 trucks there were only 75 failures, for which the railway company was responsible; 32 were sent to the manufacturer to be repaired, the average cost of repairs being $28.21 per truck; 43 were repaired at the railway shops. The latter repairs were effected without any formers, presses or other special appliances, the work being done in the boiler shops, over the flange fires, or in the smiths' shops with regular forges, the cost averaging $5.32 per truck. As all the trucks were derailed, he thought the expenses would have been much greater if the trucks had been of the diamond pattern. Mr. Mitchell considered that if all the cars on the Erie R. R. had Fox trucks, he could dispense with 50% of the truck repair men, exclusive of those engaged in repairing wheel and axle defects. As to the increase of weight in metal trucks, this is in part due to the increase in car capacity and the necessity of strengthening the body and truck bolsters so as to sustain the heavy loads without deflection.

With regard to the materials of construction, metal trucks may be divided into five classes, as follows: (1) Pressed steel; (2) Combination of special bolsters and other parts with frames of the ordinary diamond pattern; (3) Commercial rolled sections; (4) Special rolled sections; (5) Cast steel. Examples of all these are described elsewhere. Pressed steel trucks are the most numerous, with the combination diamond trucks coming next. It is claimed that the use of pressed steel enables a truck to be built which is lighter than and fully as strong as one built of commercial rolled sections, as the parts can be formed to the best shape adapted to mechanical and economical advantages, while with structural shapes the design must be adapted to certain fixed forms, with an almost inevitable excess in metal and weight. For the latter, however, the claim is made that a railway company can build or repair its trucks from material purchased in the open market, while pressed steel parts must be ordered from the manufacturer of the truck. We know of but one truck—the Hewitt—in which a special rolled section is used for the frames, but while the truck itself appears to have certain advantages, yet the difficulty of procuring special sections just when wanted is of necessity an objection. This has already been experienced with the truck in question, the manufacture having been delayed by the failure of rolling mills to furnish the special section ordered until several weeks after the required time, in consequence of having larger and more important orders on hand. The use of cast steel throughout is also confined to one truck—the Ajax—although cast-steel bolsters and transoms are used in a number of trucks.

A very important feature in truck design is the arrangement of the springs. In the ordinary diamond-frame type of truck, and in some others, the springs are under the ends of the bolster, leaving the weight of the truck frames to be supported rigidly by the axle boxes. This arrangement is in use in the majority of cases. In most of the pressed steel trucks and in some other forms of all-metal trucks, the springs are placed upon the axle boxes, no bolster then being used, but the center plate resting directly upon the transom. This appears to be the better arrangement from a mechanical point of view, since the entire weight of the car and trucks (except that of the wheels, axles and boxes) is supported by the springs, thus ensuring an easier riding car. One objection to this latter arrangement, however, is the difficulty of getting springs of sufficient strength and elasticity in the small space usually available, the springs being as a rule placed in the center line of the frame, and the web of the frame being slotted to receive them. In a report on springs for freight car trucks, presented to the Central Railway Club at its January meeting, it was stated that in diamond-frame trucks the space available for the springs is about 7 ins. high and 11 ins. wide for 60,000-lb. cars, and 9 × 11 ins. for cars of 70,000 lbs. capacity and over, while in pedestal trucks the available space is practically 7 × 7 ins. for 60,000-lb. cars, and 8 × 8 ins. for 90,000 to 100,000-lb. cars. The committee, therefore, recommended nests of four single-coil springs for diamond trucks, and double-coil springs for pedestal trucks. In the Cloud truck, however, this objection does not exist, nests of springs being used over each axle box, the web of the frame not being cut away for the springs, but passing between the inner and outer pairs of springs. With this arrangement any capacity of spring can be used, although the long and satisfactory experience with the Fox truck appears to show that the arrangement of a double-coil spring over each box is sufficient if properly designed. This arrangement was used in the old metal trucks of the Boston & Albany R. R., which have already been referred to, and in similar trucks used at the same time on the Boston & Maine R. R., and New York, New Haven & Hartford R. R.

One other point to which we may refer, is the proposition to divide the load on the truck between the center bearings and side bearings, instead of concentrating it all upon the center bearing. This latter plan, which is now universal, necessitates very heavy body and truck bolsters, especially under the modern cars of high capacity. Even with such heavy construction, however, and with metal bolsters (unless these are made very heavy) it is found difficult to keep the car bodies from coming down in contact with the side bearings. When thus in contact, the trucks cannot swivel freely, and after being slewed on a curve the trucks will often fail to return to proper line, thus causing excessive rail wear and a large proportion of sharp-flanged wheels. A recent suggestion is to adopt for the side bearings a roller or ball bearing which will not be liable to get out of order, and then to let the car body rest on the three bearings. This would seem to be a rational arrangement, but the practical objections are many, among them being the difficulty of keeping roller bearings in such condition as to be absolutely free acting, and the liability to overload these bearings where heavy freight is placed at one side of car. This question was discussed in our issue of May 26, and it seems likely to be brought to the practical consideration of car builders before long, in view of the increase in car capacity, and the consequent increase in the weight and size of bolsters, together with the desirability of reducing rather than increasing the weight of the trucks.

LETTERS TO THE EDITOR.

"Practical Man" vs. Engineer.

Sir: For the benefit of your readers, and to show what an estimate is sometimes placed on an engineering education and years of experience in the profession, I will narrate a little episode that came under my personal notice recently.

An engineer was engaged some time ago to prepare plans and specifications for an electric lighting and waterworks plant for a small town in the central part of Ohio. He did the work and bids were advertised for in your valuable journal; but a week prior to the letting he resigned for some reason unknown to the writer, and consequently the council felt that it was necessary to appoint a substitute immediately, so that they might have the advantage of his advice and experience before the contracts were awarded. Consequently the Clerk of the Council was instructed to take a copy of your paper and write to a few of the engineers who had cards in your columns.

He picked out five, and several other names were obtained from various sources. These gentlemen were invited to give bids stating what they would charge to superintend the work during construction and make some alterations in the plans and specifications.

Five engineers put in bids and three of them made two trips to the town in question to make themselves known to the members of the Council and forward their several interests as much as possible. The bids for engineering services were opened and read, and amongst them was one from a plumber who had been brought in from a neighboring town.

After the bids were read, the gentlemen present were asked to come up one by one and state their experience in the branches of the profession under discussion. Those present complied, the plumber having the last call. He stated that he had had 15 years' experience as a practical plumber, and would spend his whole time on the ground and give his whole attention to the work in hand for the sum of $150 per month. With regard to the engineering part of the work, he thought that the only thing necessary in that line was to have a surveyor set a few stakes at various times, which he thought could be done for $25 at the outside. The Council then went into executive session, and soon afterwards called the plumber in and told him that he had been appointed. For a couple of hours afterwards he sat with the Council, presumably to give his advice as to which contractors should have the various parts of the work. Fancy a plumber discoursing on the merits of the different makes of dynamos, arc lamps, pumps, boilers, engines and the various other details of the system!

Let us be thankful, however, that there are a few people in the country who can appreciate the value of an engineer's experience and who are willing to give a fair compensation for his services.

Yours very respectfully,
An Engineer.

(An excellent illustration of the deficiency of the so-called "practical man" as a professional adviser was recently brought to our attention, and may be appropriately told in connection with the above letter. A large printing establishment, designed to be a model in every way, was built a few years ago directly on the banks of a large river. The power-plant for this establishment was of considerable size, and the exhaust steam from the engines proved a great nuisance. The proprietor of the plant appealed to his "chief engineer," the man in direct charge of the engines and machinery of the establishment, as to what could be done to get rid of it. The man was a good example of the so-called "practical" man. He had had many years' experience in the care of engines and boilers; but the best thing he could suggest was the purchase of a long line of pipe, which was laid along the river banks, so that the steam was discharged into the atmosphere at some distance from the works, drifting back toward them, however, when the wind was in a certain direction. It chanced that an educated mechanical engineer came that way, and to him the "practical man" told the story of the difficulty. "But why didn't you put in a condensing engine?" said the engineer. And then it transpired that the "practical man," who had spent the better part of his life as a stationary engineer, had never heard of a condensing engine, and of the fuel economy resulting from its use wherever a supply of condensing water can be had. Doubtless this is an extreme case of the ignorance of the so-called "practical man" of everything outside the very limited sphere in which he has always moved, but it is instructive as showing what losses an enterprise may suffer through a failure to appreciate the value of the services which a competent consulting engineer might render them.—Ed.)

COMPARATIVE MERITS OF SINGLE-TRUCK AND DOUBLE-TRUCK CARS FOR CITY RAILWAYS.*

By Richard McCullough, St. Louis, Mo.

Double trucks for electric cars are of comparatively recent adoption. All of the early electric cars were equipped with single trucks, and in this, horse car and cable car practice was followed.

Double trucks were first applied to cars in the desire to use longer bodies than has been customary. In the use of a single truck the best practice has been to limit the wheel base to about 7 ft., as a greater distance than this would cause the wheels to bind in curves. Assuming that the body of the car is 20 ft. long and that the platform projects 4 ft. beyond the body, the end of the platform would overhang the axle 10½ ft. This is as great an overhang as is customary, although single truck cars have been built with bodies longer than 20 ft. In this case it is necessary to provide extension springs on the trucks to check the oscillation of the car body. With a very long car body, however, the oscillation is not entirely overcome by this device, and the rocking becomes very disagreeable to passengers and very disastrous to the car and track. 22 ft. may be arbitrarily established as the limiting length of the body of a single truck car, and if we wish to use car bodies longer than this, we must adopt some truck which will avoid oscillation and which will pass around curves without undue use of power. The double truck accomplishes this, and it was to enable longer bodies to be used that it first came into use.

The truck which was first used for long street railway cars was an adaptation of that used by the steam railways. This truck contains four wheels of equal size and is pivoted over the center. It was soon discovered that for street railway use this form of truck has two very objectionable features, first, that the floor of the car must be high enough above the rail to allow the wheels to swing freely under the car, and, secondly, the motor being geared to one axle of the truck, only half of the weight of the car was available for traction. The latter is a serious objection on roads having steep grades.

From what has been said it will appear that the single truck is the truck for short cars, and the double truck is the truck for long cars. Therefore, a discussion of the relative merits of these two types of trucks will involve a discussion as to the relative merits of short and long cars. Also, as it is customary to supply long cars with cross seats and short cars with longitudinal seats, we have, instead of the comparatively simple subject of Single Trucks versus Double Trucks, which has been assigned to your committee, the more complicated struggle between the short car with single trucks and longitudinal seats and the long car with double trucks and cross seats.

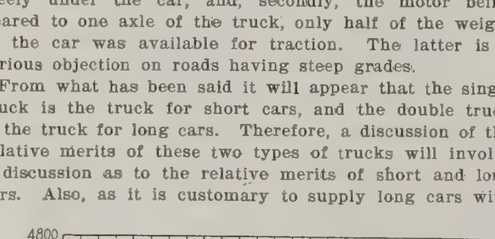

Fig. 1.—Typical Load Curve of Power Station of a City Street Railway.

It will be assumed in the discussion which follows that the road possesses the characteristic city travel, a load curve of which is shown in Fig. 1. It will be noted that two very pronounced peaks occur in this load curve, one in the morning from 6 to 9 o'clock, and the other in the evening from 5 to 7. It is at these times that the capacity of everything is tried. While the load curves of all city roads resemble each other, it is evident that local conditions will to a large extent determine the kind of car which the railroad company will operate. Some of these local conditions are, the class of people who constitute the passengers, the location of the road with reference to the established lines of travel, the amount of pleasure travel received by the road, and the keenness of competition with other roads.

The expense of the average city road may be divided up as follows:

Maintenance of way and structures	4%
Maintenance of equipment	7%
Conducting transportation	52%
General expense	8%
Fixed charges	29%

It will be noticed that the item "conducting transportation" is more than one-half of the total. This is largely made up of the wages of conductors and motormen, and is proportional to the number of cars operated. Hence, it follows that if we may by the operation of larger cars cut down the number of cars, this account may be reduced in nearly the same ratio as the size of the car is increased. There are many other reasons why the size of cars has been increased, such as the increased volume of traffic due to the higher speed and enlarged territory of the street railroads, the greater comfort demanded by the traveling public, the increased power available for the operation of cars, etc., but it is probable that the present tendency toward the increased size of car bodies is with a view of operating larger units and fewer of them.

A line operating small cars seating 28 persons, on a headway of 3½ minutes, would give the same service from a standpoint of seating capacity if it operated large cars seating 40 persons on a headway of 5 minutes. Manifestly this latter service would be preferable from the railroad standpoint for the reason just given, and the question is, would the service be equally acceptable to the passenger. In this comparison we are assuming that the larger car is the more desirable vehicle in which to ride. Would the pleasure of the ride compensate the passenger for the greater length of time which he would have to wait? This is a question which must be solved by each manager for his particular road, as its correct solution depends largely upon local conditions over which he has no control. The scrutiny with which a passenger chooses a street car varies with the length of his proposed ride. If the ride is to be short, he takes the nearest car without reference to comfort; but if he is to ride a long distance he will walk past several lines in order to choose that one on which he will have the most pleasant ride. The car question then becomes a more serious one with long roads and with roads catering to a pleasure traffic. It has usually been accepted that on those roads having a purely business traffic, the proper car is the short one operated on short headway. The author, however, is of the opinion that even in this case, the long car operated upon somewhat longer intervals would be desirable. It has often been observed that where a line operates two sets of cars a passenger will allow several cars to pass him in order to patronize that type of car which suits him best. This has been observed even in the busy hours of night and morning, when it would be fair to assume that passengers would be hurried and likely to take the first car which passes.

One of the most serious questions occurring in street railway practice is the problem of how best to take care of the rush of travel which comes morning and evening. With our present methods, there are only two ways of taking care of this travel; the first, by increasing the number of cars or units in service, and the second, by increasing the capacity of each unit. The latter method consists in attaching a trailer to the motor car, and where this is done it is usual also to increase the number of units in service. On first thought there would seem to be no better method of increasing the capacity of a road than by the use of trail cars. They are easily attached and detached, they are in service only when necessary, and they do not require the assistance of additional trainmen. An examination of the trailer system, however, will reveal the fact that it possesses serious defects. The trailer requires the services of men and horses to attach it to the cars and to move it between the car sheds and the motor cars. The opening between the motor and the trail car increases the danger of accident both to passengers and conductors. The number of entrances and exists is increased, and this augments the work of the conductor in keeping track of his fares and increases the danger of his missing some of them. If an extra conductor is placed on the trailer to collect fares, a great portion of the gain due to the trailer system is lost. The use of trailers throws an additional strain on the motors, as a heavy weight is added to the train which is not available for traction. The trouble is intensified as the load on the trailer increases; it makes the train more unwieldy in handling, and is largely responsible for the difficulty in starting and stopping quickly and in making schedule time.

To obviate the necessity of using trailers, a large car equal in seating capacity to the combined capacity of the motor and trail car may be operated. This system, however, introduces the disadvantage of the operation at all times of the day of a seating capacity needed only during a few hours of the day. It also increases the size and weight of the cars and the average power required to operate them.

In order to compare the relative economies of single and double truck cars, their advantages and disadvantages will be discussed with reference to the following points:

(1) Wear and tear on trucks.
(2) Wear and tear on motors.
(3) Power required.
(4) Wear and tear on track.
(5) The use of trailers.
(6) The seating arrangements and convenience of exit and entrance.
(7) The preferences of passengers.

These relations will, as far as possible, be reduced to a money basis, and in order to do so a comparison will be instituted between a road which operates double truck cars and one operating single truck cars, using trailers 26% of the time to take care of the heavy night and morning travel.

The bodies of the double truck cars are 26 ft. in length, and contain 18 cross seats, seating 36 passengers. The trucks are of the maximum traction type; the empty car weighs 23,500 lbs., and the motors are G. E. 800.

TABLE I.—Comparison of the Cost of Wheels and Brake-shoes on Double and Single Truck Cars for the Year 1897.

		—Truck cars—	
		Double (47).	Single (70).
Av. No. wheels used per car per year.	33-in.	8.72	6.26
	30-in. trailer	....	1.00
	24-in.	7.06	....
Cost per car per year.	Wheels	$77.92	$40.93
	Labor in replacing.	17.36	7.99
	Brake-shoes.	11.70	4.30
	Total	$106.98	$53.22
Total cost per car, year, 1,000 psgrs		$0.47	$0.38
Wheel mileage.	33-in.	17,260	25,329
	24-in.	20,916	......

The double truck car has four 33-in. wheels, four 24-in. wheels, and eight brake-shoes. The single truck car has four 33-in. wheels and four brake-shoes. Average daily car mileage, 115.

---

*A paper read at the Annual Convention of the American Street Railway Association.

TABLE II.—Comparison of the Cost of Repairs and Maintenance of Trucks and Motors on Double and Single Truck Cars for the Years 1896 and 1897.

		Truck cars	
		Double (47).	Single (70).
Average passengers per car per year		226,000	141,000
Truck repairs.	Per car per year........	$181.00	$110.00
	Per 1,000 passengers.	.80	.78
Motor repairs.	Per car per year........	319.00	196.00
	Per 1,000 passengers.	1.41	1.39
Total....	Per car per year........	$500.00	$306.00
	Per 1,000 passengers.	2.21	2.17

G. E.—800 motors on double truck cars. W. P.—50 motors on single truck cars.

The single truck car has a body 20 ft. in length; it is equipped with longitudinal seats, and the entire car weighs 16,000 lbs. It will seat 28 passengers. During the period of heavy travel, which amounts to 26% of the time, trailers are attached to these motor cars. The average seating capacity of the unit, estimating the trailer as a part of the car during the time that it operated, is 35 seats, which approximates the seating capacity of the double truck car very closely. The motors in use on the single truck cars are W. P. 50.

The number of cars operated is obtained by dividing the daily car mileage by 115. It is necessary to do this because the average mileage per car on the two roads is different. The comparison is thus between 70 single truck cars and 47 double truck cars, each car making 115 miles per day. The road operating the double truck cars has the greater density of traffic.

Wear and Tear on Trucks.—It is evident that since a car equipped with double trucks has eight wheels and one equipped with single trucks has four, the former will be the more expensive to supply with wheels. Table I. shows the comparative replacement and cost of wheels and brake shoes on the two roads for one year. Table II. shows the comparative cost of maintenance and repairs of trucks and motors for two years. It will be noted that while the cost per car is much greater on the road using double trucks, the cost per passenger is the same. It would not be fair to assume from these figures that the cost of maintenance of trucks and motors per passenger is almost the same, no matter what sort of truck is used, because these figures would result largely from the fact that in this particular case the double truck car carries the greater number of passengers, but an inspection of the table will emphasize the advantage of the large unit as compared with the small one. It will be seen by a reference to Table I. that the greater part of the increased expense of maintaining the double trucks is due to the renewals of wheels and brake shoes.

TABLE III.—Comparison of the Power Required by Double Truck and Single Truck Cars.

	Average watts.	Average watt-hours per car mile.	Average speed, miles per hour.	Average watts per seat capacity.	Average watts per ton (car empty).	Avg. watt-hours per car mile, 1,000 passengers.
Double truck car. Seats, 36; weight, 11.75 tons...... Average for the entire day........	12,040	1,334	9.03	335	1,025	5.9
Double truck car. Seats, 36; weight, 11.75 tons...... Average for the heaviest trip......	13,080	1,412	9.25	335	1,025	...
Single truck car, no trailer: Seats 28; weight, 8 tons.	8,471	921	9.20	303	1,060	...
Trailers operated 26% of the time .... Average for the entire day	9,400	1,110	8.42	254	1,088	7.9
Single truck motor and open trailer: Seats, 63; weight, 10.5 tons; average for the heaviest trip.	12,680	1,440	8.84	201	1,208	...

In examining the relative strength of the various parts of trucks, the side pieces may be compared to a beam supported at two points and carrying a concentrated load. The deflection of such a beam is proportional to the third power of the span; and in the analogy, the span corresponds to the wheel base of the truck. Therefore, the shorter the wheel base the stiffer the truck side, and in view of its long wheel bases, it is evident that the single truck is at a disadvantage in this respect. For instance, a truck side where the wheel base is 4 ft. 6 ins. is 3.76 times stiffer than a truck side of equal section where the wheel base is 7 ft.

Wear and Tear on Motors.—Table II., to which reference has already been made, gives the comparative expense of inspecting, repairing and maintaining the motors of double and single truck cars. As in the case of the trucks, it will be noted that while the expense per car is much greater in the case of the double truck car, the expense per passenger is nearly the same.

TABLE IV.—Comparison of Weights Carried by Single and Double Truck Cars.

	Single truck			
		Motor car with		
	Motor car.	Open trailer.	Closed trailer.	Double truck car.
No. of seats	28	63	48	36
Total, crowded capacity..	80	140	125	110
Weight, empty, lbs.......	16,000	21,000	21,000	23,500
Per cent. weight on driv'g wheels: Car empty.	100	76	76	70
Seats full	100	67	72	70
Car crowded	100	67	71	70
Weight per seat, lbs.:				
Car empty	572	334	438	653
Seats full	702	463	568	782
Car crowded	943	622	776	1,050
Weight per unit total capacity: Car empty..	200	150	168	214
Seats full	246	210	218	258
Car crowded	330	280	298	344

Note.—Each passenger is estimated at 130 lbs.

Table IV. gives the relative weights carried by the different cars, when empty, seats full and car crowded. It will be noted that while the percentage of weight available for traction in the case of the maximum traction truck remains constant, in the case of the motor and trailer it falls off as the number of passengers increase, and is especially small if the trailer is proportionately more heavily loaded than the motor car.

Power Required.—Table III. gives the power required to operate the different cars, and is the average of a long series of watt-meter tests. In making these tests, the watt-meter was placed on a car in actual service and allowed to remain through the entire day. An examination of the tables will reveal the fact that the power required for the propulsion of the car and the care and repairs which the motors demand are much greater in the case of the double truck car. But if the number of passengers be taken into account, it is seen that the power and the cost of maintenance are roughly proportional to the number of passengers carried with either style of truck.

Wear and Tear on Track.—The wear of the rails of a street railway track is due to the grinding action of the wheel on the rail, and this is proportional to the weight on the wheel, but is intensified by the dirt on the rail, which causes the wheel to slip and acts as an abrasive agent after the slipping has begun. The weak point of a street railway track, however, consists of the joints and the openings in the special work. The energy of the blow which the wheel strikes as it passes a low joint or a crossing is equal to the product of the weight of the wheel and the height of the drop. Therefore, on any given track both the wearing action of the wheel and the destructive action of the wheel are proportional to the weight which rests upon it. If the number of wheels under a car be increased, the number of blows which a low joint receives is also increased, but the intensity of each blow is diminished. Double trucks are at no disadvantage as compared with single trucks in this respect, unless the weight of the car be increased. By reason of the shorter wheel base, double trucks go around sharper curves and go around the same curve with less output of power and less wear on the rail than single trucks. The double truck fell into disrepute when the maximum traction truck was first exploited, on account of its liability to leave the track. This was due to the small amount of weight which was placed on the small wheels. It is now customary to place 30% of the weight on the small wheels, and with track in fairly good condition, no difficulty is encountered in keeping cars on the track.

The Use of Trailers.—In the case of the two roads under discussion, the road operating single truck cars attached trail cars to the motor car for two trips in the morning and two trips in the afternoon. For the entire year trailers were operated on 26% of the trips. Allusion has already been made to the use of trailers. The advantage of the trailer on this particular road arises from the fact that the load peaks are unusually sharp. The use of the trailer increases the capacity of each unit during the heavy hours of morning and evening travel and during rush travel due to baseball games and races. On this particular road the motormen and conductors are paid 10 cts. per trip extra for all trips where a trailer is attached to the motor car. This expense largely offsets the value of this arrangement. There is no question but that the use of the trail car increases the number of accidents, for two reasons; first, because the trailer is another car, and, second, because the opening between the motor and trail car is a dangerous one for a passenger boarding or alighting from the car. It is impossible to estimate the money value of this accident liability, because in the case of many accidents it is difficult to determine what proportion of the damage was due to the trailer. Trailers must be switched at the ends of the roads and at the car sheds, and require men and horses for this purpose. The use of trailers also entails other expenses, such as car heating, cleaning, repairing and car license, which should be charged against the trail car system. To counterbalance all these disadvantages, the only advantage which the trail car system possesses is its flexibility.

The Seating Arrangements, Exits and Entrances.—As has already been stated, the cross seat is used almost so universally in connection with the double truck car that it is fair to consider the economy and efficiency of cross seats and longitudinal seats in connection with the discussion. There is no doubt that the cross seat is preferable from the passenger's standpoint.

If two car bodies of the same size are taken and cross seats installed in one and longitudinal seats in the other, the car body equipped with the cross seats will have the narrower aisle. This induces two disadvantages in the cross seat car, one, that the crowded capacity of the car is less, and the other, that when the car is crowded the time consumed in loading and unloading is increased. The latter difficulty will be the more serious the shorter the haul and the greater the number of stops.

In the early days of the double truck car it was customary to mount the body high enough so that the wheels would swing under it. This gave the car a very unsightly appearance and made it difficult of access. Three steps were necessary to reach the platform, and as these steps were steep, this form of car was particularly objectionable to ladies. By the use of the maximum traction truck, with 33-in. wheels, however, it is possible to lower the floor to within 37 ins. of the rail. By dropping the platform 8 ins. below the floor of the car, it is possible to reach the platform by the use of a single step 14 ins. above the rail. This renders the car as easy of access as the single truck car. In the opinion of the writer, the fact that the car floor may be made so low in double truck cars is the chief advantage of the maximum traction truck.

It has been attempted to facilitate the loading and unloading of large cars by providing exits and entrances other than the rear door. This practice, however, brings about what is perhaps a more serious disadvantage, as it gives the conductor more than one door to watch, renders it difficult for him to keep track of his fares, and increases the liability of his starting the car before a passenger is on or off.

The Preference of Passengers.—The preference of passengers, to which allusion has already been made, is undoubtedly in favor of the double truck car. In cities where the entire street railroad system is controlled by one company this point may not be considered of value, because passengers are obliged to ride in whatever conveyance the company chooses to furnish. However, the experience of roads which have changed their rolling stock from small, single truck cars to large, comfortable, double truck cars is that the travel has shown an immediate increase.

Outside of the question of economy of operation, there are few roads on which the use of attractive, easy-riding, double truck cars would not create a pleasure travel, especially in the summer season. In a general way, it may be stated that the single truck car is more suitable for short hauls, dense traffic, many stops and low speed. On the other hand, the double truck car is more suitable for long hauls, high speed, few stops and pleasure travel. In the existence of either extreme condition, it would not be difficult to decide which car to use. It is in dealing with intermediate conditions that the manager must use his judgment.

COMMITTEE REPORTS AT THE ANNUAL MEETING OF THE ROADMASTERS' ASSOCIATION OF AMERICA.

The following are some of the committee reports presented at the annual meeting of the Roadmasters' Association of America, held at Denver this week. The remainder will be published in our next issue.

Best Method of Preventing Creeping Rails.

It has long been known that rails do creep, but this shifting of position is not uniform, nor is it alike for both rails. In its most aggravated form, it is confined to localities and is due to local conditions.

Rails creep in the direction of the traffic on double track lines. This creep is found to be greater on down than on up-grades, and is found in its worst form where tracks have been laid over marshes or soft, yielding sub-oil; on single track it is most noticeable on down-grades and where there is a descending grade from both directions, the rails creep down and come together in the valley, causing the rails at the foot of the grade to buckle in hot weather as a result of the space between the rails which had been allowed for expansion, being all taken up. It has also been ascertained that on curves, the outer or high rails creep the more, and where there are successive reverse curves and especially on grades, the creep starts on tangent at approach, continues on high rail to the end of first curve, then the opposite high rail on reverse curve shows the more creep. In other words, the high rail on each successive curve is found to creep more than the low rail.

The cause of creeping track is because of a rolling load passing over it which depresses the track directly under it and produces a corresponding elevation and depression ahead and behind it, which may be likened to a wave motion. To illustrate this more clearly, reference is made to a series of experiments mapped out by Mr. F. A. Delano, Superintendent of Freight Terminals of the Chicago, Burlington & Quincy Railway, and under the supervision of Mr. Jas. E. Howard, of the Watertown Arsenal, a description of which appeared in the "Railway Review" of March 24, and 31, 1894, which is in part as follows:

Facilities were supplied by the C., B. & Q. R. R. for carrying on such tests. The time selected was during the month of October when the roadbed was as firm and solid as at any time during the year. The place was Hawthorne Yard, near Chicago, and a portion of the tests were made on the main line and others on sidings. The experiments consisted of measuring under locomotives of different weights, the depression of the rail. Two weights of rails were experimented upon, one weighing 66 and the other 75 lbs. per yd., the rails rested upon oak ties in all experiments; but some were supported by gravel and others by cinder ballast. The track selected was in good condition, the spikes being redriven before the work was begun. The ballast rested on hard, unyielding clay.

For the purpose of observing the depression of the rails, in one class of experiments, bench marks were established on a row of stakes driven alongside of the rail 31 ins. distant from it. A beam carrying a micrometer and an astronomical level bubble was used in observing the depression of the rail, first measuring the height, using a point on the outer flange, when the rail was unloaded, and repeating the observation when the locomotive was in different positions with references to this point, making the observations when the observed point was directly under each wheel, and when midway between them.

After a number of experiments had been conducted in this manner, it was discovered that the roadbed in the vicinity of the locomotive was sensibly depressed, and that the bench marks were influenced by the depressions. Careful measurements were made of this depression and it was found that at a point opposite the main driver of Class "H" locomotive, three-driver, connected with bogie truck, weighing 125,000 lbs., the depressions were as follows: At a point 31 ins. from the rail, 0.047-in.; at a point 61 ins. from the rail, 0.013-in; at a point 91 ins. from the rail, 0.001-in. This discovery revealed the necessity of establishing new bench marks, and in so doing a cantilever was used, having its support 10 ft. from the rail. On a track laid with 66-lb. rails and supported by oak ties, 17 to a 30-ft. rail, and in gravel ballast, the greatest depression under an engine weighing 110,000 lbs., was 0.161-in.; this was under the middle driver.

The same weight engine on the same kind of rail and ties, but supported by cinder ballast, the depression under middle driver was 0.230-in. From this it will readily be seen that there is a marked depression of the track under an engine, and when we consider that the same depression of the track takes place when the engine is moving as well as when at rest, it can readily be conceived what a destructive effect it has. With the track depressed under the weight of an engine, a corresponding rise just ahead of it to be afterwards depressed as the engine approaches and passes over it, produces a violent wave motion under high speed which is the cause of creeping rails. The outer rails on curves creep more than the inner rails, because of the lateral lever motion imparted to them by reason of the wheels hugging the outer rail more closely as a result of their cone shaped design which enables them to travel the greater while their mates travel the lesser distance in rounding a curve and because of the inclination of moving bodies to go in a straight line, which is overcome by introducing another force when the outer rail on curved track is elevated. The rails on outer edge of embankment on double track creep most because of less support than the rails near the center of roadbed. As the rails shove ahead they drag the ties with them, the only resistance being the amount and kind of ballast between them. If the track is well filled in the center but bare at the ends of the ties, another lever movement is introduced. The ballast in the center acts as a fulcrum, the tie becomes the lever and instead of moving ahead with the rail and retaining its corresponding position at right angles with it, the one end is forced ahead of the other, especially is this the case with joint ties, and more particularly where rail is laid with broken joint, with the added result of tightening the gage. Aside from this the ties are moved off their well tamped foundation on to the softer untamped bed between the ties, and if not closely watched and early corrected, the whole track will creep the more because of the looseness of the several parts, and then a general disintegration takes place, which will require several hard season's work to restore, the only means being either to draw the rail back and straighten up the ties, or else replace all of the ties to suit the new location of the rail. To do this requires as much if not more work than to make the tie renewals and surface the track.

It is doubtful if a remedy for creeping rails exists or can be found and we are none to sure that if stopped it would be only to reappear in another form. While it cannot be eliminated entirely, it is quite possible to restrict it so that in its effect it is not so destructive. The most common method is to rely upon anchorage at the joint by spiking the tie through slots in the angle bars. The value of this style of anchorage depends upon the number of ties over which the angle bar extends, which may be one, two, or three, and resistance is directly in proportion to the number of ties. In practice it is found that the three-tie joint affords the best anchorage, but it does not entirely prevent the rails from creeping. It is also found that by placing a dummy joint in the center of the rail opposite the joint, which may be made from old angle bars bolted to the rail and spiked to the slot, that additional anchorage is afforded. On some roads, specially designed dummy joints are made in clip form; these clips fit in the web of rail the same as an angle bar, but in addition extend under the base of rail like a lip chair, slotted on the inside and punched on the outside of rail for spikes, taking the place of a tie-plate as well as affording anchorage. Either of these forms give fair results.

Another method is to bolt a flat bar of iron inside the nut at joints, the bar to be twisted half around so that the tal end will be parallel with the rail and rest flatwise on the ties to which it is spiked through holes made in it for that purpose.

Still another method is to make a clip in two parts to fit snugly under the base of rail—a clip on each side, both to be united with a bolt underneath, these clips to come in contact with the edge of the tie, depending on the tie for resistance as in the other devices.

As creeping rails are the result of both vertical and lateral wave motion, the best remedy which suggests itself is to restrict that wave motion to a minimum, which can only be done by having a rail stiff in section to transmit the weight of the load over the greatest possible area of ties and ballast, to be well tied, with spikes kept snug to base of rail, and ballast dressed off as full as can be at the end of ties, and at the same time allow for drainage.

H. W. Church, Samuel Greer, John Redington, Committee.

Advisability of Increasing the Length of Rails and the Advantages to be Derived from the Use of Rails with Miter Cut Ends.

Majority Report.—Rails of 45 and 60 ft. in length have been in use on a few railways in this country, mostly in an experimental way, for the last six to eight years. The only advantage which seems to have been developed during this time by their use is in the reduction of the number of joints.

Some of their objectionable features are as follows:

1. Rail mills do not as yet appear to be able to turn out as straight a rail of 45 or 60 ft. in length as those of 30 ft.
2. Their contraction makes them more liable to flatten on the ends than rails of shorter lengths, and their greater tendency to creep makes it necessary to put on stops, which increase the expense and does not entirely prevent the creeping.
3. They are not as readily or as economically transported or handled when new, or when taken out for relaying, or for shipment when worn out, as those of 30 ft.

Miter cut rails have been to some extent tried from remote periods, and somewhat extensively so on some few lines within the last ten years or so, and the experience with them after this length of time has not been satisfactory, and they have been temporarily, if not permanently abandoned. The principal reasons for this are that they break at the ends where the head and web join, caused generally by the extension of one side of the head beyond the other, and the angle at which they have to be cut thus far shows that there is very little or no difference in the blow received from passing wheels, from those having square ends, and further, the flow of metal at the ends appears to be greater with the miter than square cut rails.

After giving these questions due consideration and from all the information obtainable, and from the experience we have, we do not at this time deem it advisable to recommend that there is enough advantage in increasing the length of rails beyond 30 ft., or to use rails with miter cut ends, to recommend their use.

R. Caffrey, Chairman.

Minority Report.—The use of rails of more than 30 ft. in length can be said to have passed the experimental stage, and the utility and economy in the use of rails 60 ft. long have been recognized by several important lines of steam as well as electric railways. The transporting of rails up to 60 ft. in length is no longer a difficult or unusual problem. From those who have used 60-ft. rails for a sufficient length of time to enable them to give reliable figures, your committee has endeavored to learn the cost per ton of handling and laying in track as compared with the cost per ton of 30-ft. rails, also to ascertain the peculiarities, defects and advantages in their use.

Through the kindness of an official connected with one of the largest Eastern lines, and one that maintains a high standard of track, we are enabled to give the result of their experience with long rails, some sixty miles of which has been laid up to the present time. This road commenced laying 60-ft. rails, experimentally, in 1894, and the result thus far has been so satisfactory that large orders have been placed for rails of the same length for further renewals. The advantages gained are, economy in handling, reduced cost of maintenance and better riding track. On level or moderate grades, stop blocks are not found necessary and are not used. On heavy grades and on unstable marsh grounds one to two stop blocks or anti-creeping devices are used on each rail. Cost of this appliance is 13 cts., and cost of putting it on is about 10 cts. each. The unloading of the rails on this line is done in a very simple manner and with a less number of men than is necessary to handle 30-ft. rails from cars in the usual way. A rope about 30 ft. in length is supplied with a hook at one end to anchor to the track, and at the other to hook through the bolt hole at end of a rail on the car. The hooks being in place the work train is started and the rail drawn nearly off. Eight men with rail tongs then lower the end of the rail as the car is pulled from under it and two men with bars throw the rail out of the track. In laying the rails in track, double the number of tongsmen and half the number of bolters are required that would be needed in laying 30-ft. rails. The creeping of long rails has not been found the serious matter that had been anticipated. The average saving on the road in question is fully 15% in handling and laying 60-ft. rails over the same number of tons of 30-ft. rails.

Through the courtesy of Mr. M. J. Caples, Assistant Engineer of the Norfolk & Western Railroad, we have information as follows as to results obtained from the use of 60-ft. rails on that line: They have 18 miles laid in winter of 1892-3, and 29 miles laid in 1894-5. The rail is 85 lbs. per yd., 5 ins. high and laid on grades ranging from 9% to 2.4% (47 ft. to 126 ft. per mile) and on curves as high as 16°, with about 40% of all the curvature over 8°, single track. Traffic over this piece of track averages four passenger trains and forty freight trains per day. Passenger engines, 10-wheel, with 98,000 lbs. on three pairs of drivers, and consolidation freight engines with 106,800 lbs. on the drivers. Ballast nearly all furnace slag. Joint fastening, "Churchill" patent 23-in. angle bar extending 3¼ ins. below base of rail between the joint ties, and a 7-16-in. plate of the same length as the angle bar. No stop-block or anti-creeping device is used.

After 5½ years' service under these conditions, Mr. Caples says of the 18 miles laid in 1892-3: "We have had no trouble whatever by reason of expansion from any of the 60-ft. rails. The ends have not been battered sufficiently to enable us to determine that it is greater than 30-ft. rails laid at the same time where the normal expansion distance has been preserved. There has been no greater tendency on the part of 60-ft. rails to creep than with 30-ft. rails." He adds that in his opinion a stop-block would be beneficial, and that battering of the ends consequent on creeping and expansion will make necessary the changing out during the present season of 130 rails (4%) of the 18 miles laid in 1892.3. The cost of unloading and laying in track has been 20% less than unloading and laying an equal number of tons of 30-ft. rails under the same conditions.

One complaint which is general, but not universal, is that rail mills send out 60-ft. rails without their having been properly straightened. It would seem that this is simply a question of mechanical skill, and the fact that some mills do straighten 60-ft. rails would bear out this view. If one mill can do it, all can be brought up to the same standard by a system of careful inspection before acceptance of rail.

After carefully considering all the information obtainable, your committee is of the opinion that the increase of the length of rails to 60 ft. is entirely practicable, and that the benefits to be derived are, a reduction of the cost of handling and laying in track, a reduction of 50% in the cost of joint fastening, if no stop-blocks are used, and of at least 25% if such a device is used, a reduction in cost of maintenance and better riding track.

The use of rails with miter ends, although not a new idea by any means, may be said to be still an experiment, and trials that have been made on several roads have been disappointing in some respects. It is certain that the principle is sound, that a diagonal opening between the rails, so adjusted that the tread of the wheel before leaving one rail engages the next, will relieve the joint from the blow incident to the passing of wheels from one rail to another over square cut ends. In 1894-5 a trunk line road laid three-quarters of a mile of 75-lb. 60-ft. mitered rails. These rails were cut at an angle of 45° and laid in single track, thus the points were facing on one side and trailing on the other. Joint fastenings, 34-in. angle bars, suspended joints. After 3½ years' hard service the joints are in excellent condition and the rails show no signs of wearing or battering at the ends. The officials who are interested and are watching this piece of track feel hopeful that the mitered 60-ft. rail is the coming rail.

In 1894-5 the Norfolk & Western Railway laid in single track, 29 miles of 85-lb. 60-ft. mitered rails, cut at an angle of 45°. Joint fastenings, "Churchill" patent. Traffic same as detailed in that part of this report referring especially to 60-ft. rails. During the 3½ years' service three or four mitered points on 29 miles of track have broken off. No trouble with wheels catching the points. The mitered rails on this road are not giving good satisfaction, as under the heavy traffic the joints are battering badly, and it is estimated that the rails will give not more than two-thirds the service of square cut rails under the same conditions.

In April, 1893, 16 miles of 75-lb. 4¾-in. mitered rail, cut at an angle of 55°, were laid trailing points on double track on the C., M. & St. P. Ry.; joint fastening, 30-in. angle bar, with six bolts, suspended joint. Traffic over it has averaged about 10 passenger trains and 10 freight trains per day. Passenger engines are 8 and 10-wheel, with 60,000 lbs. and upwards on three pairs of drivers; freight engines, standard and compound, with 84,800 lbs. on three pairs of drivers. By reason of crude or careless work in the mechanical part of the rail mill process, the rails were in bad surface when laid. One end of a large percentage of the rails were bent or dipped 1-64 to 1-16-in., apparently by having been thrust against a dog at the rail saw while hot, the ends not having been sawed simultaneously. The result was that in track, the mitered point being bent downward, the weight was thrown on the point, and some 60 rails in the 16 miles of track had 3 ins. of the mitered points broken off. Aside from this defect, the mitered rails make good riding track, and after five years and four months of hard service, show no signs of flattening or flowing at the joint; however, it can be said that neither does square cut rail laid at the same time and under the same conditions.

Good surface at joints is more easily maintained on mitered than on square cut rails. There has never been an instance of rail points slipping by or overlapping so as to form a lip.

The majority report of this committee shows unsatisfactory results obtained on the Lehigh Valley R. R. from mitered rails that have been in service about the same length of time as that on the C., M. & St. P. R. R. This rail was cut at an angle of 55° and laid with 30-in. angle bars, suspended joints.

In all the tests of mitered rails that have come under our observation, the rails have been laid without a tie under the joint, and with the exception of the N. & W. Ry., with no support for the base of the rail at the joint. Although the mitered rails, concerning which we have information, have not been in track long enough to fully develop the strong and weak points, from data obtainable your committee is of the opinion that much better results can be obtained by cutting the rails at an angle of 65° and using a tie under the joint, or a joint fastening that will give full support to the base of the rail. At an angle of 65° it is certainly not necessary to restrict the use of mitered rails to trailing points. No instance has come under our observation of any trouble with the rails cut at an angle of even 45°. Gurdon W. Merrell.

Latest Improvements in Frogs and Switches.

Your committee finds that there has been but little that may be considered new, and yet has had sufficient use to prove its value, introduced since the report of last year on this same subject. The spring rail frog and split switch continue in general use for main track work, and are constructed on general lines which are very familiar Special attention has been paid during the last year by designers and manufacturers to improving in detail the separate parts of these devices, in order to make a safer and more serviceable whole.

Frogs.—With spring frogs, the following details are carefully looked after:

(1) Anchor of spring rail or anti-traveling device. On plate frogs, this is accomplished by a link attached to a pivot on the plate and one on the movable rail. On frogs without bottom plates the spring rail is secured by means of an anchor block at the joint at the toe of frog bolted to both the fixed and movable wing rails of frog, or the spring rail is attached to plates fastened to under side of frog and spiked down to the ties. The spring rail should be so secured that the maximum amount of travel possible will not cause the spring rail to bind in either opening or closing.

(2) Holding down devices. These prevent vertical motion of spring rail and generally consist of pockets enclosing a lug which is fastened to the movable rail. These lugs are allowed a vertical play of not to exceed ⅛-in. and sufficient longitudinal play to prevent binding.

(3) Grooving of movable rail. The groove is parallel to gage line of main track side of frog, the outer line of the groove being 4¼ ins. from the gage line and inner line distant from gage by width of head of rail.

(4) Springs. The size and number of springs to each frog vary, as does also the location of the springs with reference to point of frog. The power of the spring should be ample to close the spring rail under all ordinary conditions, and should be placed as near as practicable to the center of that portion of the wing rail which fits up against the frog point. If a spring bolt is used, it should be of the best quality iron.

(5) Stops. Spring frogs should be provided with stops, which will absolutely prevent the spring rail from opening to any greater extent than the standard width of throat in a rigid frog.

(6) Heel Riser. Spring frogs, as well as all other main track frogs, should be provided with a heel riser of steel rail run back far enough so that combined width of riser and head of point rail will at least equal the width of tread of engine driver.

Rigid frogs, as their name implies, should be as substantial as possible. If of the filled, bolted pattern, the bolts should be 1 in. in diameter for rail from 4¼ ins. to 5 ins., and 1⅛ ins. in diameter for rails more than 5 ins. in height. If plate frogs, the bottom plate should be not less than ¾-in. thick, and the rails secured to it with ¾-in. rivets having a pitch of not more than 3 ins.

Switches.—The split switch, otherwise known as Clarke, Jeffery or Lorenz, is in general use throughout the country.

The general features of this switch are common to most roads, but there is a great variation in details. One of the features that has been discussed largely of late years is the number of tie-bars, and uniformity of practice in this respect has not yet been attained. While some lines show a tendency to increase rather than diminish the number of tie-bars, your committee is of the opinion that with splice switches 15 ft. long, properly re-enforced and provided with stop lug, two adjustable tie-bars are all that are necessary. The use of a wrought-iron plate extending through under both rails at the point of switch, with the ends fitted with rail braces, is an improvement that is becoming more general.

Slide plates should extend under the main rail and be heavy enough to keep from bending and should be fitted with a rail brace on the outside. Bolts and pins in connecting rods and tie-bars, except those fastening lugs to split rail, should be turned to exact size, be a neat fit, provided with nut and spring cotter, and as far as possible be of uniform size throughout the switch. We believe that the general practice is to make these bolts too small. While the essential features of the split switch are common to the switches in general use in this country, there are scarcely any two lines whose switches do not vary in some detail. Your committee believes that much greater uniformity in this respect is possible and desirable.

C. Dougherty, S. P. Adams, Peter Clark, Thos. McKune, E. H. Bryant, Committee.

Discipline, in Its Practical Application to Track Forces.

There are at this time two distinct methods of the application of discipline. The one which educates by regulations and special instructions, where the breach is regarded as an offense to be corrected by punishment which takes the form of reprimand, suspension and dismissal. The other, known as the "Brown" or "Fall Brook" system, which, according to the report read at the 27th annual meeting of the American Society of Railroad Superintendents, had at that time been adopted by 28% of the 180,000 miles of railway in the United States. In this latter system the educational feature predominates, the idea of punishment being entirely eliminated. Under it the employee is not subjected to fines and suspensions, but is judged wholly by his record, and is retained or dismissed accordingly as his record is good or bad.

Of each case requiring disciplinary action, a record is kept, and demerit marks are entered against the one at fault. All meritorious acts are likewise recorded and merit marks given. A given number of merit marks are cancelled by a like number of demerit marks, or vice versa. This gives an opportunity to retrieve a previous good standing. Further than this, each employee having a clear record for a given length of time, say six months or a year, is entitled to a certain number of merit marks, which emphasizes in a measure an appreciation of his service. It stimulates his pride and conduces to further effort to maintain his standing. At the end of each year the record is closed and a new one opened. All cases after being fully and fairly investigated are issued in bulletin form, omitting names, places, dates, etc., that there may be nothing to identify the individual with the bulletin. These bulletins point out the errors and consequences, and how they might have been avoided, that each may profit by the experience of his fellows. All meritorious acts are recorded and bulletined in like manner.

Abolishing from our minds the idea that discipline means punishment, but is purely educational, and bearing in mind that the success of any undertaking depends largely upon the skill of those engaged in it, the query naturally arises as to which of these two systems is the better as applied to track forces.

In the event of a suspension under the first-named system, it is necessary to put a substitute in charge, who, as a rule, is less skillful, lacks knowledge of the localities and conditions, and where the suspension is for a considerable length of time, the company would suffer because of this lack of skill and knowledge. The suspended employee would not only lose his time, with the consequent hardship entailed upon his family, but it causes him to feel a secret dislike for his superior and the company he serves.

With the "Brown" system, instead of the employee losing his time and his family being inconvenienced, if not immediately suffering by reason of his enforced idleness, a given number of demerit marks would be entered against his record. The company would be the gainer by his retention in the service, not having to educate a new man, with the possibility ever present of his making a still greater mistake. The retained employee would feel his error more keenly and would, I think, be less likely to err in the future, and so far as the others are concerned the lesson would be equally as good. H. W. Church.

◆

WIRE NAILS, says the "Iron Trade Review," have reduced the output of cut nails to less than one-fifth of what it was in 1886. About 40 years ago the United States annually produced about 2,000,000 kegs of cut nails, or about 89,000 tons; and in 1886 the maximum output was reached with 360,000 tons of cut nails. Until 1880 cut nails held the field; but in 1892 the wire nail output was the greater, with 4,750,000 kegs, as compared with 4,500,000 kegs of cut nails. This total of 9,250,000 kegs is the high-water nail output in any country at any time. In 1895 a maximum output of 5,841,000 kegs of wire nails was reached, while the output of cut nails for 1896 was less than 900,000 kegs. At the present time there are 79 wire nail factories operating in the United States, as compared with 53 in 1896. There are now 4,544 cut nail machines working, as compared with 4,598 in 1896. Cut nails have fallen in price to an average of $1.60 in the six years ending in 1896. Wire nails cost for small sizes an average of $10.90 per keg in the four years ending in 1880; while in the four years ending in 1896 the average was $3.62, and the lowest annual average was $2.93 in 1894. In standard sizes of wire nails the prices are lower; the average for 1887 was $3.15 per keg, and in 1896-97 prices fell to $1.60. But cut nails are cheaper still, the average for 1894 being $1.08 per keg of 100 lbs. This latter rate is equivalent to about $23 per ton, or little more than the English price for steel rails.

◆

THE PATENT ON THE JONES MIXER, an apparatus used in connection with the direct Bessemer process, has been adjudged valid by Judge Buffington, of the U. S. Circuit Court, at Pittsburg, in an infringement suit brought by the Carnegie Steel Co. against the Cambria Iron Co. The mixer patent was issued June 4, 1889, to the heirs of the late Capt. Wm. R. Jones, general superintendent of the Edgar Thompson Steel Works of the Carnegie Company. The mixer is a large covered vessel, lined with fire brick, holding 200 to 300 tons of molten iron. The pig metal is drawn from the blast furnaces into ladles, in which it is carried to the mixer and poured into it. At the same time the metal in the mixer is drawn off from time to time into other ladles, which carry it to the Bessemer converters. The mixer performs the double function of storage, enabling the converters to run regularly, while the rate of production of the furnaces is irregular, and, of mixing, by which variations in the quality of the iron received by the mixer from different furnaces are evened up, and the quality of the iron delivered to the converters is made practically uniform.

◆

THE COMBUSTIBLE CITY REFUSE OF BOSTON is to be disposed of under a contract made on Sept. 10 with the City Refuse Utilization Co., of which Mr. Herbert Tate, of New York, is president. The contract is for ten years, the city of Boston retaining the option of buying the plant under appraisement at the end of five years. The refuse is to be sorted and the worthless parts are to be destroyed by fire; and the compensation is a cash payment of $5,500 per annum by the city of Boston, the contractor reserving the right to all valuable material saved from the refuse. The firm of Jones & Meehan, of Boston, is now building the plant from plans made by Mr. W. F. Morse, M. E., of New York. This plant is to cost $29,000, and is to be completed in December next.

◆

THE SANITATION OF SANTIAGO, CUBA, under American control, is showing quick results. Gen. Wood, the Military Governor of this old and always unhealthy Spanish city, has divided Santiago into five sanitary districts, each under a physician, with inspectors of sewers, streets, houses and dispensaries, assisted by 100 street cleaners. About 500 cu. yds. of refuse are burned daily, disinfectants are distributed where needed, and a heavy fine is imposed for uncleanliness or failure to report cases of sickness or death. As a result, there is a marked decrease in sickness among the poor, and the average death rate has fallen from 70 to 20 per month. There is also decreased sickness among the new troops. The harbor is now the chief source of trouble, as the current is slight near the city. It is proposed to dredge the muddy shallows, protect the banks with stonework, or piles, and to carry the present infectious sewage two miles down the bay to a swifter current. Gen. Wood expects within another month to make Santiago as healthful as the ordinary Southern town in the United States.

◆

RAILWAY TICKET SCALPING is to be regulated—if not suppressed—by ordinances lately passed in Cincinnati and other Western cities. These provide that the ticket-scalpers shall take out a license and give bonds against selling spurious, counterfeit or stolen tickets. Cincinnati has lately arrested and fined eight dealers in these tickets for unlawful selling, and six others are in jail in that city. A number of railway companies have also recently made it a condition, in making reduced rates for conventions, etc., that the city where the meeting is to be held shall undertake to clear out scalping offices, which have been proven to deal in counterfeit or stolen tickets.

◆

THE CYLINDRICAL COTTON BALE is gaining in favor, and the American Cotton Co., John E. Searles, President, controls the system and has opened its commercial department in Nos. 11,12 Cotton Exchange Building, New York. This part of the company's business is in charge of Mr. John Martin. About 150 of the cylindrical compresses are now in operation; and the output is said to command a higher price than for cotton as ordinarily baled, as it is more compact, more symmetrical and practically non-combustible. The machinery is now perfected and the operations of the company are to be "aggressively extended."

◆

A RAILWAY IN HAYTI is proposed, extending from Cape Haitien to La Grande Riviere du Nord, a distance of about 18 miles to the northeast. The capital stock is fixed at $450,000, and the estimated cost is $250,000 for a narrow-gage road; the Haytien government is to guarantee 8% interest and the material is to be purchased in the United States. Mr. Henri Thomesset is the engineer, and the government grants to Cincinnatus Leconte and

Blanc Eusebe, the former being the present Minister of the Interior and Public Works, an exclusive privilege and concession for 60 years. The country traversed is a beautiful plain; adapted to the cultivation of the peculiar products of the island, and especially suitable for the growth of the banana. Mr. Lemuel W. Livingston, U. S. Consul at Cape Haitien, has forwarded the above information to the State Department.

HAWAIIAN RAILWAYS include the three following lines: The Kahului railway, 13 miles long, on Maui Island; the Hawaiian railway, 20 miles long, on the island of that name; and the Oohu Railway & Land Co.'s Line, running from Honolulu to Waianae, with a total length of 38½ miles, including sidings. The first two lines are chiefly used for carrying plantation products to shipping points. The last named line was opened in 1890, and in the year 1897 it carried 85,596 passengers, paying $30,993, and 66,430 tons of freight, paying $69,753. The equipment of this line includes 5 locomotives, 14 passenger cars and 132 freight cars.

PROGRESS ON THE TRANS-SIBERIAN RAILWAY, at the beginning of 1898, is reported as follows in the "Revue Scientifique." Commencing at Tcheliabinsk, the western terminus of the Siberian line, the railway is opened to normal traffic to Krasnoiarsk, a distance of about 1,347 miles. From the latter point to Klioutchinsk, 218 miles, the line is opened temporarily; and it will be definitely opened upon the completion of station and other necessary buildings. Beyond Klioutchinsk the rails are laid for about 20 miles, to Touloune; two bridges are to be built upon this section. From Touloune to Irkoutsk, 238 miles, and from Irkoutsk to Lisvenitchnaia on Lake Baikal, 40 miles, the roadbed is completed and nearly all the bridges and station buildings are finished. On Lake Baikal, the ice-breaker ferryboat which is to transfer trains from one bank to the other, is being erected, and it is expected that it will be finished in 1899. Surveys are still in progress for a line around Lake Baikal, but nothing will be done in constructing this road until the whole line is open. In the Transbaikal section the roadbed is graded and rails were laid between Strietensk and Mitrophanor, a distance of 200 miles; but the floods of last year carried away some of this track, and only 71 miles of rails were left in January, 1898. The eastern section is finished, the first train leaving Vladivostock for Khabarovsk on Sept. 15, 1897. The preliminary survey but not the final location has been made for the line across Manchuria.

A PER DIEM SYSTEM OF FOREIGN CAR RENTAL, devised by Mr. J. M. Daly, Superintendent of Transportation, Illinois Central R. R., is being tested, apparently with considerable success, by a number of Western railways. At present, as is well known, the general practice is for railways handling the cars of other lines to pay for their service according to the mileage made, regardless of the time consumed in making this mileage. It has been found that this plan results in a great many irregularities, one road perhaps paying its neighbor at the rate of 50 car miles per day, while it might receive from that neighbor payment based upon less than 20 car miles per day. Under the Daly plan the roads exchange car day for car day and pay mileage only on the remainder of days. The railways which have been testing the new plan are the Illinois Central, the Atchison, Topeka & Santa Fe, the Hocking Valley & Toledo, the Chicago, Milwaukee & St. Paul and the Missouri, Kansas & Texas, and at a meeting of the car service officials of these companies recently held in Chicago the following figures of foreign car service for July 1898, as compared with the same month of 1897, when the old mileage plan was in operation were presented by the committee having the experiment in charge:

	1898.		1897.	
	Days.	Miles.	Days.	Miles.
I. C.	7,644	202,776	9,737	151,009
C., M. & St. P.	7,054	188,938	7,808	136,235
Santa Fe	4,584	141,104	4,626	102,985
Il. V. & T.	201	3,205	202	2,044
M. K. & T.	1,336	49,975	1,347	54,322
Totals	20,819	585,998	23,720	446,595

According to this statement the average car miles per day increased under the Daly plan to 28.6 miles per day, against 18.8 miles per day under the old straight mileage plan, a gain of 52.1% or 9.8 miles per car per day. While it would be incorrect to conclude from these figures that the gain is due alone to the new system of paying for foreign car service, the experiment is an interesting one and should be carefully watched by railway traffic managers.

THE BRIDGE DISASTER AT CORNWALL, ONT.

The fall of two spans of the New York & Ottawa R. R. bridge over the American channel of the St. Lawrence River, near Cornwall, Ont., was briefly reported in our last issue. The number of men killed in the accident is now given as 15, while 16 were seriously injured. At the time of the accident the erection of both the fallen spans had been practically completed, and under one the falsework had been removed. On the other span the workmen had begun to take down the traveler, but most of them were working on the floor of the bridge when the accident occurred.

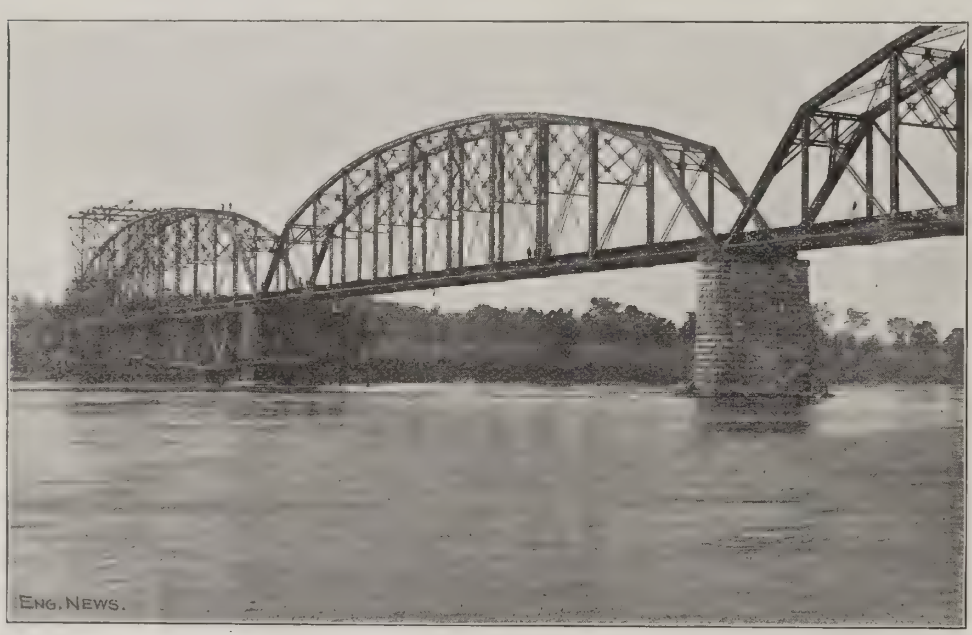

FIG. 1. THE NEW YORK & OTTAWA R. R. BRIDGE OVER THE AMERICAN CHANNEL OF THE ST. LAWRENCE RIVER, NEAR CORNWALL, ONT.

(From a photograph taken on the morning of Sept. 6. The two spans shown and the pier on the left fell at noon on that day.)

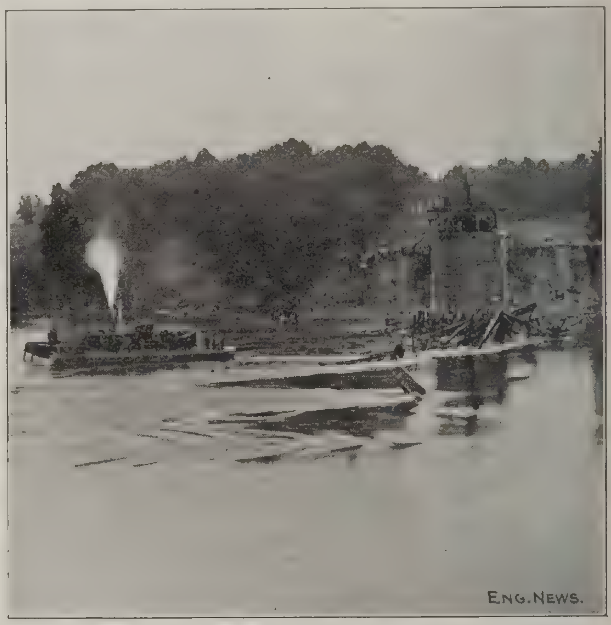

FIG. 2. VIEW OF WRECK OF THE NEW YORK & OTTAWA R. R. BRIDGE, LOOKING SOUTH FROM PIER 3,

(From a photograph taken on the afternoon of Sept. 6.)

Principal interest, of course, centers in the construction of the pier which went down with the two spans. The river at the site of the pier is about 35 ft. deep, and has a swift current, said to be about 5 to 8 miles per hour. The river bottom is a clay hard-pan in which are imbedded boulders, many of them of large size. The pier was founded by sinking a timber crib 18 ft. wide, 62 ft. long and 38 ft. in height, and filling it with concrete deposited under water by buckets arranged to empty automatically on striking the bottom. The anchoring and sinking of this large crib in the deep water and swift current was a task of great difficulty. To accomplish it a small crib filled with stone was sunk upstream to serve as an anchorage and a 3-in. steel cable was led from this to the pier crib, which was also supported by a barge on each side. Cables led to the river bank were used to swing the crib in the stream till it was in the correct position,

The swift current made it impossible to examine the bottom by divers before sinking the crib. Soundings were taken over the site of the crib, however, and the crib bottom was scored to correspond to the depth thus obtained.

After the crib was down divers went down inside and obtained samples of the bottom, which was deemed satisfactory by the engineer, and the work of concreting began. The first concrete laid, to the amount of about 50 cu. yds., was deposited in bags, all of which were placed by divers around the sides of the crib. The remainder of the concrete was then deposited from a bucket holding about 1 cu. yd. arranged to dump automatically on contact with the bottom. The concrete was deposited in successive layers of about 18 ins. over the whole area of the crib, and divers reported it as setting satisfactorily.

The concrete was mixed by hand in the proportions of 1, 2 and 5, using Glen's Falls Portland cement. It may be said here that the crib itself was built of 12-in. timbers, drift-bolted together, crossties of the same size were inserted at 10 ft. intervals, the vertical spacing being about 4 ft.

The concrete was carried up to a point 4 ft. below water level, and was then pumped dry, the top of the crib projecting above the water forming a coffer-dam. The top of the concrete appeared in good condition, and upon it the masonry was started. Two courses were laid and then work was shut down for the winter, all the above-described work having been carried out last fall. During the winter the pier was subjected to heavy ice pressure, which, as most engineers know, is a severe test of any pier built in the swift current of the St. Lawrence; but it was not moved. Early in the spring, we are informed, it was struck by a heavy timber raft, which was broken up by the collision, and the pier showed no injury.

Work on the piers was resumed in the spring and they were built up to their full height of about 35 ft. above the water, making the total height about 70 ft. from the river bed to the pier coping. The masonry of the piers was rock-faced ashlar, with a backing of Portland cement concrete.

The specifications and working drawings for the bridge were made under direction of Mr. F. D. Anthony, Chief Engineer of the New York & Ottawa Ry. Co., and were approved by Mr. A. A. Stuart, M. Am. Soc. C. E., now Engineer of the Degnon-McLean Construction Co., of New York city, who was consulting engineer to the railway company. They were also approved by the Canadian Government engineers.

The report has been widely published that a tugboat captain who witnessed the accident declared that he saw one of the spans break in two first and pull the pier over. Later accounts are to the effect that this man now says he was in the engine room when the accident occurred, and was not in a position to see whether span or pier fell first.

The accompanying illustrations, reproduced from photographs, will, we doubt not, be examined with interest by our readers. We may note that the north end of each span is in each case the fixed end. Thus on Pier 2, which fell, the channel span rested on expansion rollers, while the shore span, which still had the falsework under it, was anchored to the coping. The channel span turned partly on its side in falling, and its end-shoe is now about 25 ft. south of Pier 3, on which it formerly rested. The shore span carried the falsework down with it, and, falling into shallow water, made a tangled mass of wreckage, as shown in the illustrations.

Fig. 4 shows the masonry of Pier 2 just started. It will be noticed that it is located considerably to one side of the concrete base. We understand that this was made necessary to bring the pier in correct position, the crib being sunk a little to one side of its correct location.

The above comprises practically all the facts we have been able to obtain bearing upon the causes of the accident up to the time of going to press. The mass of debris in the river and the swift current have thus far prevented any examination by divers of the base of the fallen pier.

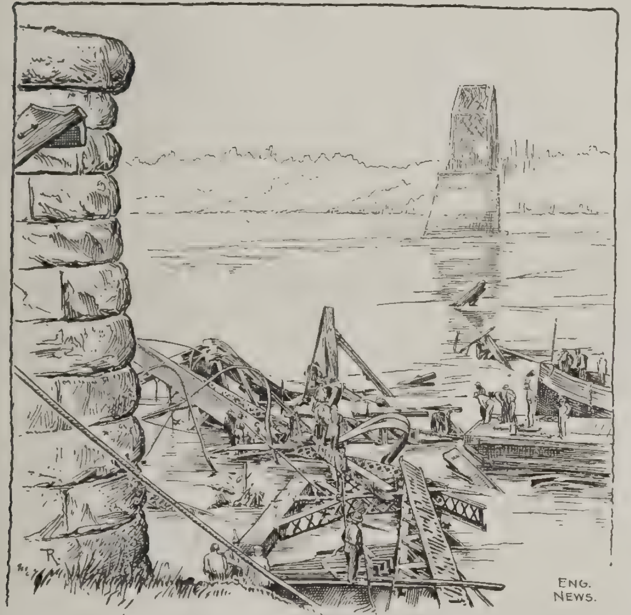

FIG. 3. VIEW OF WRECK OF THE NEW YORK & OTTAWA R. R. BRIDGE LOOKING NORTH FROM ABUTMENT ON AMERICAN SHORE.

(Sketches from a photograph taken on the afternoon of Sept. 6.)

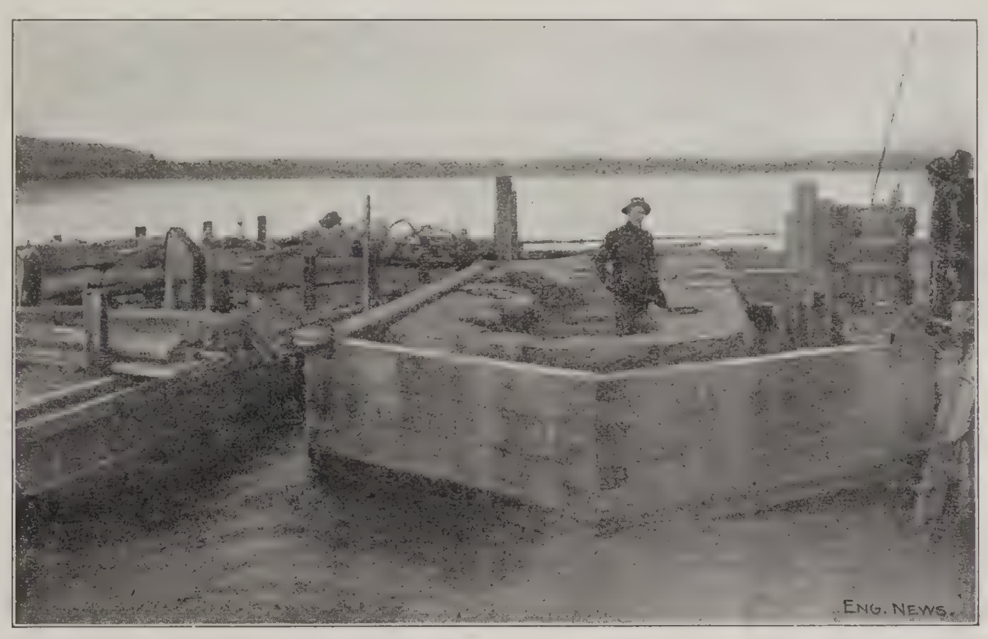

FIG. 4. VIEW OF PIER 2 FOR NEW YORK & OTTAWA R. R. BRIDGE UNDER CONSTRUCTION.

We believe engineers will generally agree that the facts thus far presented all point to the pier and not the span as the point of original failure. It is difficult to conceive how it would be possible for the failure of a member in either of the spans, and its consequent fall, to pull the pier over. There are many accidents on record of bridge spans falling or being blown down, but we cannot recall one case where a falling span took the whole pier with it. Besides this, of the two spans that fell, the falsework had been removed from under the river span; but this fell practically intact, showing that it did not break in two and drag the other down. The falsework was still under the other span, and in case any member of that span had failed, the falsework would have supported it, in all probability. Still again, the testimony of eyewitnesses is that the pier "crumbled away."

Assuming, then, the pier to be the cause of the accident, let us see where the failure was most likely to occur. In this connection, it seems to us, that a most noteworthy feature of the accident is that it came absolutely without warning. There was no premonitory cracking or settling. Now this is exactly contrary to the way in which masonry structures act. Overloaded masonry cracks and gives warning of its condition long before final failure occurs; overloaded footings give evidence by settlement that something is wrong. To account satisfactorily for the failure of the Cornwall pier, therefore, we must find some cause which would drop the pier into the river without previous settlement or cracking of the masonry; and the only cause which seems sufficiently probable to deserve acceptance is the gradual undermining of the pier by the current.

The bed of the river is a clay hardpan, according to our best information, overlaid with the usual layer of pebbles and boulders common to swift running streams in this region of glacial action. If the current is increased in swiftness enough to remove this protecting layer of boulders the clay beneath might be gradually washed away.

It is possible that the driving of the falseworks for erecting the spans so increased the current next the piers as to wash away the boulders and clay, until finally the structure became so unstable as to topple over.

The narrow base of the pier (18 ft.), in proportion to its height (70 ft.), has been criticised. It will be readily seen that two or three feet erosion under the side of so narrow a pier leaves an uncomfortably small margin of stability.

This is especially the case if the pier masonry was placed on the same side of the concrete mass as that under which erosion occurred. The reason for using such narrow cribs was, doubtless, the swiftness of the current; the difficulties of sinking cribs in such a channel, of course, increase greatly with every foot of width.

Besides erosion under the pier, the only other hypothesis which could account for the sudden failure of the pier is the bursting of the crib. If the concrete deposited under water did not set, but remained a semi-fluid mass, then it might eventually exert a pressure upon the sides of the crib which would pull out the cross braces and the whole pier would settle down. It seems quite impossible, however, that the concrete can have so absolutely failed to set as would be necessary to make this hypothesis true. It seems much more reasonable to ascribe the accident to erosion, at least until such a time as the condition of the fallen pier and crib is more fully known.

ANNUAL MEETING OF THE AMERICAN STREET RAILWAY ASSOCIATION.

The seventeenth annual convention of this Association was held last week at Boston. At the opening session on Sept. 6, President A. E. Lang introduced the Hon. Josiah Quincy, Mayor of Boston, who made a brief speech of welcome. President Lang then gave an address in which he referred to Boston as the birthplace of the Association, and the home of the electric railway, it being the first large city in the country to adopt the trolley system on a large scale. That the founders of the Society "builded better than they knew" was shown by the fact that no changes in the constitution had been necessary, notwithstanding the remarkable advances in street railway construction and operation. Attention was called to the need of discussion of live subjects in the convention, and the following were suggested as topics possessing considerable interest: "The Suburban Railroad;" "On What Terms and Conditions Should They Enter Over Our Tracks?" and "How Can Their Building Be Encouraged?" "The Issuing of Transfer Checks or Tickets, and How Abuses Connected Therewith Can Be Limited;" "The Equipment of Buildings with Automatic Sprinklers, and the Economy Resulting Therefrom;" "The Discussion or Agitation of Municipal Ownership of Franchises, and the Most Intelligent Way to Meet the Subject;" "To What Extent Should Companies Engage in the Amusement Business, and the Best Methods of Conducting the Same;" "How Best to Promote the Interests of Employees and in Return Secure from Them the Highest Degree of Service and Loyalty."

The report of the Secretary-Treasurer, Mr. T. C. Penington, showed a present membership of 161 companies. The total a year ago was 178, of which number 17 had withdrawn, or consolidated with other companies. The financial statement showed a balance of over $3,000 in the treasury.

The first paper, entitled "The Comparative Earnings and Economy of Operation of Single and Double Truck Cars for City Use," by Richard McCulloch, Electrical Engineer, Cass Avenue and Citizen's Railway Companies, St. Louis, Mo., is abstracted elsewhere in this issue.

In introducing the discussion which followed, Mr. Ira A. McCormack, of Brooklyn, stated the experience of his road, which operated between 300 and 400 cars, had been quite different from that given by the author of the paper, and in no instance had they been able to lengthen the headway by operating cars of larger capacity. In fact the contrary was true, and cars are now being operated under a reduced headway. As now operated, on holidays the cars which ordinarily seat 60, carry a standing total load of from 150 to 180 persons, and run on the line from Court St. to Coney Island on a 1-minute headway.

Mr. John I. Beggs, Milwaukee, Wis., gave his experience in Milwaukee, where, for the past three years, experiments have been under way to determine the advantages and disadvantages of the double truck. As a result, in 1896, 20 cars were equipped with double maximum traction trucks, and put in operation. These trucks had 30-in. wheels and the cars had 18 double seats, giving a capacity of 36 passengers. A year ago these cars were enlarged to 20 seats, holding 40 passengers, and the "maximum traction trucks" were abandoned on account of their jumping the track. The past year the car length was again increased, this time to 22 seats, holding 44, but the length between buffers was maintained the same.

In a climate such as Milwaukee, it is necessary to employ one style of car throughout the year, as the short summer season, chilly winds and cold rains, make it desirable to use only closed cars, which can be operated 12 months in the year. Notwithstanding the use of a 33-in. wheel on the cars as constructed, a distance of only 32 ins. between track and sill was obtained, which made the cars easy to enter and practically removed one of the chief objections to double truck cars. Passengers are found to prefer the comfort and higher speeds of the larger cars. On the Milwaukee roads the average speed has, within two years, been increased one mile per hour, and is now 9 miles per hour. Another factor in favor of the double truck car is the reduced wear and tear due to easier riding, and better distribution of weight, which causes lighter blows at joints, frogs, etc. Notwithstanding the increased number of trucks, wheels and springs, car repairs cost less.

His company is now operating under an increased headway as a direct result of the use of double truck cars. In reply to a question by Mr. H. N. Sloan, he stated that his company is now operating 10 interurban cars over a line 26 miles long. These cars have double trucks, and are equipped with four G. E. 1,000 motors, geared to run at a speed of 50 to 55 miles per hour. These cars weigh, when complete, about 40,000 lbs., and gave no trouble from lack of traction, or track jumping. In the near future it is the intention of the company to place four motors on all cars as two-motor cars have difficulty in mounting some of the grades, which are in a few instances from 6 to 7%.

This concluded the morning session, and the afternoon was spent in an excursion to Concord and Lexington. A special train was provided by the Massachusetts Street Railway Association, which had charge of all local arrangements, and fully 300 delegates, supply men and ladies, took advantage of the opportunity to visit these historic places.

At Concord the party walked to the park. Here two monuments mark the spot where on April 18, 1775, the British troops were opposed by the "Minute Men." Rev. C. A. Staples, of Concord, in a quaint and most interesting way, told the members of the excursion party the story of the Concord battle, and pointed out the spots of historic interest.

Again boarding the train the party was carried to Lexington, where carriages were waiting to carry them about the town. The many monuments, the battlefield, Sleepy Hollow Cemetery, where Emerson, Hawthorne, Thoreau and the Alcotts are buried, and the other historic points were viewed with interest by the visitors.

In the evening a reception was held in the Paul Revere Hall, and passed most pleasantly under the efficient direction of the Ladies' Committee of the Massachusetts Street Railway Association.

Wednesday, Sept. 7.

The first paper was read by Mr. W. S. Dimmock, General Superintendent Omaha & Council Bluffs Ry. & Bridge Co., Council Bluffs, Ia., and discussed the postal service on street railways.

Mr. Dimmock said that the advantages to the business community of a street railway postal service were conceded on all hands, and the only ground for discussion, was the compensation given the companies for this valuable service. In the beginning street railway companies were anxious to carry the mails, believing as they did, that it would insure to them a complete protection by the government during strikes. In consequence they accepted rates, which when they found the protection was not as complete as expected, were considered too low. At present a fixed rate of 3 cts. per car-mile has been established by the government for street railway postal service, while the "Star Route" service costs 4.94 cts. per mile. Congress fixed this rate and made the appropriation; and it is quite within the province of the American Street Railway Association to sufficiently influence Members of Congress to have the present injustice to street railway companies remedied.

Mr. John I. Beggs, Milwaukee, Wis., said that the company which he represented was considering the carrying of U. S. mail upon its lines. So far he had opposed even carrying pouches, since it did not seem to promise any adequate return and the resulting protection did not seem to amount to much. The low rates were originally accepted by some railway companies solely to obtain the protection of the government, and the government was now attempting to force these low rates on all companies, regardless of location or surrounding conditions. The rate offered was really below the cost of operation in several cases, and yet the mail car must always have the right of way. The advantages of carrying mail pouches on platforms was questionable, as the space could be put to far more profitable use in carrying passengers, many of whom would rather ride on the platform than any other place.

Mr. Robert McCulloch, St. Louis, Mo., stated that his company had equipped two cars for postal service, intending to operate them at an inadequate rate, but expecting to derive the benefits of a United States mail route. Upon their first appearance, orders were given to have the U. S. mail signs removed from the cars.

Mr. H. C. Payne, Milwaukee, Wis., thought that the postal authorities were willing to treat the railways fairly. The trouble lies with the Congressional appropriations and not with the Department. If the matter were properly presented to the committee having in charge the Post Office appropriations there was good reason to believe that a change would result, for he found the Department officials uniformly willing to do what was fair. It would be necessary to have a committee with proper data visit Washington, and present the matter to the Congressional committee. A motion was carried to this effect; the committee to consist of five members to be appointed later.

The Secretary then read a paper by Mr. M. S. Hopkins, Electrician, Columbus Street Ry. Co., Columbus, O., entitled "Maintenance and Equipment of Electric Cars for Street Railways." The paper is abstracted elsewhere in this issue.

Mr. H. N. Sloan, Chicago, Ill., disagreed with the author regarding the inadvisability of night inspection. With his company this inspection had proved very satisfactory, all motor brushes being changed each night. As a result, commutators required turning down less frequently.

Before the adjournment of the morning session, President Lang announced the Nominating Committee as follows: W. W. Bean, D. G. Hamilton, E. C. Foster, W. F. Kelly, J. R. Chapman, Henry C. Payne and E. H. Davis.

The excursion of the afternoon included a steamer trip down the bay to Nantasket Beach, affording on the way down an excellent view of the battleship "Massachusetts," the "Solace," several smaller gunboats, and the shipping of Boston Harbor. At the Beach the visitors divided, some going in bathing, and others taking a trip over the Nantasket Beach Electric road. Later a "clam bake" was participated in by all, over 700 sitting down in the large dining-room of the Ocean View Hotel.

Thursday, Sept. 7.

This session began with the reading of a paper by Mr. Walton H. Holmes, General Manager, Metropolitan Street Ry. Co., Kansas City, Mo., entitled "To What Extent Should Street Railway Companies Engage in the Amusement Business." In this paper it was stated that conditions varied in each city, but there were certain general rules which could be laid down. The conditions of life in most cities has changed during the last few years, and in addition to police and fire protection, means of amusement, such as parks, and boulevards, were now provided. Municipal authorities were only too glad to have street railways help by constructing lines to city parks, or by constructing and operating parks of their own. Many roads did not consider new resorts paying investments, and found it advisable to improve transportation facilities to parks already existing. In many large cities the question was, however, how to properly take care of existing traffic, and not so much how to increase it. Smaller cities do without doubt afford an opportunity for recreation parks such as defined in the title of the paper. There is little difference in the kind of recreation required at these parks, usually music, baseball, football, roller coasters, boats, chutes, light comedy, balloon ascensions, etc., suffice to increase the light traffic of summer and bring the balance on the right side of the ledger.

Mr. C. D. Wyman, New Orleans, La., said that at one time he was firmly convinced that a railway man should stick to his own line of business. Recently, however, he had discovered that local conditions affect the question. In his experience the people who conduct recreation grounds, outdoor sports, etc., were not always reliable, and some supervision by the railway company was advisable. In some cities, especially in the South, it was at present not customary for people to leave their homes in the afternoon or evening of the summer months, and it was for the progressive street railway companies to break up this custom. The road he represented had established parks, with attractive entertainment, with very gratifying results. Considering the question as a whole, he was convinced that the amusement business in connection with street railways paid.

Mr. John I. Beggs, Milwaukee, Wis., said that his company had for some time given, at its own expense, band concerts in one of the city parks, and had a standing offer to duplicate any money raised by the city or any public spirited citizens for similar entertainments. The result had finally convinced him that the gain in traffic income did not warrant the increased expense, and that it did not pay street railways to go into the amusement business, at least in this way. While the company's income was increased, the operating expenses were also increased at a greater rate, and in his case the returns were found to be only about 75% of the expenditures. In many cities considerable traffic was concentrated on one line and forced in one direction which would ordinarily have distributed itself in several directions.

Mr. W. E. Harrington, Camden, N. J., said that his company had a free park, and the number of outsiders caused so much trouble that it was necessary to charge a small entrance fee. The number entering was registered by turnstile, and it had been found that they were receiving only about 70% of the money expended.

Mr. A. E. Lang, Toledo, O., remarked that his city had a population of about 140,000 inhabitants, and the railway owned a park on the lake front about 5½ miles distant. The original owners had started on rather a large scale, charging no admission and furnishing seats in any part of the Casino building free. The original cost of park and equipment was $65,000. As soon as his road came into control an admission fee of 5 cents was charged, all coming by car, or 15 cts. for the round trip. Instead of free seats, a number were reserved and charged for at 10 cts. Last year, instead of a loss, the Casino cleared a few hundred dollars, and the increased earnings of the railway company amounted to $40,000. This year the Casino Company will net $6,000 and the railway company about $50,000.

Col. N. H. Heft, Meriden, Conn., was glad that railway men were maintaining their reputation for honesty and truthfulness by telling just what they were doing. His company had inherited a park costing $45,000, with free launches, switchback, pavilion, etc., and their experience with it had been somewhat unfortunate. Street railway men were running wild over the amusement question. The whole matter must be run on a sound business basis.

Mr. W. W. Bean, chairman of the nominating committee, presented the following list for officers for the ensuing year:

President, Chas. S. Sergeant, Boston, Mass.; First Vice-President, H. C. Moore, Trenton, N. J.; Second Vice-President, Earnest Woodruff, Atlanta, Ga.; Third Vice-President, W. H. Holmes Kansas City, Mo.; Secretary-Treasurer, T. C. Pennington, Chicago, Ill.; Executive Committee, A. E. Lang, G. E. Yuille, Frank Jones, John I. Beggs and Ira A. McCormack.

For the next annual convention Chicago, Ill., was chosen. The report was accepted and the secretary ordered to cast the ballot for the nominees.

President Lang named the following gentlemen as members of the committee having in charge the question of carrying United States mails on street railways: J. T. Burnett, Boston; H. C. Payne, Milwaukee; Ira A McCormack, Brooklyn; D. G. Hamilton, Chicago, and W. S. Dimmock, Omaha.

The President also announced the presence of two railway engineers from Japan who had been attending the Association meetings, Messrs. T. Y. Dzushi, Chief of Finances and Manager of Stores of the Imperial Government Railways, and K. Sugahara, Chief Engineer of the Kobe Railway and of some street railways built in Japan. Upon motion, the privileges of the floor were extended to both gentlemen.

The second paper of the morning session, by Mr. Frederick B. Perkins, electrical engineer, Toledo Traction Co., Toledo, Ohio., entitled "Inspection and Testing of Motors and Car Equipments by Street Railway Companies," is abstracted elsewhere in this issue. There was no discussion.

The afternoon was occupied pleasantly by a trip to Plymouth, the special train leaving Old Colony Station at 2 p. m., and returning about 6 p. m., in ample time for the annual banquet, held at the Hotel Brunswick, the convention headquarters, at 8 p. m. Covers were laid for 350 persons, and the after-dinner speakers included Mayor Quincy, Hon. Geo. G. Crocker and other prominent men.

Friday, Sept. 9.

The session was opened with the reading of a paper by Mr. R. W. Conant, Electrical Engineer, Boston Elevated R. R. Co., entitled "Cost of Electric Power for Street Railways at Switchboard; Both Steam and Water." This was, without doubt, the most complete and valuable paper of the convention. We postpone its publication to our next issue. There was no discussion upon it.

The Committee on Rules for Government of Motormen and Conductors asked for an extension of time and the appropriation of $200 to permit the printing and mailing of the code prepared by them, the intention being to submit it to the members for revision and criticism. Both requests were granted. The new President, Mr. Chas. S. Sergeant, briefly addressed the members, and the final adjournment was then taken.

The convention, as a whole, is generally conceded to have been the most successful in the history of the Association, unquestionably so from the exhibition and entertainment standpoint.

While the street railway managers and engineers were in session in the main hall the Street Railway Accountants' Association was busily engaged in another part of the building.

The papers read were as follows:

"Statistics—Their Use and Abuse," Mr. E. D. Hibbs, Auditor, North Jersey Street Railway Co., Jersey City, N. J.; "Car Mileage—How Arrived at and Its Use," Mr. A. H. Ford, Secretary and Treasurer, New Orleans Traction Co., New Orleans, La.; Report of the Permanent Committee on "A Standard System of Street Railway Accounting, Covering the Classification of Operating Expenses, Classification of Construction and Equipment Accounts and Form of Annual Report." Chairman C. N. Duffy, Secy., Citizens' Ry. Co., St. Louis, Mo.

The election of officers for the ensuing year resulted as follows: Pres., J. T. Calderwood, Minneapolis; First Vice-Pres., E. R. Tighe, New York; Second Vice-Pres., R. L. Williams, Richmond, Va.; Third Vice-Pres., F. E. Smith, Lynn; Secy. and Treas., W. B. Brockway, Toledo, O.; Executive Committee, Chn., H. L. Wilson, Boston; H. E. Babcock, Elmira, N. Y.; H. O. Mackay, Milwaukee, Wis., and J. D. Fraser, Ottawa, Canada.

The selection of the Mechanics' Building, Boston, Mass., as a place of meeting insured an ideal location for both the exhibition of street railway appliances and the regular business session.

The attendance was most gratifying, including, as it did, about 900 supply men, 300 delegates and about 300 ladies, a total of about 1,500 persons. All were accorded the freedom of the Boston street railways, the convention button serving as a pass on all the city and suburban lines. The exhibition was, as already stated, the largest in the history of the Association. The exhibits, which occupied two full floors of the Mechanics' Building, are briefly described in the Supplement of this issue.

THE BROOKLYN, N. Y., WATER SUPPLY SYSTEM is in need of extensive additions and improvements, according to a report recently made by Mr. James Moffatt, Deputy Commissioner of Water Supply of the Borough of Brooklyn. The list of improvements which are needed, and their cost, according to Mr. Moffatt, are as follows:

Additional conduit		$1,200,000
Millburn engines and coal sheds		150,000
Additional water supply, part of estimate		300,000
Improvements at Gravesend and New Utrecht		75,000
Storage reserve, postponing Millburn		600,000
Protection from pollution, postponing filter beds		100,000
Extension of distribution		150,000
Improvements:		
Sinking test wells	$10,000	
Electric light plant at Millburn and Mount Prospect	8,000	
Monuments	1,000	
		19,000
Cleaning of Ridgewood reservoir		50,000
Total		$2,644,000
Cost of engineering and contingencies		256,000
Grand total		$2,900,000

Mr. Moffatt states that as a result of insufficient conduit capacity millions of gallons of water east of Millburn have been wasted, and the pumps have often been kept idle, while at other times they are under a great strain. The present storage reservoirs keep on hand only three days' supply, so he proposes to build at Forest Park an additional reservior with a capacity of 250,000,000 gallons. Such a reservior could be built in two years, he states, at a cost of $600,000. In order to protect the water of the borough from pollution, Mr. Moffatt proposes to spend $75,000 for filter beds at Baisley's, in case it is decided that that water can be used. The report points out that the net income from the water department of the borough for 1898 will be $445,820, which will justify an additional issue of $3,940,000 in bonds to pay for the proposed improvements.

◆

WORK ON THE NEW CLEVELAND, O., WATER-works tunnel has been abandoned in the heading from the shore shaft lakeward, where the recent accidents from gas explosions have taken place. Hereafter all work on this section of the tunnel will be conducted from the first lake shaft shoreward. By working the single heading this section of the tunnel will, it is stated, be completed as soon as the portion farther out in the lake, and all danger from further explosions will at the same time be avoided. A full description of this tunnel was published in our issue of Aug. 11, 1898.

◆

THE BIRMINGHAM WATER SUPPLY, of England, is to be increased upon plans drawn up by Mr. James Mansergh and Mr. Gray, the corporation engineer. To this end the city has already acquired 45,562 acres of water shed on the rivers Elan and Claerwen, in Wales, about 73 miles from the service reservoirs of Birmingham. Storage dams will be built in the two valleys, storing about 18,000 millions of gallons of water and supplying 27,000,000 gallons per day to Birmingham. The present supply is about 18,000,000 gallons per day, with an average demand of 17,000,000 gallons, and an emergency daily demand of 22,000,000 gallons. The plans contemplate a tunnnel 6,600 ft. long, leading from one water shed to the other. Of the 74 miles of aqueduct, about one-half will be in cut-and-cover work and in tunnel; the longest tunnels will be 4¼, 2½ and 1¼ miles long. The other half of the aqueduct length will be in siphon; that across the Severn Valley being 17 miles long, with a dip of 547 ft. below the hydraulic grade line. The estimated total cost of the project is $29,255,000. It is the present intention to do all this work by the corporation; by day's labor.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred Sept. 15, on the Denver & Rio Grande R. R., in Black Canyon, Colo., a few miles west of Sapinero, in which three railway employees lost their lives. According to reports an empty passenger train west bound ran into a pile of rock which had fallen from the sides of the canyon and was thrown into the Gunnison River.

◆

SPONTANEOUS COMBUSTION OF DUST in a grain elevator at Toledo, Ohio, on Sept. 20, caused an explosion and fire which cremated 8 men and fatally burned 8 more.

◆

THE "AURANIA" OF THE CUNARD LINE, which sailed from New York on Sept. 6 for Liverpool, broke her crank shaft on the morning of Sept. 13 while about 110 miles from Fastnet. She was sighted by the British steamer "Marino," from Montreal for London, and towed into Queenstown on Sept. 16.

◆

FIRE DESTROYED THE TOWN OF JEROME, ARIZ., on Sept. 11, depriving 1,500 persons of homes and killing between 10 and 20. The loss is estimated at about $1,000,000. New Westminster, B. C., suffered a like fate on Sept. 11, the entire town being burned to the ground. Several lives were lost and $2,500,000 worth of property was destroyed.

◆

A FIERCE HURRICANE swept over Barbadoes in the wnidward group of the Lesser Antiles on Sept. 11, and according to reports several hundred persons were killed and as many as 40,000 rendered homeless. The storm was accompanied by a tidal wave and heavy rains which added to the destruction. Kingston, the capital of St. Vinicent, is reported totally destroyed, and it is estimated that in this city alone 300 were killed and 20,000 made homeless.

◆

THE PROGRESS IN APPLYING AUTOMATIC COUPlers and train brakes is briefly stated in the first semi-annual report of the delinquent railways to the Interstate Commerce Commission. The report shows that of 294 petitioning carriers, 290 owned, on June 1, 1898, 1,153,290 freight cars, an increase of 20,567 over the number reported owned on Dec. 1, 1897. There are 119,614 freight cars reported equipped with automatic couplers and 67,202 reported equipped with train brakes in the six months ending June 1, 1898, which makes a total of 792,443, or 69% of the freight cars equipped with automatic couplers, and 510,636, or 44% equipped with train brakes up to June 1, 1898. Of 32,323 locomotives owned on June 1, 1898, there are 29,102, or 90%, which are equipped with driving-wheel brakes. There are 360,487 freight cars out of 1,153,290, or 31%, that are still unequipped with automatic couplers, and 642,654, or 56%, that are unequipped with train brakes, and 3,221, or 10% of the locomotives unequipped with driving-wheel brakes up to June 1, 1898. In explanation of this report, it may be stated that when the Interstate Commerce Commission granted the extension of the date when the Federal safety appliances law should go into effect until Jan. 1, 1900, one of the conditions was that every delinquent road should make a semi-annual statement of progress to the Commission.

◆

THE CONTRACT FOR THE CANTON-HANKOW Railway was signed in Washington by the Chinese Minister and representatives of the China Development Co., on Sept. 15. Ex-Senator Calvin S. Brice is the head of the American company, and this concession grants it the right to build and control a railway about 800 miles long, traversing the richest and most populous section of China. This road would connect with the Belgian road from Pekin to Hankow, now said to be under construction, and the coming connection of Pekin with the Siberian railway would make an all-rail communication between Canton and St. Petersburg.

◆

THE SHANSI, CHINA, IRON AND COAL CONCESsion to the Pekin syndicate of London was granted on May 21. The concession gives this syndicate the right to open and work the enormous coal and iron deposits in the Province of Shansi, described in Engineering News of March 31, 1898, and also the right to build and operate all railways necessary to connect these deposits with main trunk lines and navigable rivers. The bituminous coal measures cover 12,000 sq. miles; anthracite coal covers 13,500 sq. miles, in beds varying from 25 to 50 ft. in thickness; and excellent iron and petroleum abound in the same sections. This is the country examined and reported upon by Mr. C. D. Jameson, M. Am. Soc. C. E., and Mr. W. H. Shockley, M. E., also an American.

◆

THE PERUVIAN ANTHRACITE COAL DEPOSITS are reported upon by the Bureau of the American Republics. The deposits are on the summit of the Andes, in the Province of Hualgoyoc, and a twenty-year concession was granted to Mr. C. B. Jones, in 1892, covering a section of land 100 miles long and from 25 to 125 miles from the coast. Engineers from the United States are now surveying a route for a railway from Pacasmayo, on the coast, to the coal lands, and a line is already in operation from Pacasmayo to Yonan, a distance of 41 miles. The total distance from the coast to the mines by the proposed route is 121 miles. Mr. G. Clinton Gardner, late of the Pennsylvania R. R. and the Mexican National Ry., says that the supply of coal is almost inexhaustible, and 10,000,000 tons are within easy reach. He estimates that 2,000,000 tons can be mined annually and delivered at the sea cost for $2 per ton. The coal fields of the Andes include both anthracite and lignite, the anthracite lying on both the east and west slope of the mountain; that on the east lies 1,500 to 2,000 ft. below the summit, and is fully equal in quality to Pennsylvania anthracite. The railway will have to cross the Andes at an elevation of 14,000 ft. above sea level, though this summit is only 75 miles from the coast in a straight line. The Pacific Co., which has the exclusive right to mine the coal, is said to be backed by $20,000,000 capital; this company also has the exclusive right to build railways to the mines.

◆

THE PRODUCTION OF PETROLEUM in this country in 1897, according to the annual report of the U. S. Geological Survey, is almost exactly the same as in 1896, the figures being for 1897, 60,568,081 barrels, and for 1896, 60,960,361 borrels, which figure was the highest ever reached in the history of the industry. The total production since 1859, when the first oil well was drilled, at Titusville, Pa., amounts to 831,150,595 barrels.

◆

NEW RUSSIAN IRON AND STEEL COMPANIES are being constantly organized, according to foreign news items. The latest formed are as follows: The Riga Cast Steel Co., capital $375,000; the Gerlach & Pulst Machine Co., Warsaw, capital $500,000; the Falga Hardware Manufacturing Co., capital $200,000, and the Metalfabrik Co., of Kounl. formerly Schmidt Bros., capital $750,000. Most of these new works will need improved tools and machinery, and it is expected that much of this will come from America. There is also a large demand in Russia for railway supplies, including rail-benders, jacks, wrenches, track-drills, road-levels, etc.; but American manufacturers sending circulars to the several U. S. consuls for distribution should see to it that they are printed in Russian; any other course is a waste of time and effort. The trade in textile machinery is also a rapidly growing one in Russia. This machinery is now supplied by English and German firms; but energetic effort might secure a share of this trade for the United States. There are about 230 mills in Lodz, Poland, for the manufacture of cotton goods.

◆

THE INTERNATIONAL SOCIETY FOR THE TESTING of Materials has practically doubled in membership since the Stockholm Congress of 1897. According to the official list of members lately sent out, the membership in the several countries is as follows: Argentine Republic, 1; Australasia, 1; Belgium, 18; Chili, 1; Denmark, 39; Germany, 387; England, 83; France, 66; Holland, 48; Italy. 35; Japan, 1; Luxembourg, 5; Norway, 42; Austria-Hungary, 111; Hungary, 47; Portugal, 8; Roumania, 20; Russia, 315; Sweden, 68; Switzerland, 83; Servia, 5; Spain, 36; United States of America, 68. The total membership is 1,528. This society has for its purpose the unification of methods of testing materials used in construction, with the view of ascertaining their true technical properties and of improving methods of testing. The present President of the Society is L. V. Tetmajer, of Zurich, and American engineers desiring further information concernits objects should address Mr. Gus. C. Henning, Consulting Engineer, 220 Broadway, New York city. The annual dues are $1, or 5 francs.

◆

THE LARGEST DYNAMO IN THE WORLD is now being constructed by the Walker Co., of Cleveland, O., for the Boston Elevated Ry., Boston, Mass. This generator will have an output of 3,000 K-W. at 550 volts, or about 4,000 HP. Its speed will be between 75 and 80 revolutions per minute, its total weight 250,000 lbs., and the diameter of the circular cast-steel field frame 21 ft. 7 ins. The weight of this ring without field magnets will be 25 tons. There will be 24 inwardly projecting laminated cores and pole having a combined weight of 15 tons. The armature hub is 13 ft. in diameter and is in two parts, each of which weighs 10 tons. The shaft is 37 ins. in diameter. The armature laminations add 15 tons, and the armature will have in all 594 slots. The commutator will be 105 ins. in diameter, and will have 1,188 bars. To facilitate regulation and remove a portion of the strain from the shaft, the flywheel will be bolted directly to extensions on the armature hub. If this machine were to run at the speed of the Niagara generators, 300 revs. per min., it would have an output of 16,000 HP.

◆

A CONSOLIDATION OF THE WESTINGHOUSE ELECtric Mfg. Co., Pittsburg, Pa., and the Walker Co., Cleveland, O., has been officially announced. The capital stock of the Westinghouse Co. is given as $15,000,000, and that of the Walker Co. $2,500,000 with a like amount of bonds. This divides the street railway field between two companies, the General Electric Co. and the new combination.

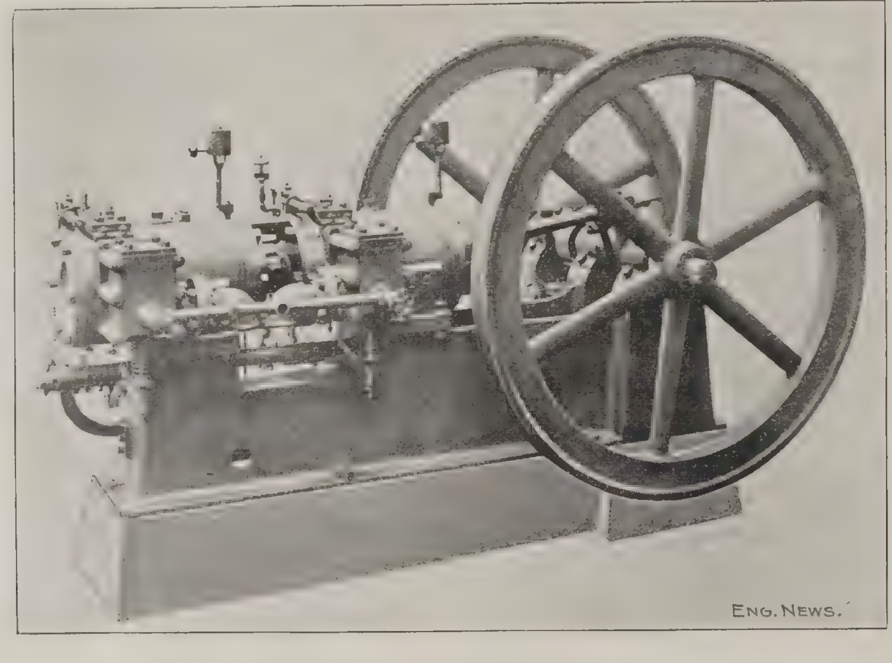
A NEW DOUBLE-CYLINDER GAS ENGINE.

One of the difficulties in the operation of gas engines is that of ensuring steadiness of running, the violent impulse given periodically to the piston by the ignition of an explosive compound within the cylinder tending to cause greater irregularity than in a steam engine where the impulse is given by a steady stream of steam, even under high pressures.

Steady running is a very important requirement, especially for electric light plants, and the double cylinder gas engine which we illustrate herewith has been designed specially to meet this requirement. This result is obtained by using two cylinders acting alternately on the four-cycle principle, thus securing a two-cycle effect, or an impulse at every revolution, instead of at every second revolution, while retaining the advantages due to the four-cycle system. The cylinders are placed tandem and have a single piston rod, and single connecting rod and crank. A sleeve supports the piston rod between the cylinders. The crank shaft is supported by three bearings, and has two outside-hung flywheels. The valves are of the vertical lift poppet type, operated from a rod driven from the crank shaft by means of a spiral gear. The fuel consumption is about the same as in a single-cylinder four-cycle engine, but there are twice as many impulses, each of which has only half the force of these in the single cylinder engine.

Gasoline or any kind of gas may be used, and for the former the charge is delivered by a feed pump. The charge is exploded by an electric-spark igniter, and the point of ignition can be changed while the engine is running. On the larger engines a compressed air starting device is used, in which the air drives the engine during its first revolutions.

These engines are built by the Frontier Iron Works, of Detroit, Mich., to whom we are indebted for information. They are made in several sizes, ranging from 10 HP. to 100 HP. on the brake, with speeds of 240 to 160 revolutions per minute, respectively. Most of the engines thus far built have been of 30 to 60 HP. Some of them are in use in driving electric light plants and others for driving pumps for water supply. All the engines are tested for steadiness at the works by driving a dynamo furnishing current to 300 to 600 incandescent lamps. The average variation is said to be only 2% to 3% under varying load, the effect on the lamps being practically as good as when the dynamo is driven by a steam engine. This is accomplished without the use of a heavy flywheel on the countershaft or any other regulating device outside of the engine.



DOUBLE-CYLINDER GAS ENGINE.
Frontier Iron Works, Builders.

DIAGRAMS OF JOHNSON'S STRAIGHT LINE FORMULA FOR DETERMINING THE STRENGTH OF COLUMNS.

By John S. Fielding.

(With full-page plate.)

The accompanying diagrams, representing the well-known straight line formula for determining the strength of columns, which were worked out by Mr. Thomas H. Johnson, M. Am. Soc. C. E., and published in the "Transactions" of that society for July, 1886, may be of interest and value to engineers. For some years the writer had had a number of tables of values of the straight line formula in use in his office. These tables had been prepared by an assistant, and some of them had never been checked, and, wishing to check them, an endeavor was made to discover some easy method for so doing. In the search for this method the writer found that since the length of the column is assumed in inches, the variation in such length for each foot is 12, and the value of the allowed unit stress varies by $b\,\frac{12}{r}$. The formula $9{,}000 - 40\,\frac{l}{r}$, $b = 40$ and $r = 1.0$, the variation is 480 lbs., and with $r = 1.1$, the variation is 436 lbs., and so on. From this it was concluded that the values could very well be plotted and made into a diagram. The five diagrams illustrated represent the formulas $9{,}000 - 30\,\frac{l}{r}$; $10{,}000 - 30\,\frac{l}{r}$; $9{,}000 - 40\,\frac{l}{r}$; $10{,}000 - 40\,\frac{l}{r}$, and also a diagram comparing the different formulas with values of y from 8,000 to 16,000 and with values for b of 30, 40, 50, 60 and 70.

Mr. Fielding's article and the diagrams accompanying it were sent to Mr. Thomas H. Johnson, the author of the straight line formula, with the request that he should give his opinion as to their value and usefulness. Mr. Johnson's letter in reply to this request is as follows:

Sir: I do not know that any diagrams representing the straight-line formula have ever been published, other than as illustrations to articles upon the subject in the "Transactions" Am. Soc. C. E., and in Engineering News. Certainly I have seen none developed on the plan of those submitted by Mr. Fielding. Mr. Fielding's scheme is all right, and I have no criticism to offer to it as a method of graphically representing the formula. I would venture to say, however, that the numerical values assigned to f and b, in the formula used Mr. Fielding, do not represent the true equation for strength of columns, as they have been arbitrarily chosen without regard to the mathematical relation to the elementary moduli of the material, and its resistance as a column. In the original paper on this subject ("Transactions" Am. Soc. C. E., Vol. XV., p. 517), it was shown that the straight line representing the strength of columns is a tangent to the curve of Euler's equation, which depends on the modulus of elasticity of the material. If the constants used are such that the line will not be tangent to Euler's curve for the given material, the line does not and cannot represent the law governing the problem. The law is represented by a straight line; but not by any straight line.

In Engineering News of Dec. 22, 1888, and again in the discussion of Mr. Waddell's paper on "Bridge Designing" ("Transactions," Am.Soc. C.E.,Vol. XXVI.,p. 115), I sought to check the tendency to the use of arbitrarily-chosen constants in the straight-line formula, by pointing out their dependence on the physical properties of the material. In the last-named paper I carried the subject further than I had done previously, and showed the relation that must be maintained by the values of f and b (Mr. Fielding's notation) in order that the equation may truly express the proper working stresses in the column.

Mr. Fielding presents five diagrams as follows, for the formulas:

$$P = 9{,}000 - 30\,\frac{l}{r};\quad P = 9{,}000 - 40\,\frac{l}{r};$$

$$P = 10{,}000 - 30\,\frac{l}{r};\quad P = 10{,}000 - 40\,\frac{l}{r},$$

and one for values of $f = 8{,}000$ to 16,000 inclusive, each in combination with values of b, of 30, 40, 50, 60, and 70. There is nothing to show what materials these respective formulas are intended to represent, nor whether for round, hinged or flat ends. I suppose, however, Mr. Fielding's object is simply to obtain the arithmetical solution of the equations as he finds them stated in various specifications. It is the persistent use of wrong constants in such specifications that I would like to correct if possible.

For any assumed value of f there can be only one value of b that will make the corresponding line a tangent to the curve of Euler's equation for the given material reduced to corresponding factor of safety, and for the same value of f the value of b will be different for each kind of material. The following table gives the correct values of b for wrought iron, mild steel (carbon 0.12), and medium steel (carbon 0.20) for the several values of f embraced in Mr. Fielding's diagrams, and for columns with hinged ends. The table assumes $E = 27{,}000{,}000$ for all three grades of material.

f	Wrought iron, b	Steel.	
		Mild, b	Medium, b
8,000	30	33½	36½
9,000	34	37½	41
10,000	37½	42	45½
11,000	41½	46	50
12,000	45	50	54½
13,000	48	54½	59
14,000	52½	58½	64
15,000	56½	63	68½
16,000	60	67	73

In Mr. Fielding's general diagram he gives too few values of b to make it available for all proper formulas. The only criticism which I have to offer is that these diagrams would tend to confirm instead of correcting the erroneous practice of writing the straight-line formula with arbitrary constants. You will note that my criticisms are directed chiefly to the latter. Yours truly,

Thos. H. Johnson, M. Am. Soc. C. E.,
Chief Engineer, P., C., C. & St. L. Ry.

Pittsburg, Pa., July 16, 1898.

EXPERIENCE WITH ACETYLENE GAS FOR CAR LIGHTING.

In our issue of March 31 last, we published some account of the experience with acetylene gas for car lighting on the Pontiac Pacific Junction Ry. Recently Mr. P. W. Resseman, general superintendent of this road, received a request for information concerning his use of this system of lighting from the Inspecting Engineer of the Government Railways of Egypt, Col. J. H. Western. From Mr. Resseman's reply we are permitted to publish the following extracts:

> We have been using the Holland system on the Pontiac Pacific Junction and the Ottawa & Gatineau Ry. for nine months. There is really no comparison between the effectiveness of acetylene gas and coal oil for car lighting. With coal oil at 14 cts. per gallon, and carbide at 5 cts. per lb., the cost of acetylene gas for car lighting is somewhat less than the same lighting by coal oil. I consider that it is the coming light for railways.
>
> We have in Canada a problem to face, however, that would not have to be met in any warm country. Owing to the severe frost in winter we have to place the gas generators inside the car to prevent them from freezing. The disadvantage of this lies in the fact that acetylene gas is most difficult to control, and the slightest leak in the generator causes a disagreeable smell in the car. This we hope to overcome and have been experimenting with better connections from generator to pipe.

I find that an ordinary passenger coach, such as we run here, previously lighted by 14 coal oil burners, can be brilliantly lighted with five 25-c. p. burners, consuming each ½-ft. per hour. The carbide supplies 5 cu. ft. of gas per lb., making the total cost of the lights 2 cts. per hour, or for a run of 4 hours, 20 to 21 cts. per car. Of course, there is incidental waste that we cannot get fully controlled. The gas is lost by the vibration of the car, but on the whole, the light is efficient and inexpensive. It is absolutely safe as far as fire or explosions are concerned. The gas is generated in small quantities, confined beneath a 7-in. column of water, and any that may escape is so speedily diffused in the surrounding atmosphere that its explosive nature is at once neutralized. In the event of a car turning over, the lights go out immediately, and the gas escapes so quickly that fire cannot affect it. So far we have had no accident from acetylene gas, and I cannot conceive how an accident can occur. In Egypt or South Africa, where the generators could be placed on the roof or underneath the car, no difficulty would be apprehended from the acetylene gas smell. We have three small generators in each car, placed directly over the top of the toilet-room inside the car. We have experienced very little trouble other than the escape of gas by improper connection. Low-pressure gas is not affected by heat or cold. The generators cost here $12. The carbide is sold here at $4.50 per 100 lbs. Side lights give us the best results. We are using the ordinary gas fixtures, and porcelain globes with 5-in. rings.

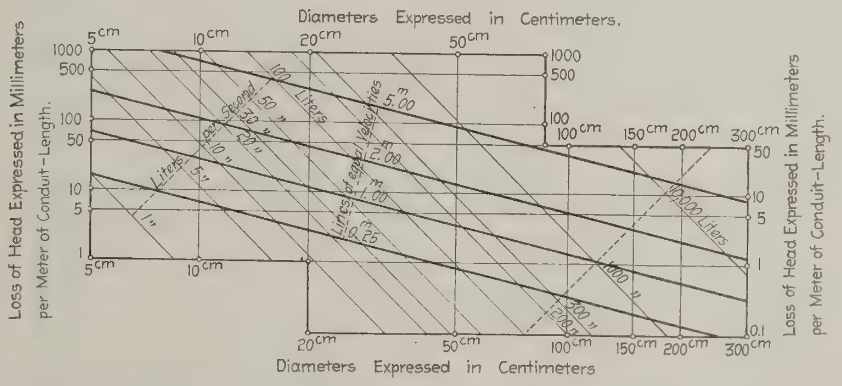
◆

LOGARITHMIC DIAGRAM FOR CALCULATING THE FLOW OF WATER IN CONDUITS UNDER PRESSURE.

In "Le Genie Civil," for June 18, M. Jean Rey describes a logarithmic diagram for the calculating the flow of water in pipes under pressure, devised by Civil Engineer A. Van Muyden. He calls it a universal diagram, and proposes it as a useful and simple tool exact enough in its results to satisfy all ordinary requirements in hydraulic estimates.

The original diagram of Van Muyden was based upon the experiments of Mr. Darcy, made in 1857, with an empirical formula applicable to pipes up to one meter diameter, and was thus published in 1884. In a new edition of his work, just issued, Mr. Van Muyden employs the formula of Maurice Levy, and extends its applicability to conduits up to 3 meters diameter. The results are practically in accord with the Darcy formula from 0 to 3 meters; beyond that they diverge and more nearly approach the theoretical law.

In the simplified diagram here presented the abscissas represent the diameters of the conduit, and the ordinates the losses of head expressed in millimeters per meter of conduit length. The transverse straight lines represent the delivery in liters per second, from 1 to 40,000 liters. The other transverse lines join the points of equal velocities.



LOGARITHMIC DIAGRAM FOR CALCULATING THE FLOW IN CONDUITS UNDER PRESSURE.
Devised by A. Van Muyden.

A simple reading enables us to solve a variety of hydraulic problems. For example, the velocity of flow and the volume being given, the diameter of the pipe and loss of head can here be read; and this is true of the inverse statement. It is useful in calculating branches from a conduit, in establishing a flow for feeding a hydraulic motor and in arranging for the delivery from pumps, etc. The exactness of the diagram has been verified by numerous hydraulic installations in Switzerland, France and other countries. M. Rey deems the diagram so self-explanatory that he does not enter into further details.

A NEW FORM OF METER RECORD AT ATLANTA, GA.

The accompanying illustration shows a new system of recording meter readings which was recently put in operation at Atlanta, Ga. The reader uses a diagram on which the position of the hands is recorded, there also being a printed form to fill in, as shown by the illustration. We are indebted to Mr. Park Woodward, Superintendent of Water-Works, for the copy of the record blank reproduced herewith.

THE RAILWAYS OF THE UNITED STATES IN 1897.

From the advance sheets of Poor's Manual for 1898 the following statistics are taken relating to railway construction and operation in the United States for the year ending Dec. 31, 1897. As will be noticed, these figures cover railway operations for a period six months later than the statistics of the Interstate Commerce Commission, published in our issue of Sept. 1, 1898. The accompanying statement explains itself:

	Miles.
Mileage or railway	179,692.57
Second track, sidings, etc.	57,218.95
Total track	236,911.52
Steel rails in track	211,928.31
Iron rails in track	24,983.21

Number of locomotive engines		35,810
Cars	Passenger	25,275
	Baggage, mail, etc.	8,133
	Freight	1,229,335
Total revenue cars		1,262,743

Liabilities.

Capital stock	$5,453,782,046
Bonded debt	5,411,058,525
Unfunded debt	374,389,673
Current accounts	392,481,496
Total liabilities	$11,631,711,740
Excess of assets over liabilities	299,901,913
Total	$11,931,613,653

Assets.

Cost of railroad and equipment	$10,029,151,607
Real estate, stocks, bonds and other investmts	1,509,841,062
Other assets	222,089,700
Current accounts	170,531,284
Total assets	$11,931,613,653

Miles of railroad operated	181,132.70
Rev. train mileage:	
Passenger	342,464,408
Freight	500,326,372
Mixed	15,235,049
Total	858,026,179
Passengers carried	504,106,525
Passenger mileage	12,494,958,000
Tons of freight moved	778,385,448
Freight mileage	97,842,569,150

Traffic earnings: Passengers	$253,557,936
Freight	780,351,939
Miscellaneous	89,636,791
Total	$1,123,546,666
Net earnings	338,170,195
Receipts from other sources	95,013,907
Total available revenue	$433,184,102
Payments: Rentals, tolls, etc.	$58,600,768
Interest on bonds	231,046,819
Other interest	5,633,298
Dividends on stock	82,630,989
Miscellaneous	28,124,474
Total payments	$406,036,348
Balance, surplus	27,147,754

Summarizing some of the most important of the items in the above table and comparing them with the corresponding figures for 1896, we have the following results:

		Years		Rate of increase or decrease
		1897.	1896.	
Miles road operated.		181,132.70	180,891.19	+0.13
Tons, freight moved		788,385,448	773,868,716	+1.88
Freight mileage		97,842,569,150	93,885,853,634	—4.21
Passengers carried		504,106,525	535,120,756	—5.80
Passenger mileage		12,494,958,000	13,054,840,243	—4.29
Earnings	Freight	$780,351,939	$770,424,013	+1.29
	Passenger.	253,557,936	265,313,258	—4.43
	Other	89,636,791	89,894,754	—0.29
	T'l, gross	$1,123,546,666	$1,125,632,025	—0.19
	Net	338,170,195	332,333,756	+1.76
	Ton-mile,ct	0.798	0.821	+2.08

The share capital corresponding to the mileage completed at the end of 1897 equalled $5,621,340,647, against $5,373,187,819 in 1896, the increase equalling $248,152,828, the rate of increase being 4.6%. The funded debts of all the lines at the close of the year aggregated $5,516,056,292, against $5,461,856,598 in 1896, the increase equalling $54,199,694, being an increase of 0.99%. The other forms of indebtedness of the several companies at the close of the year equalled $380,769,705 against $344,499,969 for 1896, an increase of $36,269,736. The total share capital and indebtedness, exclusive of current accounts of all the roads making returns, equalled at the close of the year $11,518,166,646, an increase in the year of $338,622,260 over the total of 1896 ($11,179,544,386), the rate of increase for the year being 3.3%. The cost per mile of all roads making returns, as measured by the amount of their stock and bonded indebtedness, equalled $60,679 against $59,732 for 1896.

The total mileage of new railway constructed during the year was 2,188.43 miles, divided among the different groups of states as follows:

States.	Constructed in 1897.	Total mileage on Dec. 31, 1897.
New England	46.79	7,265.52
Middle	236.90	22,123.64
Central Northern	381.81	40,112.14
South Atlantic	310.46	20,496.75
Gulf and Mississippi Valley	407.98	14,918.93
Southwestern	415.62	35,533.88
Northwestern	107.39	29,719.59
Pacific	281.48	14,432.74
United States	2,188.43	184,603.19

A DIAGRAM FOR FINDING THE TRANSVERSE STRENGTH OF STEEL RAILS.

(With full-page plate.)

We are indebted to the courtesy of Mr. W. M. Wickham, of Wilkinsburg, Pa., for the privilege of reproducing the accompanying diagram for the ready computation of the transverse strength of steel rails, of the American Society of Civil Engineers' standard section, and of weights up to 100 lbs. per yd.

It will be seen that the diagram includes both beams fixed at one end and beams supported at both ends, and that bending moments up to 17,000 ft. lbs., and fiber stresses up to 15,000 lbs. per sq. in. are included, while lengths up to 30 ft. are given. Steel rails are now used so extensively in structural work, for foundations, etc., and in bridge and culvert construction on railways, that we believe this diagram will be found a great convenience by very many of our readers. While the diagram is plotted for the Am. Soc. C. E. section of rail, it can be used for almost any section with little error by measuring the height of the section and taking the corresponding height on the diagrams. The following explanation by Mr. Wickham gives a clear understanding of the manner of using the diagrams:

Diagram for Strength of Standard Rails Used as Beams.—Case "A." Given the length of beam, load, method of loading, and fiber stress to find rail section:

(1) Compute bending moment due to load in pounds feet, and from corresponding figure on lower side of diagram, trace vertically to corresponding Case line (a, if beam is fixed at one end, or b, if supported at both ends), thence to right to intersection with line marked the given length; thence vertically (up or down as the case may be) to the given fiber stress, thence to the right, passing through the required rail section.

Corrections to bending moments due to weight of rails are based on the supposition that the rail resists bending with a fiber stress of 10,000 lbs. per sq. in., so that great accuracy can only be expected when using that stress. Where great accuracy is required for other stresses than 10,000 lbs., first find a trial section, by proceeding as above, then with a bending moment equal to the sum of those due to the load and to the weight of that rail, as found above, trace through the diagram, neglecting, of course, the correction due to weight of rail. If the resulting section is the same as the one used in finding the bending moment due to weight of rail, it is the required section. If it is not, repeat the operation, using a new section until that rail is found, the bending moment due to the weight of which, added to that due to load, is the same as the one found by tracing through the diagram. Bearing in mind that for stresses less than 10,000 lbs. the diagram gives a section too small and for stresses above 10,000 lbs. gives sections too large, only one or two trials need be made to find the correct section.

Case "B." Given the rail section, load and method of loading, to find fiber stress: Compute the bending moment due to load and add to that, that due to weight of rail; from corresponding figure on diagram trace vertically to intersection of horizontal line between given rail section and the one next heavier, and note the position of the intersection with respect to fiber stress lines.

ANNUAL CONVENTION OF THE STREET RAILWAY ASSOCIATION OF THE STATE OF NEW YORK.

The sixteenth annual meeting of this Association was held at the Manhattan Beach Hotel, Tuesday and Wednesday of last week. The morning session of the first day began with a fairly good attendance, and after the roll call, the President, Mr. G. T. Rogers, of the Binghamton R. R. Co., read his annual address, in which he said:

> Rapid transit in large cities has exerted a marked influence for the health, comfort and welfare of the resident poor and working classes, and has resulted in an equalization of real estate values, thereby avoiding a congestion of the population that has existed in the past, and creating better living conditions for all.
>
> The return upon the capital invested in street railway enterprises is generally overestimated by the public; many lines are constructed or extended and operated at an actual loss for years, but I believe that the public begins to see and appreciate the great advantage on their side, and that a more liberal policy will prevail.
>
> The resolution, recently offered in the City Council of New York, "No seat; no fare," is simply another manifestation of the old delusion that all that is necessary to get rid of an evil or an annoyance is to pass a law against it. The question is not one of making the companies do something they are not willing to do, but one of making them perform an impossibility.

Considering the question of municipal ownership, President Rogers insisted that neither state nor municipal governments should enter into industries that can be as well or better conducted by private capital.

The report of the Executive Committee stated that nearly all street railways in the state were members of the Association. The appointment of Hon. Edwd. O'Connor, as counsel, and his untimely death were mentioned. Attention was called to the fact that out of the 190 measures and amendments affecting street railways, which had been introduced in the state legislature during the year, only a very small proportion had become laws.

The first paper of the morning session, by Mr. H. M. Kennedy, General Passenger Agent Brooklyn Heights R. R. Co., Brooklyn, N. Y., was on

"Methods of Developing New Traffic on Street Railroads."

This was a consideration of the advisability of establishing the office of general passenger agent on street railways. Some of the duties of the general passenger agent were to establish happy relations with the press, to advertise the existing attractions of the road, and to establish or encourage the establishment of pleasure resorts, etc. As an instance of the successful outcome of advertising, an ice-skating rink, where the owners were losing money, was mentioned. The company was induced to invest in some posters, which were displayed on the street cars, with the result that the rink became a paying investment, and street railway traffic on the lines leading to it was largely increased.

Mr. H. H. Vreeland, President of Metropolitan R. R., of New York, said that his road was not engaged in stimulating traffic, but was doing its best to take care of the traffic it now had. In New York, on the long lines, the daily travel was almost uniform, and in winter the night traffic was the largest. On other lines throughout the country in which he was interested systematic methods of increasing traffic such as had been outlined had been adopted, and by special arrangement and advertising a considerable traffic had been built up. In only one case, however, had he recommended a railway company to build a pleasure resort. Generally speaking he was of the opinion that a manager operating his line in the proper way, which included his being out of the office a good part of the time, had little time for other things.

Other speakers described what had been done in the smaller cities of the state to stimulate travel, and it was the general sentiment that by catering to the respectable element and offering attractions suitable for women and children, operated either by the railways or under their direction, a substantial increase in traffic would follow, which would amply repay the time and money expended. The matter of bicycle riding was introduced, and, after a brief discussion, it was agreed that the use of the wheel was at least not increasing. It was further stated that by a system of charging for entrance to parks, etc., the railway company need not suffer from the use of bicycles, horses or carriages.

The next paper, by Mr. H. S. Cooper, of Schenectady, N. Y., entitled "Signal Systems for Single Track Roads," was a consideration of the requisites for a satisfactory signal system. In conclusion, ten rules were formulated, which must be fulfilled by a signal system before it could be considered satisfactory. The discussion on this paper was brief, but clearly indicated that there was no street or suburban railway signaling system on the market which could be called rapid, safe and satisfactory. The opinion seemed to be about as stated by Mr. W. Caryl Ely, of Brooklyn, "the only safe way to run a single track road at high speeds is to double track it, and that as soon as possible."

The third paper, "By-Products at Power Stations," by Mr. M. M. Penner, Fredonia, N. Y., was a description of the experience his company had had with the sale of exhaust steam. The trials and tribulations encountered with some early apparatus and the successful operation of a later type was amusingly told. In the course of his paper it was stated that the exhaust from a 100-HP. engine would heat 1,000,000 cu. ft. of building.

At the afternoon meeting, called for 3 p. m., the reading and discussion of papers was continued, the first one being by Mr. W. J. Clark, Manager of the Railway Dept. of the General Electric Co., on "Electric Railways as an Auxiliary to Coast Defense."

The next paper presented, and the one of greatest interest to engineers, was by Mr. A. J. Moxham, Assoc. Am. Soc. C. E., President of the Johnson Company, Lorain, O. We present it practically in full as follows:

"The Composition of Steel Rails to Insure Maximum Resistance to Wear."

Many years ago the London & North Western Ry. Co. reached the conclusion that what was known as a "soft" or low carbon rail gave the longest life. This was reinforced shortly afterwards by Dr. Chas. B. Dudley, of the Pennsylvania R. R., who gave the result of tests that on the face of them were to be relied upon. His paper was an able contribution to the knowledge of the day. His general conclusions led to the "soft" rail, and he went further and endeavored to determine by comparison a factor for each special chemical ingredient. His conclusions created something akin to a sensation, and they were bitterly opposed by the steel experts of the time. Perhaps the fact that the steel manufacturer of that day was not sufficiently master of the situation to economically produce the ideal rail, according to Dr. Dudley's standard, may account for a good deal of the opposition.

During the same period, however, notwithstanding these deductions, the tendency in actual specification was always toward higher carbon. The writer during this interval was a supporter of the "soft" or ductile steel for rails; and even to this day, and in view of what is to follow, it is to the writer's mind a questionable thing whether a steel of great ductility and only of moderate hardness is not the steel for steam railroad purposes. It must be remembered, however, that the problem of wear upon a steam railroad is a very different thing from that of wear upon a street railroad. The rail in steam railroad use presents a clean head, because the rail is not buried. It has to oppose principally a rolling friction, for the number of times per mile that steam railroad trains are stopped is very few, taking a general average. The street rail, on the other hand, has not only to meet this rolling friction, but has to contend with the grit from the surrounding road-bed, and with stops every few feet. Not only are the stops incomparably more frequent, but they are again multiplied into a greater number of units, as many individual cars are the rule on street railroads as against the occasional train of the steam road.

Being unable to reach positive conclusions from the published authorities and from personal contact with the steel experts of the country, or even from our own experience, it was determined to conduct experiments to this end. It was accepted to begin with, that it would be folly to try to finesse in the matter; that the best that could be done would be to try to find general, safe indications. When it is remembered that each chemical ingredient puts its own particular stamp upon the steel, and a different stamp in each particular combination with the other ingredients, and that the number of such combinations may be infinite; when it is remembered that each different heat at which the steel is rolled affects the problem; that the amount of draft put upon each successive pass should not be ignored, the necessity of this conclusion becomes evident.

The experiments have lasted for three years. The first endeavor was to take broadly a "soft" steel and a "hard" steel for the rails to be tested, securing the difference by carbon alone, leaving all other ingredients as nearly as possible the same. The experiment with these was started in Octoer, 1895, and has been continued ever since. In June, 1896, rails were added to the experiment, supplied by the West End Street Railway Co. of Boston, who at that time had determined (with wisdom as will be seen subsequently) upon a steel both hard and ductile. The conclusions, therefore, are based upon what may be described as soft steel, hard steel and steel both hard and ductile.

The rails (some 33 in all) were laid in the South 8th St. tracks of the Nassau Electric of Brooklyn. They were laid continuously, so that the same car is obliged to pass over every rail, and therefore each rail is subject to the same wear, and the wear on the head only is considered. Street traffic is ignored. This point was selected in order to reach early conclusions, as the cars pass this point at extremely short intervals, thus giving a considerable wear in a short time.

Every rail has been measured at two points, taken about 10 ft. from each end, in order to eliminate the special wear at the joints. Each rail has two cast iron boxes bolted to the outside, at the points to be measured, to permit access for purposes of measurement without disturbing the road-bed. Originally the wear was registered both by actual measurement and by taking an impression of the head of the rail by means of type-metal castings. Two slots were provided in the tram of the rail to guide the type-metal mold. Notwithstanding the great care that was exercised in taking the impressions, this method of measurement was quickly given up as the results were far from being as accurate as those taken by micrometer calipers. With these calipers, measurements of each rail were taken at three points across the head of the rail: point No. 1 being near the gage line; point No. 2 being nearly in the center of the head, and point No. 3 being nearer the outside of the head.

Speaking accurately, point No. 1 is 2 ins.; point No. 2 is 1⅝ ins., and point No. 3 is ⅞-in., all from the outside of a head 2¼ ins. wide. Methods were adopted for accurately locating the same lines, so that the comparisons in the different measurements of wear could be relied upon.

There were 17 rails of low carbon averaging 0.28; fourteen rails containing high carbon (0.59), and two were West End rails. The least wear shown was in the West End rail, the hard rail follows a good second, while the greatest wear is shown in the soft rail.

Table I.—Composition and Specific Gravity of Rails Tested.

	Soft.	Hard.	West End.
Carbon	.280	.59	.570
Silicon	.026	.056	.234
Phosphorus	.106	.097	.050
Sulphur	.066	.059	.078
Manganese	.790	.83	.980
	1 268	1.632	1.912
Iron	98.732	98.368	98.088
	100.	100.	100.
Specific gravity	7.855	7.841	7,825
Based on iron only, ignoring the metalloids	7.956	7.971	7.977

The average monthly wear amounted to .0007 in. for the West End rail, .0012 in. for the hard rail, and .0017 in. for the soft rail. The results of the experiments are conclusive on this point.

It will be noted in Table I. that the West End rails show a specific gravity of 7.825, the hard rails 7.841, and the soft rails of 7.855. But in considering specific gravity it had best be based alone upon the iron in the composition. It is well known that the other chemical ingredients affect the net result almost imperceptibly in the matter of weight, but very greatly affect density of the iron (which is the bulk of the composition) in the matter of its physical property. It will be found that where specific gravity is referred arbitrarily to the iron and the metalloids are ignored, or rather deducted, the specific gravity will tally closely with what is to be expected from the actual use of the metal. For instance in this case, ignoring the metalloids, the specific gravity of the iron in the different rails will stand as follows:

Soft rail	7.956
Hard rail	7.971
West End rail	7.977

It is interesting to note the very close relations of this arbitrary specific gravity to the relative wear as shown in the test. This is not a point to be ignored, because it is an exponent of the mechanical treatment, and it explains consistently in this, as in many other cases, why the material with apparently (but not really) the least specific gravity will show the best results in use. The analysis shows that what is needed, as may be expected, is the densest steel.

In the tension tests the results were as follows:

	Ultimate tensile strength, lbs. per sq. in.	Elastic limit, tension.	Elastic limit of compr'sion.
Soft rail	75,860	45,730	35,000
Hard rail	118,100	62,500	50,300
West End rail	120,380	53,160	47,100

The first column follows closely the determined wear.

Column two, it will be noted, does not follow the rule of wear, and in this is a lesson, the indication being that having secured a given amount of hardness, and consequently of strength, the more ductile the rail, the better the wear. In the compression tests the same lesson is learned. The elastic limit of compression standing as given in column three.

At a glance it would appear that the rail which compressed the least would wear the longest, but where difference in compression is indicative of greater elasticity without a sacrifice of ultimate strength, the more elastic rail is better.

As stated before, the only variation in chemical composition which we need look at in this comparison is the carbon, for while there is a slight variation between the two silicons in the given rails the total percentage of silicon in either is not a factor, and can therefore be ignored. The greater durability of the hard rail as compared with the soft rail speaks for the higher carbon, and it may here be noted, that so far as the higher carbon is concerned, it involves no higher cost to the street railway men.

On comparison the carbon of the West End rail is practically the same as that of the hard rail and the silicon considerably higher; but the real point of difference between the hard rail and the West End rail lies in the lower phosphorus and higher manganese. It is well known that the low phosphorus, accompanied by an increasing manganese, conduces to greater ductility. On this point, however, a word of caution is necessary. Any decrease of phosphorus from what is known as standard in Bessemer steel (0.10) can only be achieved at a greatly increased cost of manufacture, and therefore, so far as the chemical constituents of the rail are concerned, the whole problem to the street railway man is how far it is economical to go in lower phosphorus, the other hardening elements remaining the same. A steel such as is represented by the West End rail, or even a steel still lower in phosphorus it is possible to make, the question being purely one of cost. On to-day's basis an extra cost of $1.50 per ton on the low phosphorus steel is a low estimate; it would be safer to take it at $2.00. Taking the average price of girder rails at, we will say, $25.00, the extra cost of the low phosphorus would be 8%. What would be the increased wear of the rails?

The average monthly wear of the hard rail is	.0012
The average monthly wear of the West End rail is	.0007

On the face of it, it would appear, therefore, that those who could afford it were amply justified in demanding and purchasing the low phosphorus steel, but there is a hope for those who cannot afford it; and there is some doubt, after all, as to the advantages to be gained from the use of low phosphorus steel.

It is well known that a steel rail can be used until at least ½-in. is worn away from the head, or 0.5 in. On this basis, and taking the average wear of the different rails as shown in the test, it would take

25 years to wear away ½-in. with the soft rail;
35 years to wear away ½-in. with the hard rail;
60 years to wear away ½-in. with the West End rail;

and this is the case of a road which represents not average, but excessive wear; the rails in question having borne the wear of heavily loaded cars running on an average of 580 per hour for 20 hours per day, during the time of the experiments, or a two-minute headway. This means during the busy part of the day less than ½-minute headway, and during the night hours a wider interval. Taking the ordinary line, its average headway is greater than this, consequently the theoretical wear would be less. Now, all who are interested in electric roads, and have used girder rails are aware of the fact that nothing like this wear can be obtained in practice. This being the case we must look to something else besides quality of steel. The entire defect is in the rail joints used.

Had these measurements of wear been taken at the joints instead of elsewhere, the lesson would have been different. Rails are taken out of the track to-day, not because the rail as a whole has reached the point of destruction, but because the joints have become too bad for further use. It must be remembered that the experiments in question have not been extended long enough to show the effects upon the rail of the degeneration of the joints. On the wear at the joints reaching a certain point, the wear of the rail increases rapidly. For instance, in the soft rail the average monthly wear being .0017 during the time of this experiment, in 7 or 8 years from this date the wear will have continued to go on at a constantly increasing ratio, starting from the point of defect at the joint.

In the early days of girder rails the joint construction was so light that the joints quickly went to pieces. During later years, using a heavier rail and larger and better fitting splice bars, we have heard less of the joint question, for compared with the earlier roads the present track is smooth. Nevertheless, the evil still exists, and a few years from now those who to-day are deluding themselves in the belief that they have a long life for their existing tracks will awake to find out that even the construction of to-day is wasteful and extravagant. The joint which is accepted now as being passably fair is reducing the life of the rail to one-half, or perhaps even one-third of what it should be.

The conclusions to be drawn seem to me to be as follows:

First. That for street railway use, a hard rail will give the best results.

Second. That the most economical way to secure this hardness is by increase of carbon, accepting the manufacturers standard specifications for the other ingredients.

Third. That the next step should be towards an improvement of the joints.

As is well known to all present, the writer has pinned his faith to the electric welded joint as settling the question once for all, by making the union homogeneous with the rail and possessing an advantage from an electrical standpoint in the matter of conductivity. Nevertheless the cast-welded method also demands careful consideration. It is certainly preferable to anything in the nature of splice bars that we know of, provided one glaring fault can be overcome, viz.; the softening of the steel that occurs from the large body of hot cast metal located at that point, and it would appear that some means could be devised to overcome this evil.

Fourth. After making the joints perfect, what we have termed the "West End rail" would certainly justify its extra cost.

It is unnecessary to give the analysis applicable to each of these classes. I would caution, however, against the use of carbon as high as 0.59, as that was purposely taken high in what we term the "hard" rail in this experiment, the object being to reach an extreme. Carbon should be limited to from 0.50 to 0.55, with the usual leeway to cover manufacturing contingencies. It also remains a question whether the reduction of phosphorus to 0.08 (which may be done within economical limits of cost) will not give results so closely approximating the 0.05 of the West End rail as to make that figure an economical one. In any case the certainty exists that so far as the steel is concerned, a rail of the following analysis should give a theoretical wear, if the joint is perfected, of from forty or fifty years, viz.: Carbon, 0.55; silicon, 0.10 or under; phosphorus, 0.08 or under; sulphur, 0.06 or under; manganese, 0.83 or over, not to exceed 1.00.

The great lesson I would once more emphasize is that until you get the joints perfect you need not worry about the quality of your steel.

Anything in the shape of steel—the very cheapest you can buy will last longer than the joints will permit you to keep your rails in the track.

(Concluded on page 187.)

COST OF ELECTRIC POWER FOR STREET RAILWAYS AT THE SWITCHBOARD.*

By R. W. Conant.†

It is my privilege to be able to communicate to you facts and figures bearing on the operation of 44 power stations located at the important street railway centers throughout the country. These figures cover for the most part the operation of the stations during the past year, and include the experience on the roads in Boston. The aggregate capacity of power stations represented is 98,387 K-W., or 134,800 electrical horse-power. The total actual cost of operations for the production of power alone from these stations during the past year has been $1,825,000, and if the power had been produced by all at as low a cost as it was in a number of the more economical stations the savings for the year would have amounted to $443,300.

There is a great variety of opinion as to what should be included in the cost of power, and also as to whether the basis of comparison should be the car-mile or kilo-watt hour, this latter being due to the fact that up to within a few years there has been no reliable instrument for the measuring of station output. The car-mile basis is not a fixed standard. A car-mile up hill takes a great deal of power, while a car-mile down hill should take none and may be a source of power.

In the analysis of costs of operation of power stations of various sizes and types, it is first necessary to adopt a standard for the unit of power. We have seen that the car-mile is unreliable. Recording watt-meters are at present constructed which will measure the output in kilo-watt hours within a very few per cent. This statement is abundantly verified by actual experience and is gradually becoming universally recognized. It is no doubt difficult for one who has been accustomed to figure cost of power production on a car-mile basis to reconcile himself to the kilo-watt hour. It should, however, be very easy for the steam engineer who is accustomed to deal with horse-power, since the kilo-watt hour equals 1.34 electrical HP. hours.

It was evidently the idea of your executive committee in limiting the title of this paper to cost at the switch-board to abolish the car-mile and adopt the K-W. hour as the unit of power. In comparing the costs from the various stations I shall use this unit, and for the benefit of those who are accustomed to considering the costs per car-mile it will be interesting to know that on many roads a car-mile takes just about 1 K-W. hour. This is not true where grades and equipments are extremely heavy, for in such cases two or three times this amount may be required.

In the costs of power, whether it is produced by steam or water, should be included the fixed charges, as well as the cost of operation. Under fixed charges are interest, depreciation, insurance and taxes on the capital invested in the land, buildings and machinery of the power station. Under operating expenses are fuel, labor, supplies, repairs, superintendence and general expenses.

In both the fixed charges and operating expenses the component items vary between widely different limits, and it becomes impossible to construct a law that will predict the cost under all circumstances.

On the other hand, for one who has had experience it is comparatively easy to predict what the power ought to cost under a given set of conditions. What it will cost must, of course, depend on management.

In view of the variety of the circumstances governing these costs, I have deemed it advisable to establish for purposes of comparison a standard plant whose conditions are fixed. There is no intention to imply that the performance or equipment of this "standard" station is ideal, or could not be bettered, but rather to assume equipment and performance based on facts obtained from stations in actual commercial operation for some time.

This station may seem to border on the ideal, and there is no question but that its performance is consequent on favorable circumstancmes, very nearly we may say test conditions.

The station is assumed to be located on the water front, the exact spot is unimportant. The building and chimney are brick, erected on firm ground, requiring but little piling or filling. The capacity is assumed at 3,600 K-W.

For equipment three cross-compound condensing engines, cylinders 28-in. and 56-in. by 5-ft. stroke, are selected; speed 80 revolutions per minute; 150 lbs. steam pressure. There will also be 3-1,200 K-W. direct connected generators, 6 water tube safety boilers 500 HP. each; economizers and exhaust fed water heaters, electrically driven feed pumps and coal handling apparatus. Such a station would cost to install as follows:

Building, foundations for engines and boilers, chimney, coal handling apparatus, etc.	$120,000
Engines and condensers, heaters, separators and piping	91,800
Feed pumps and economizers	18,000
Boilers and flue connections complete	61,000
Generators and Switch-board complete	73,800
Land and docking facilities	17,000
Engineering and sundries	5,000
Total	$386,600

This gives about $107 per K-W. capacity.

To obtain the figure for fixed charges, I assume interest at 6%, insurance and taxes 3%, depreciation 2%, total 11%, which makes an annual fixed charge of $42,526.

I shall assume that this station produces 10,500,000 K-W. hours per annum, dividing the annual charge by this figure gives 0.4 cents per K-W. hour for the fixed charges. The depreciation is not intended to cover repairs which will be included under operating expenses. The 2% assumed for depreciation is to establish a sinking fund against the time when the station will have to be entirely replaced by one of more modern and economical design. The time of replacement is taken at 50 years,* although a few years ago this time should have been assumed much shorter, owing to the imperfect design of power station apparatus then existing. But with the present advanced state of the art, improvements cannot be expected to develop as rapidly.

In making comparisons between stations of different sizes and types, the cost of labor is the most perplexing item.

Some stations operate with two shifts, others with three. Some have engineers paid at different rates, and men which appear on the records of some are in a capacity which in others is absent or replaced by men of another class and rate of pay. I therefore give the following method of analysis of the labor item which gives satisfactory results when applied to station operation. The method can be illustrated and at the same time the operating expenses can be derived by applying it to our standard station. It is assumed that this station operates with three shifts of men, the duration of each shift being 8 hours. This makes the shift hours per day 24 or 8,760 for the year. The same number of shift hours would of course be obtained by two

---

* Condensed from a paper read at the annual meeting of the American Street Railway Association held at Boston.

† Electrical Engineer, Boston Elevated R. R. Co., Boston, Mass.

* A sinking fund contribution of 2% per annum if placed at interest at 4% would equal the entire investment in only 28 years. See Wellington's "Railway Location," p. 82.—Ed. Eng. News.

TABLE I.—COST OF OPERATION OF VARIOUS STREET RAILWAY POWER STATIONS.

*D. C.—Direct-connected. †.5 anthracite and .5 bituminous. ‡.6 bituminous and .4 anthracite. §Includes repairs, all supplies other than coal, superintendence and office expenses.

shifts of 12 hours each, as is the cast with some stations. For the three shift station, the first two probably would have the full complement of men, while the third would not, as the station might be shut down on that shift. But as there is considerable inspection, cleaning and overhauling, this shift requires almost as many men, though their rate of pay may be less. The highest rates of pay would be on the shift of heaviest load. The crew to operate the standard plant would be about as follows: Two engineers, 1 oiler, 1 helper, 2 firemen, 1 coal passer, a total of 7 men per shift.

The average rate of pay per man is taken at 27 cents per hour. This would be calculated from an actual station by dividing the total amount paid for wages, including the chief engineer's salary, by the product of the number of men operating with the hours each has worked. The number of men per shift for this station (7), divided by 3.6, which is the figure expressing the capacity in 1,000 K-W. units, gives 1.94 as the number of men per shift per 1,000 K-W. capacity. This figure will vary with the type and size of station, as we shall see later. Multiplying 1.94 by the rate of pay (27 cents) gives 52 cents as the cost of labor per hour per 1,000 K-W. capacity. This multiplied by 3.6, the number of 1,000 K-W. capacity, gives $1.87 as the total cost of labor required to operate the station per hour.

It will further aid in the analysis of the labor item to introduce the load factor. As this term is sometimes employed in a different sense from that used in this paper, I shall define it to be that per cent. which, when multiplied by the capacity of the station in kilo-watts and by the shift hours for the period gives the K-W. hours output for the time considered. In this case the average load factor for the year is taken as 33⅓%. The kilo-watt hours output of the station was given at 10,500,000, which is 33⅓% of 3,600 K-W. multiplied by 8,760, the shift hours per annum.

It has been shown above that $1.87 is the average cost of labor to operate the station for one hour, and if we obtain the average K-W. during the hour, which is K-W. hours for that period, a simple division will give the figure for the cost of labor per K-W. hours. The load factor gives the means of obtaining the K-W. hours, and by multiplying 3.6 by 1,000 and 33⅓% gives 1,200 as the average K-W. for the hour, or K-W. hours for that period. Dividing $1.87 cost of labor to operate the station per hour by 1,200 gives 0.157 cents as the cost of labor per K-W. hour. As 3.6, the figure representing the station capacity, was used as a multiplier in obtaining both the cost of labor $1.87 and 1,200 K-W. hours, it, therefore, disappears in the division and the expression for the cost of labor per K-W. hour is made independent of the capacity of the station to that extent. The rule then for obtaining the cost of labor per K-W. hour for any station is: Multiply the rate of pay of the men by the number of men per 1,000 K-W. capacity, and divide by the product of the load factor and 1,000.

The diagram, Fig. 1, gives the results of this expression for cost of labor for all usual rates of pay, load factors and men per 1,000 K-W. This diagram is based on a rate of 27 cents per hour, and there is also given a reduction table which gives the per cent. to be added or subtracted for other rates than this. To illustrate its use, suppose we have a station whose equipment requires five men per shift per 1,000 K-W. capacity. During a month of high output it might operate at a 30% load factor. On the diagram, following 5 up to 30 gives cost of labor at 45 cts. per K-W. hour. In a lighter month the station might operate at a 15% load factor. Following 5 up to 15 gives 0.90 cts., or twice as much for labor per K-W. hour.

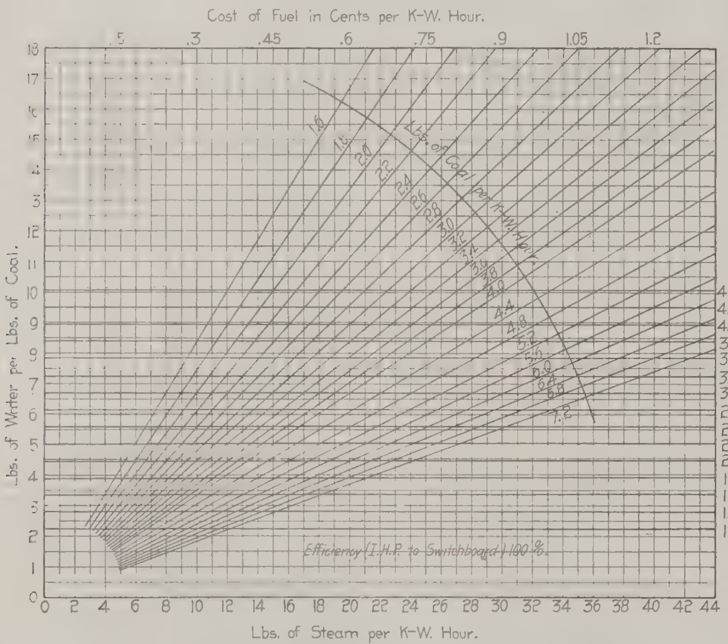

FIG. 2.—DIAGRAM FOR FINDING COST OF FUEL PER K-W. HOUR OF TOTAL OUTPUT OF A STREET RAILWAY POWER STATION, THE PRICE OF COAL, THE BOILER, ENGINE AND DYNAMO EFFICIENCY BEING KNOWN.

The diagram (Fig. 2) is calculated for 100% efficiency; for any other efficiency, add value given in right-hand column opposite that efficiency.

Per cent.		Per cent.		Per cent.

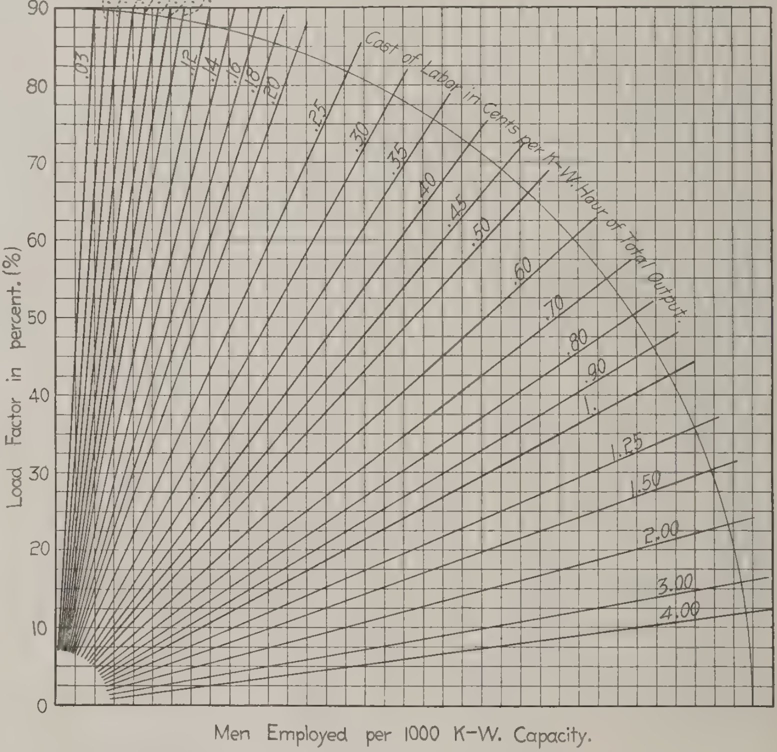

FIG. 1.—DIAGRAM FOR FINDING COST OF LABOR PER K-W. HOUR OF TOTAL OUTPUT OF A STREET RAILWAY POWER STATION, THE NUMBER OF MEN PER 1,000 K-W. CAPACITY, THE LOAD FACTOR AND THE AVERAGE RATE OF PAY BEING KNOWN.

The diagram (Fig. 1) is calculated on a basis of 27 cts. per hour as an average rate of pay. For any other rate add the percentage given in the right-hand column of the table opposite the rate employed.

Rate of pay per hour, cts.	Per cent. to be added or subtracted.	Rate of pay per hour, cts.	Per cent. to be added or subtracted.	Rate of pay per hour, cts.	Per cent. to be added or subtracted.
15	— 44.4	24	— 11.1	29	+ 7.4
17	— 37.0	25	— 7.4	30	+ 11.1
19	— 29.6	26	— 3.7	31	+ 14.8
21	— 22.2	27	0.0	33	+ 22.2
23	— 14.8	28	+ 3.7	35	+ 29.6

The cost of fuel is the next item to be considered in the operating expenses of the standard station. Considering coal as the fuel used, its cost per K-W. hour depends on the price per ton and on the efficiency of the station, which is best expressed in pounds of coal consumption per K-W. hour. The coal for standard station is assumed to be clear bituminous, costing $3 per short ton delivered.

As to the efficiency, I am able to quote from tests on a station of the same size and similar equipment. The duration of the test was 45 hours, made under actual conditions of railroad service during the day, and at night the load was kept on the station by means of a water rheostat. The average efficiency of transformation, I. HP. to E. HP. at the switch-board, was 90%. The steam consumption of the engines was 14.5 lbs. per I. HP. hour. The boiler evaporation was 9.4 lbs. water per lb. of coal from actual conditions. The coal used was New River bituminous. The economy of the station, represented by the coal consumption in lbs. per K-W. hour was 2.3. I have therefore assumed 2.2 for this figure for the standard station.

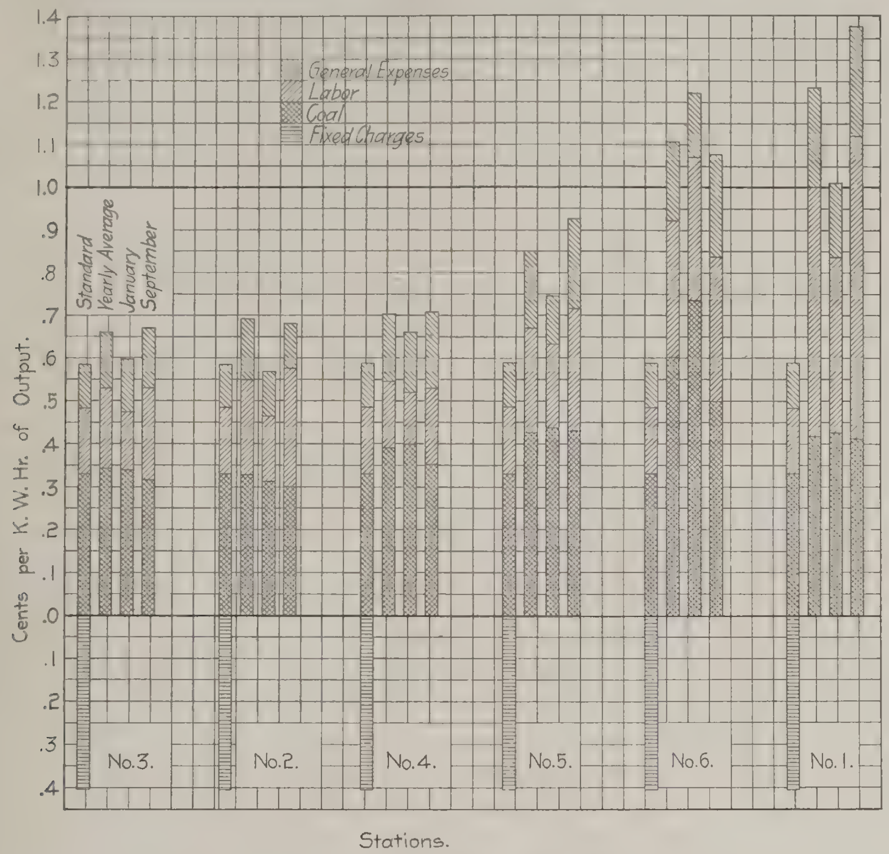

FIG. 3.—COSTS OF FUEL, LABOR AND GENERAL EXPENSES PER K-W. HOUR OF TOTAL OUTPUT IN SIX STREET RAILWAY POWER STATIONS.

(In each group of four lines, the first line gives the operating expenses (and fixed charges plotted below the base line) of the "standard" station, the second gives the average for the year's output for the station under consideration, the third is for a month of the heaviest load (January), and the fourth for a month of the lightest load (September).

Reducing price per ton to price per pound and multiplying by 2.2 gives 0.33 cts. as the cost of coal per K-W. hour. This appears in table I. under cost of fuel. As an illustration of what the cost would have been had the engines required more steam, say 26.6 lbs. per I. HP. load, as might be the case with a non-condensing engine, referring to the fuel diagram, Fig. 2, and considering the electrical efficiency boiler evaporation and price of coal to remain the same, 26.6 to 9.4 lbs. water per lb. of coal gives 3.8 lbs. coal per K-W. hour. Following this line down to horizontal $3 coal line and verticaly upwards from this point to cost of fuel in cts. per K-W. hour, we obtain 0.57 cts., were the efficiency of transformation 100%, but since it is assumed to be but 90%, 11% has to be added to this cost, as shown in the reduction table. This gives the cost of coal per K-W. hour 0.63 cts., as against 0.33 for the condensing engine.

There remains to be included in the operating expenses for this station water, oil, small supplies, repairs, superintendence and general expense, which I have estimated at 0.093 cts. per K-W. hour. The total operating expense foots up to 0.58 cts., which, added to the fixed charge of 0.4 cts., makes the total cost power from standard 0.98 cts., or very nearly 1 ct. per K-W. hour.

The application of water power to street railways has the following points of advantage. In plants operated under any but very low heads the generating machinery may be installed at a less cost than for steam. Also the fuel expense disappears, as well as a portion of the cost of repairs. A part of the labor expense will be saved, inasmuch as no engineers, firemen or coal handlers are required.

Water power produced in various parts of the country varies greatly in its cost. It is reported that the electrical energy so produced costs from $14 to $32 per annum per K-W., continuous output. This expense is largely made up of fixed charges, which increase rapidly as the expense of making the necessary improvements is greater. The standard steam plant produces power with $3 coal for $29, and with 80-ct. coal for $22 per K-W. per annum, which compare very favorably with the above for water power.

There can be no general rule given that will determine whether it is more advantageous to use water or steam power. Each case must be figured by a competent engineer, and decided on its merits.

I have compiled and classified the data of a number of representative street railway plants throughout the country which are given in Table I. In this, the numbers at the top, 10, 11, 12, etc., indicate the several stations, while the figures in the vertical columns are the data for each station derived from records extending over some time. The first column, headed S, refers to the standard hypothetical station above described. The left-hand column explains itself, the first portion describing the plant equipment, the number and kind of engines and generators, etc., the remainder giving labor, fuel and general expenses, the latter including repairs, supplies other than coal—that is, water, oil, waste, lamps and miscellaneous, as well as superintendence.

As a supplement to the table, in order to more clearly illustrate the relation of the costs, I have constructed diagrams (Figs. 3 and 4), in which the principal items of cost are plotted and the costs in the different stations are more readily comparable. In Fig. 3 the variations in the cost in the same plant at different seasons is also shown. The third line in each of the groups represents the operating expenses for January, a month of heavy load, and the last column, that for September, a light month. The first line in each group shows the operating expenses and fixed charges for the standard station. It will be seen that in general the fixed charges are approximately equal to the coal cost. Labor is roughly about half the coal, and general expenses about half the labor. These proportions are simple and easily remembered.

The author describes in some detail the equipment of the six stations, whose expenses are set forth in Fig. 3, showing the causes for increased or decreased expenditures over those of the standard station, as indicated by the diagram. To illustrate the utility of this form of diagram, and these in particular, we select two examples. The first is a large direct-connected plant and the second a small belted station, of which the author says:

Group 4 (Fig. 3) illustrates a large station including 6 1,200-K-W. generators direct connected to triple condensing engines, 2 1,500-K-W. generators direct connected to compound condensing engines, and an auxiliary plant of 40 62-K-W. generators belted to compound non-condensing engines and only used in case of emergency. Economizers, heaters and electric feed pumps complete the important part of the equipment. Group 4 indicates the costs for this station. The yearly average shows that we are approaching standard figures in labor. This item is not much less as the units are only slightly greater capacity. Load factor, rate of pay and men per 1,000 K-W. correspond very closely with standard. The general expense and coal bring the total somewhat higher. General expense is high on account of the heavy repair account. The station is about eight years old and repairs are heavy, due to replacing of worn out parts. The decrease in efficiency, as shown by the pounds of coal per K-W. hour, might be shown by a test to be due to old boilers.

Group No. 6 represents the costs for a belted plant of about one-fifth the capacity of the standard. Its equipment is 12 generators belted to 4 simple high-speed non-condensing engines. There are feed water heaters, but no economizer. High coal consumption is the feature of this diagram. The cost of fuel alone for the year is equal to the total operating expenses for the standard. Labor is also high, and the total cost of power per K-W. hour is nearly double the operating expense of the standard. This station furnishes a good illustration of the effect on the cost of power of a simple non-condensing belted equipment. It is to be remarked also that this plant has the benefit of a high load factor.

The diagrams given in Fig. 4 are plotted in the same way as those given in Fig. 3, the difference being that only the yearly average is given in each case. In examining the different stations represented the same method of analysis is followed. The author takes up each station separately, calls attention to the large or small expenditure for any one item, and traces this back to determine the cause. The equipment is in most cases outlined and other information given which can be obtained from Table I. It will be noticed in Fig. 4 that the lines representing stations 34, 35 and 40 are shorter than the standard, showing that the standard plant so fully outlined by the author is well within possible practice. In referring to the diagrams for these stations, the reason for the remarkably small operating cost is briefly explained as follows:

Station No. 34 operated at a lower cost than standard on account of the high load factor, 57%, reducing the cost of labor, and the low price of coal, $1 per ton. No. 35 is a one unit plant of 1,200 K-W. capacity. It operates with 2.1 men per 1,000 K-W., and a load factor of 37%, using coal costing $1.24 per ton. Its costs are quite a little lower than standard. No. 40 has a capacity of 9,200 K-W. It is direct connected, has economizers and compound condensing engines. Anthracite coal is burned, costing $1.60 per ton. This plant operates at less than standard figures. No. 37 is a record breaker in the opposite sense. It is of slightly greater capacity than 35, but has 3 engines and 11 generators, which require 8 men per 1,000 K-W. capacity. It has a load factor of but 11% during 151 days, from Jan. 1 to May 31, 1898. The effect of this on the cost of labor is very apparent. The cost of coal in this case is greater than the total operating expense for standard. This station pays but $1.75 per ton, but it uses 7.3 lbs. per K-W. hour, while No. 35, about the same size plant, pays $1.24 for coal, and uses but 4.7 lbs. per K-W. hour. Labor is easily 7 times as large in 37 as in 35. The load factor of 11% as against 37% would make this item three times as great, and 8 men per 1,000 K-W. as against 2.1 would again increase the cost of labor three times. The higher rate of pay in plant No. 35 prevents the discrepancy being greater.

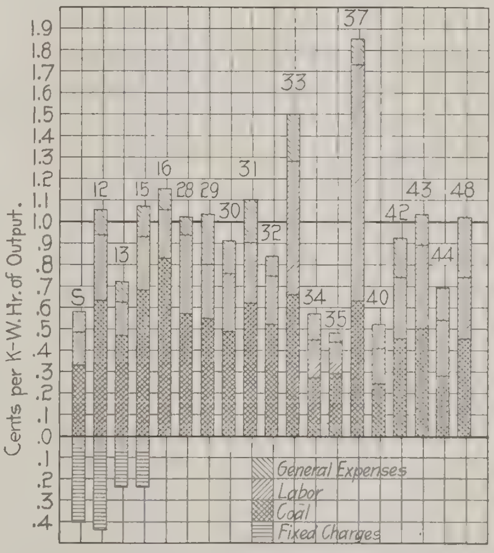

Fig. 4.—Costs of Fuel, Labor and General Expenses and Fixed Charges per K-W. hour of Average Yearly Output, in Various Street Railway Power Stations.

(Plotted from Figures in Table I.)

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; *6 months,* $2.50; *2 months,* $1.00. *To all other countries in the Postal Union: Regular Edition, One Year,* $7.60 (31 *shillings*); *Thin Paper Edition, One Year,* $6.31 (26 *shillings*). *SINGLE COPIES of any number in current year,* 15 *cents.*

In ordering changes of mailing addresses, state BOTH old and new addresses; notice of change should reach us by Tuesday to be effective for the issue of the current week. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number 328 *means that subscription is paid to the 32d week (that is the issue of Aug.* 11) *of the year* 1898; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line. Want notices, special rates, see page* 18. *Rates for standing advertisements sent on request. Changes in standing advertisements must be received by Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

In the report of the meeting of the New York Street Railway Association, in another column of this issue, will be found an interesting paper by Mr. A. J. Moxham, Assoc. Am. Soc. C. E., describing tests to determine the proper composition of steel rails to secure the best wearing qualities. The conclusions he reaches as the result of actual test of rails in the track are that high carbon rails wear better than low carbon rails, but that rails of high carbon with low phosphorus wear better than either. These conclusions are in entire accord with the opinions of the majority of expert metallurgists at the present day, who have given this subject consideration. That rails of fairly high carbon give better wear than the soft rails which were advocated some ten years ago is now attested by the practice of most of the leading railway companies in this country. The question which Mr. Moxham's paper leaves unsolved, however, is whether it will pay to specify lower phosphorus than the ordinary Bessemer practice gives in rail compositions, in order to secure still longer life for the rails. In street railway practice, Mr. Moxham says, the life of the rail is fixed by the wear at the joints, and he concludes that so long as this is the case, the Bessemer quality rail is as good as the low phosphorus rail. It seems to us, however, by no means impossible that by putting a better quality of steel in the rail, a longer life might be secured for the joints. The joints get low because the splice bars wear the under side of the rail head, and fail to give it the support it should receive. Now, if low phosphorus steel reduces the wear on the top of the head, there is good reason to suppose that it might also reduce the wear at the joints, especially if a similar grade of steel were used for the splice plates. Again it will be noted that the wear which Mr. Moxham measured in his experiments was the wear upon rails laid on a tangent. On steam railway lines, however, a large proportion of the track is on curves, where the wear is much more rapid. If, therefore, by paying $2 per ton more for a rail of lower phosphorus, its resistance to wear can be increased some 70 per cent., the matter is one which managers of both steam and street railways will do well to carefully investigate.

Mr. Moxham's estimate of $2 per ton as the extra cost of a rail of .050 phosphorus over a rail of .097 phosphorus, is, we presume, based on the acid process, using a higher grade of ore in the blast furnace. It is quite among the possibilities, however, that in the near future it may be possible to secure basic steel rails with even less phosphorus than that above specified, and at an increased cost little or no greater than the $2 per ton estimated by Mr. Moxham for 0.50 phosphorus acid steel. Such rails should safely take a considerably higher percentage of carbon than the rails tested by Mr. Moxham, and the final result should be a rail of maximum hardness, combined with high elastic limit and ultimate strength and entire safety against breakage in the track.

◆

The widening of the gage of railway track on curves is discussed at some length in a report made by a special committee of the Roadmasters' Association of America, at the annual convention held last week at Denver, Colo., and fully reported elsewhere in this issue. As many of our readers will remember this subject was brought up anew about a year ago by the committee of the American Railway Association on wheel and track gages. According to the report made by this committee (Eng. News, Oct. 14, 1897,) a considerable number of railways, including several well known for the excellence of their track construction, had abandoned or else had never adapted the practice of widening the gage on curves. On the other hand, a number of railways widened curves as flat as 1°, although hardly any two roads used the same rule for widening. A more notable feature of the report, however, was not only the great variety of practice that was shown to exist but the fact that the ideas of railway managers regarding the reasons for widening the gage were as diverse as their practice. In discussing this report in our issue of Dec. 2, 1897, we pointed out that while many railways did not widen the gage on curves this was due in a great many cases to the fact that the maximum curves on those roads were not sharp enough to demand theoretically that the gage should be widened in order to pass the locomotives and cars in common use. In the same issue we published and discussed at some length a paper by Mr. Wm. H. Searles, M. Am. Soc. C. E., which presented clearly the mechanical reasons for widening the gage on curves, and gave a number of simple formulas for calculating any special case which might occur in ordinary practice. The committee of the Roadmasters' Association which reported at Denver last week, it will be noted, indorse with slight modifications the argument and formulas given by Mr. Searles in his paper published in our issue of Dec. 2, 1897. For practical use by trackmen, however, the committee recommends the inclusion in these formulas of a factor of safety to allow for the failure of the swing motion of locomotive trucks to work perfectly, and also for irregularities in wheel gages. The amount of this factor of safety and the method of including it in Mr. Searles' formula are clearly stated in the abstract of the committee report published elsewhere, and will not be restated here. The report of the committee is on the whole an excellent one, and it must be admitted, we think, that it is very timely. As we pointed out in our issue of Dec. 2, 1897, there is no theoretical or practical reason for such diversity of opinion and practice as now exists among trackmen in this problem of curve construction. By setting this fact clearly before trackmen and giving them a simple and reliable standard of practice for all conditions of curvature and locomotive wheel base, the committee of the Roadmasters' Association has done a commendable piece of work.

◆

One of the most serious sources of complaint in the present war has been the treatment which the soldiers received on board the transports, while en route to Cuba and Porto Rico and on the return journey. From authentic reports it appears that in many cases the soldiers were subjected to conditions beside which the steerage accommodations on a merchant vessel may be considered palatial. The reason for this was that at the outbreak of the war, the Government had not a single vessel at its command fitted up as a troop transport. The best that could be done was to take merchant vessels and fit up such temporary bunks, etc., as time permitted. The absence of proper ventilation systems, sanitary conveniences and cooking arrangements on the vessels made the voyages upon them a severe ordeal even for men in robust health; and was doubtless responsible for no small amount of illness and for deaths among the sick and invalids who had to be carried on these vessels.

This great defect in our army system is now to be remedied by fitting up a number of the Government transports as regular troop ships with the most approved appliances and conveniences. No less than eleven vessels are to be thus fitted up, and the first of these, the "Mobile," is already at the Cramp yards in Philadelphia for that purpose. From the present outlook the transport of troops to and from Cuba, Porto Rico and the Philippines is likely to be frequently necessary in the future; and the fitting of vessels to carry comfortably large numbers of soldiers is a most sensible one.

◆

An excellent illustration of the fact that it costs much more to heat the fresh air that must be supplied for good ventilation than merely to maintain the temperature of a room or building is afforded by the heating and ventilating plant of the new buildings of Columbia University. These buildings are supplied with enough direct steam radiators to overcome the loss of heat through walls, windows, etc., and the entering fresh air for ventilation is blown over stacks of heating pipes so that it enters the rooms at a temperature of about 70°. The buildings have a total cubic contents of about 9,700,000 cu. ft., the heating surface in the direct steam radiators is about 56,000 sq. ft., and the ventilating system is designed to furnish about 50,000,000 cu. ft. of air per hour. When the outside air is at zero, the steam consumption of the plant is estimated as follows, in horse power: Condensed in direct heating radiators, 560 HP.; condensed in heating stacks in connection with blowers, 2,205 HP.; power required for electric motors operating blowing and exhaust fans, 635 HP. In other words, the heating and distribution of the fresh air for ventilation takes about six times as much coal as is required to simply maintain the inside temperature of the buildings. In a lecture describing this plant, delivered before the Engineering Society of Columbia University,* Mr. G. A. Suter, under whose direction the plant was constructed, gives the following useful figures from the experience with this plant:

1 HP. of steam supplies 100 sq. ft. direct radiating surface.

1 HP.-hour of steam supply heats 20,000 cu. ft. of air from zero to 70° F.

1 HP. on the shaft of an electric motor driving a blower will move 75,000 cu. ft. of air per hour into and out of the rooms.

The very large amount of power required for moving the air will be, we presume, a surprise to many engineers; but it is to be remembered that as all the exhaust steam is utilized for heating and the power applied to the air, for the most part, also appears as heat, the fan system of heating and ventilating is really not so expensive in operation as might at first sight appear.

◆

TYPHOID FEVER IN THE ARMY.

If one were asked what topic had been uppermost in the minds of the American people during the past few weeks, there could be but one answer, the condition of the returning troops. It is, or was, a common idea that army service is calculated to toughen a man. The trooper who left home pale and stoop-shouldered was expected to return from a season of drill and camp life bronzed and straight, with muscles hardened, and constitution fitted to endure hardship and fatigue. This is the ideal. The reality is that a wofully large percentage of the men who left home in perfect health and passed a medical examination of great rigor are now returning as

helpless invalids, and many more of those who stayed in the home camps have fallen victims to typhoid than all who were killed by Spanish bullets in Cuba.

The question that is now agitating the American people is, where does the responsibility lie for this vast loss of life and this great amount of sickness and suffering? They will not accept any assurances that this was all a necessary feature of army service; and they are right. Other countries assemble great numbers of troops every year in camps for practice manoeuvers; and their ranks are not decimated by typhoid. Of course when troops are engaged in actual campaigning, care for the health of the men must often be a secondary consideration. Strategic positions must be held in the face of the enemy though troops lie in pools of water in the trenches, and camps have to be made in fever breeding swamps. There is little fault finding heard because of the sad condition in which the captors of Santiago came home. There would have been none at all except that the loss of health by the soldiers who never left the home camps gives ground for belief that all was not done that might have been done to care for and restore the health of those who suffered from wounds and pestilence at Santiago.

That, however, is a matter by itself. The fact to which we desire to call especial attention is that the sickness and deaths from typhoid have been the one great blot on the administration of army affairs in the campaign just closed. Compared with that, all the other delinquencies and shortcomings complained of in the administration of army affairs are trivial. Deduct the deaths and illness from typhoid, and the hospital record for the past four months would be little worse than must inevitably be expected when an army is hastily assembled, chiefly from the Northern states, and is put into semi-tropical camps, in a region where malaria is more or less prevalent, at the beginning of midsummer.

The fact that the public desires to learn more than any other is, where does the blame lie for the great prevalence of typhoid in the army camps, and how is similar illness and mortality to be prevented among the troops that must soon be sent away to garrison Cuba, Porto Rico, and, perhaps, also the Philippines? Certainly, if it were generally believed that new regiments would suffer from typhoid as did the troops at Chickamauga and Camp Alger, it would be a difficult matter to find volunteers to fill them.

In the voluminous criticisms of the War Department which have been current during the last few months a great deal has been said concerning the unfitness of the camp sites selected. It has been alleged that the selection of this or that or the other location as the site for a camp was due to "political influence." The soil, the water-supply and the atmospheric environment of almost every camp have been denounced in the public press. One camp was in a barren desert of sand, where the heat was excruciating; another was a malarial and fever-breeding spot, and was inundated at every heavy rain. One was supplied with water from a running stream, which became so foul that its use was well-nigh impossible; another relied on driven wells, whose pollution, according to the reports, was a matter of certainty.

How much or how little truth there may have been in these criticisms as to particular camps, we shall not take space to discuss; but the fact that typhoid has been seriously prevalent at every large camp that has been established, except those most recently opened in the Northern states, is good proof that it was not the camp sites that were responsible in the first place for the epidemic that prevailed in them. It is easy to condemn a camp site after an army has lived upon it for weeks and scattered its debris over it; and it is easy for an unthinking man to say, as was so many times said: Why was such a site chosen when thousands of better sites are to be found in every state? Few appreciate the requirements that must be met in selecting a site for the encampment of an army of fifty thousand or more, such as that at Chickamauga. Military considerations, at the time the camp sites were chosen, were of the first importance. The army had to be gathered in camps large enough to enable brigades and corps to be formed so that there might be some practice in the movement and handling of large bodies of troops. These camps had to be located within quick rail communication of the points on the seaboard from which a forward movement might be made, and rail communication with the principal markets and supply depots was essential. The water supply of a large camp is a most difficult problem. Lakes in the South are few, and an army camped on the shore of any lake of small size would soon seriously pollute it. Running streams in the South are generally very muddy; and besides, an army of considerable size camped along a stream will quickly foul it. Under these circumstances, underground supply from driven or bored wells seems practically the only source from which an army of 50,000 men or more can derive a reasonably pure supply of water; but every sanitarian knows that such wells are liable to surface contamination unless great care is taken. For general sanitary reasons a sandy soil is the best on which to locate a camp; but wells in such a soil are more liable to surface pollution than those driven through clay.

When one bears in mind the limitations with which at the opening of the war the choice of camp sites was hedged about, it is hard to believe that Chickamauga, for example, was selected with any other idea than that it was the best adapted for the purpose. It is located in a high mountain region, the coolest and most salubrious in the South. Its railway communications with the North and East are better than those of any other center in this mountain region, and its rail communication with the seaboard is also excellent. Besides this, its proximity to Lookout Mountain, a natural sanitarium, would seem to make it a place where troops should have been kept in excellent health. It is now said, we are aware, that the soil at Chickamauga was too stony to make it a sanitary camp site; but while it is doubtless more difficult to keep a camp healthful on a rocky or clay soil than on sand, it can be done nevertheless.

Again, the fact that typhoid has raged at Chickamauga, at Camp Alger, at the Presidio, at Camp Black, at Jacksonville, and at various other camps proves not only that the camp sites were not the original cause of the trouble, but that it was not due to the mistakes of any one particular commander, or the inefficiency of the officers in any one camp or locality. The wide prevalence of the disease proves that something was wrong with the system as a whole. Just what that something is it will be the most important task of the President's proposed investigating commission to find out. At present we can only say, without pretense of having made an exhaustive inquiry, that all the information at hand inclines us to believe that the main source of trouble was, first, the ignorance and inefficiency of the officers in immediate charge of the volunteer troops; and, second, the system under which army affairs are administered. Almost all of the officers appointed to the volunteer regiments were absolutely without experience in the making or policing of army camps; and it is safe to say that in the minds of nine-tenths of them, sanitary matters were given little attention. Those who were industrious and faithful had their minds chiefly set on drilling their men into soldiers. Those who were not, paid as little attention to the sanitary condition of their men as they did to their other duties.

It may be said with truth, however, that this is no explanation of a typhoid epidemic. Decaying garbage and uncared-for sinks about a camp may offend the eye and the nostril, and these and similar unsanitary conditions may produce malaria, bowel troubles and such disorders. But to propagate typhoid, a germ from the discharges of a typhoid patient must be taken into the alimentary canal. To prevent the spread of typhoid, therefore, all that is necessary is to disinfect or absolutely kill the germs in the discharges of every typhoid patient, and this is the most important duty of the nurse in charge of a typhoid fever case, while the responsibility is the attending physicians to see that it is done. With this single precaution the disease is not contagious at all. Without it, a single patient may, under favorable conditions become a center of infection for hundreds.

Now there is good reason to believe that in their zeal to show a good health record and to keep men from "playing sick" to escape discipline or drill, the medical staff have tried to keep men out of the hospitol who ought to have been in it. The men themselves, too, in nine cases out of ten, were never willing to go to the hospital while they had any strength left; especially after the regimental hospitals were abolished and transfer to the division hospital meant leaving everyone they knew.

Of course in gathering thousands of men together, all of them traveling long distances and drinking all sorts of water on the way, some cases of typhoid are certain to occur; and a considerable percentage of these cases, there is little room to doubt, were not taken to the hospital until they had been ill for many days; in fact it is likely that not a few light cases were never in the hospital at all. As evidence of this neglect to identify typhoid in its early stages and to keep the patients in the hospital where their discharges can be disinfected, we find in the current "Medical Record" the testimony of a prominent New York physician, who diagnosed, on Sept. 5, 17 cases of pronounced typhoid fever among soldiers in the Presbyterian and Bellevue hospitals in New York city. Most of these patients were from Camp Wikoff, and not one of those who came from there had been in the hospital at all. The physician, from whom we quote, after sarcastically commenting on "the new army treatment of typhoid fever by prescribing thousand-mile railroad journeys," calls attention to the danger to the public health in the following vigorous words:

> A patient having six or a dozen diarrhœal enteric stools a day, using the ordinary closet of a railroad car travelling, say, thirty miles an hour, distributes a trail of fæces along the track, to be washed by the first rain into neighboring streams, and sets a rather bad example of hygiene to the country at large.

But besides the infection of the camps and their water supplies, by the cases of "walking typhoid," it is by no means certain that the hospitals were so conducted as to remove the danger of infection from the discharges of typhoid patients. The same physician from whom we have just quoted describes the methods of disinfection which he witnessed at Camp Wikoff as "obsolete, inefficient and farcical." On the other hand, Dr. Benjamin Lee, of Philadelphia, who visited the camp at about the same time and published a report of his visit in the Philadelphia "Public Ledger," said: "In the hospitals great care is taken in the disinfection of the excreta of typhoid patients." Here is a disagreement of doctors. The truth probably lies between the two extremes. It would be equally wrong to draw a wholesale indictment of the sanitary conduct of the hospitals or to declare that they were all conducted in a faultless manner. Knowing, as we do, that the nurses were largely men inexperienced in the care of the sick, that frequently both doctors and nurses had twice as many patients as they could properly care for, and that medical supplies were too often found inadequate to the demands, bearing these facts in mind, it seems altogether probable that at many, if not all, of the camps, at times, the discharges of typhoid patients in the hospital have been thrown out untreated, and the germs in them have been scattered broadcast by rains, dust and flies, have polluted food and water supplies by the wholesale, and thus have caused the remarkable spread of the disease that has been witnessed.

We view the vast total of death and suffering, the grief and anxiety in thousands of homes, and wonder that it was not foreseen and guarded against. But it is no wonder after all. Who, among sanitarians even, would have predicted six months ago that some carelessness in permitting cases of "walking typhoid" to stay outside the hospital and more carelessness in neglecting the well-known sanitary precautions in the care of typhoid patients in the hospitals, would have produced such terrible results? It is easy to be wise after the event. In the light of our present knowledge, we can easily say that vigilance in isolating and caring for cases of typhoid should be the very first duty of those in charge of troops; but who appreciated to the full importance of this precaution six months ago? Some did, unquestionably. The army surgeon in charge of one of the hospitals at Chickamauga is quoted as saying that it was an ideal site for a camp; that its soil and sanitary surroundings were excellent, and that the sole cause for the epidemic of typhoid which has raged there was the disregard, by those in charge of the troops, of the rigid sanitary regulations which the medical staff of the army promulgated at the opening of the campaign.

Experience shows, however, that not all the surgeons in charge by any means were sufficiently well posted in sanitary matters to appreciate and insist upon the care necessary to stamp out and prevent the spread of typhoid. Even when surgeons were competent and faithful, their efforts, it is feared, were often neutralized by lack of cooperation on the part of line officers and lack of military discipline and strict obedience to orders on the part of the soldiers who had to do the actual work of keeping clean the camps and hospitals.

The fact is that the nation improvised an army on short notice from a mass of raw recruits, some of whom knew something of military drill, but nothing else of the things which an efficient private soldier must know. The officers over these men were for the most part as ignorant of military matters, aside from the mere matter of tactics, as their men. Camp sanitation, camp cooking, and the provision of food, clothing and other supplies to large bodies of troops in camps or traveling from point to point by rail or transports, was a matter in which all alike were wholly inexperienced. To what extent this condition has been aggravated by the selection of inefficient youths as officers, because of political influence exerted on their behalf, we cannot say; but it would be strange, indeed, if in selecting some thousands of officers, a large percentage of incompetents did not manage to secure sufficient backing to enable them to creep in.

The inexperience of the officers alone, however, is quite sufficient to account for all the soldiers have suffered in the way of bad rations, improper clothing, and illness and death from bad sanitary conditions. In fact some contrasts in the condition of regiments which had the good fortune to have an experienced soldier at their head and those in charge of volunteer officers furnishes additional proof as to where the fault lies for the illness and loss of life in the war from what are well called "filth diseases."

We are aware that a great deal has been said about "military red tape" being a chief cause of the troubles experienced in the army. But it is too often overlooked that "red tape," as it is commonly called, is an absolute necessity in any large organization, civil or military. There must be a definite system for the performance of duties, and a definite assignment of duties and responsibilites throughout every grade of the service, in order to secure proper co-operation, and the orderly prosecution of business. It is probably true, however, that too many hampering and embarrassing restrictions have been embodied in the army regulations, and it should be one of the earliest duties of an investigating commission to determine to what extent those restrictions can be removed and the army routine methods can be amended so as to promote efficiency. The tendency in the framing and amending of such rules is all the time to prevent the wrong thing being done, and to overlook the fact that it is more important after all to ensure that the right thing is done. Rules should be found to facilitate action and not embarrass it.

In conclusion, then, we would emphasize the fact that the illness and deaths from typhoid in the army have been primarily due, not to the camp sites as has been alleged, but to the neglect of simple sanitary precautions on the part of those in charge of the troops, chiefly through ignorance of their importance.

With the dearly bought experience that the nation has now had, such epidemics of typhoid as have raged in the army should hereafter be impossible. The means of preventing the spread of this and similar filth diseases are so simple and so widely known that they should be familiar to the officers in every grade; and their neglect should receive punishment proportionate to the loss of life and suffering which such neglect will cause.

LETTERS TO THE EDITOR.

Moving Electric Cars Across a Weak Bridge.

Sir: Your issue of Sept. 15 contains a short article on "A Plan for the Safe Movement of Electric Cars Across a Weak Bridge," according to which, after an examination and report by me on Sept. 3, 1897, in which the structure was pronounced unsafe and after a further examination and report by an unnamed engineer representing the Capital Railway Company, whose tracks crossed the bridge, in which it was declared to be safe, the final result was "that the railway company has now obtained a permit to construct a double-track trolley line over the bridge." The clear inference of the article is that a difference of opinion between the District Engineer Department and the Capital Railway Company as to the structural sufficiency of the Navy Yard Bridge was resolved by the issuing of a permit to the railway company in accordance with their expert's contention that the bridge would safely carry the loads, and in contradiction of the office's contention to the contrary. The circumstances really are that the company received the charter right to cross this bridge with its cars from Congress prior to the date of my investigation and report which you quote. This right could not be denied them, and has been exercised by them for some time past, the cars being hauled across the bridge by horses. By subsequent legislation of Congress the right to construct a trolley on the bridge to supplant the horse traction, subject to approval as to details by the Commissioners of the District, was granted the company, and the permit for putting up these wires is the one your article refers to. The details employed in this trolley construction were calculated to accomplish the result of preventing cars passing on the bridge, but to publish the circumstances as they appear in your article without such an explanation as the foregoing would make a presentation unfair to the Engineer Department of the District of Columbia and to myself.

Very respectfully,

C. B. Hunt.

Office of the Engineer Commissioner of the District of Columbia, Washington, D. C., Sept. 17, 1898.

(We did not intend, in the article referred to, to imply that in the disagreement between experts, the railway company's expert was sustained. On the contrary, it was our understanding (and the above letter makes it entirely clear), that the exact opposite was the case. We regret that some of our readers may have been misled by the ambiguous wording of the article referred to. It appeared to us that the engineer had contrived a very ingenious scheme for preventing the bridge being overloaded by two cars crossing in opposite directions at the same time, and our readers will now understand what was not clear before, why a double-track was laid across the bridge.—Ed.)

Tests of the Stress in Plate Girder Stiffeners.

Sir: I have read with considerable interest the discussions which have appeared in several of your recent issues on the subject of web stiffeners in girders. It seems to me that there are two distinct conditions of a girder to be kept in mind: First, a girder in which incipient failure, by buckling or otherwise, has not even begun; and, second, a girder in which certain parts have partially or wholly failed. The model shown by Mr. Wilson exhibits the girder in the second condition, and I agree with "E. M.," and with Mr. Buel, that from the behavior of such a model, correct conclusions cannot readily be drawn as to the stresses which exist when the same is in perfect condition.

I take it that the question of chief interest relates, however, to a girder in the first-named condition. In such a girder with vertical stiffeners, it appears to me that the character of the web stresses are, so far as the intermediate stiffeners are concerned, exactly the same as in a girder without stiffeners; and for the following reasons. 1. In a girder without stiffeners (assuming no buckling to occur), the web is subjected to stresses which are tensile or compressive on surfaces inclined at 45° with the axis, and pure shearing stresses on surfaces parallel to, or at right angles with, the axis. 2. Granting 1, it follows that in such a girder the longitudinal distortion of a vertical strip of the web is zero, there being no tensile or compressive components in a vertical direction. 3. An angle riveted to a vertical strip of the web in which there is no longitudinal distortion produced will not itself be distorted, and therefore will receive no strain.

The above may be objected to on the ground, that, while it may apply to girders with thick webs, it may not apply to those with thin ones; but I see no reason why the general distribution of stress should be any different in girders with thin webs and stiffeners, than in those with thick webs and stiffeners, provided always that incipient failure has not occurred. End stiffeners, and others attached in the vicinity of heavy concentrations, will receive more or less stress; as the tensile and compressive stresses in the web at such points vary more or less from a 45° inclination.

In applying Professor Johnson's proposition regarding the distribution of a load over several paths, there appears to be some confusion in the use of the terms "rigidity" and "strength." A web plate, no matter how thin, is just as rigid in compression as in tension so long as buckling does not actually take place, though it is of course ultimately not as strong. In a girder, then, in which buckling is prevented, there is as much reason to suppose that the web stresses follow down the web and up the stiffeners, as in a Howe truss, as to suppose that they follow the lines of a Pratt truss. The stresses are, indeed, all provided for without distorting the stiffeners at all, as I have attempted to show.

The behavior of a girder after partial failure has occurred is very clearly illustrated by Mr. Wilson's model; and it is readily seen that as soon as buckling begins and the distortion of the web in compression is greater than in tension, compressive stresses will be developed in the stiffeners and total failure cannot take place by the buckling of the web alone.

I have recently made some observations on the siffeners of a through girder of 75-ft. span by means of a Fraenkel extensometer, and the results are given herewith, together with a sketch of the bridge, on which are indicated the position of the stiffeners tested. Stiffeners b and d were on the inside, as shown, while a and c were on the outside of the girder:

No. of experiment.	Stiffeners tested.	Observed max. stress. (Lbs. per sq. in.)	Calculated shear on girder. (Approx.) (Lbs.)
1	d	500, tension	50,000
2	c	600, "	57,000
3	b	300, compression	62,000
4	b	300, "	62,000
5	b	300, "	62,000
6	a	1,200, "	72,000

The extensometer was adjusted in each case to measure the distortion of a meter's length of the stiffener about midway between top and bottom. The calculated shears are for sections taken at the stiffeners in question; they indicate what the small column, consisting of two stiffeners and a narrow strip of web, would have to carry under the assumption that the web acts as a Pratt truss.

Extensometer Curves from Stiffeners on 75 ft. Plate Girder Bridge.

The small stresses actually observed in the intermediate stiffeners, some tensile and some compressive, are, no doubt, secondary stresses due either to the effect of local loading or to some slight lateral bending in the girder. The considerable compression in the end stiffener shows the effect of concentrated loads.

I enclose also a tracing of three of the curves obtained. No. 1 was caused by the passage of two locomotives and caboose, while Nos. 5 and 6 were in each case produced by a locomotive running light. The diagrams were drawn from left to right.

Yours truly,

F. E. Turneaure.

University of Wisconsin, Madison, Wis., Sept. 14, 1898.

Notes and Queries.

Concerning the casting of large size wheels for locomotive and car trucks, discussed in our issue of June 9 and Sept. 8, Mr. Andrew J. Vaughan, of Providence, R. I., who was at one time foreman of the old Hinkley Locomotive Works at Boston, writes us that chilled wheels as large as 42 ins. were successfully cast at those works.

E. D. S. asks whether brass pipe laid underground would be affected by electrolysis, or would be liable to corrosion from other causes?

It is now definitely established that pipes of any material, or metal covered cables are subject to electrolysis when in the vicinity of electric street railway systems or lighting plants using a ground return. Corrosion occurs independent of any electrolytic action in nearly all localities, and especially in cities and places where the soil contains chlorides, sulphates and nitrates, together with any moisture. Temperature of the pipe also plays a part in the corrosive action, there being what may be termed a "critical temperature" at which the action is most rapid. In other words, a pipe conveying steam will be corroded more rapidly than one carrying water.

Regarding the amount of eating away by either electrolytic action or corrosion, or both, of brass pipe in comparison with other materials, such as iron, copper or lead, we know of no positive data. A study of the chemical equivalents of the various metals used in underground construction will, however, indicate that common brass pipe, containing about 70% of copper and 30% of zinc, would suffer from electrolysis somewhat more than iron pipe and not so much as lead. Approximately, a current of one ampere flowing steadily from an iron plate of ample proportions will remove about 20 lbs. of iron per year. Under the same conditions 75 lbs. of lead could be removed and brass would suffer a loss somewhere between these figures.

MUNICIPAL ASPHALT PLANTS are recommended by Mayor Van Wyck for New York city, to meet an alleged combination among asphalt paving companies. This resolve is a result of the late bidding for laying asphalt strips for bicycles on streets connecting the Borough of Queens and Long Island City. The engineer's estimate was $22,000, but the bids received were $14,000 in excess of this estimate. The comparative narrowness of the strips may have something to do with the excessive price.

◆

THE ORIGINAL PAIGE TYPE-SETTING MACHINE, one of the most ingenious and intricate pieces of mechanism ever invented, has been presented to the museum of Sibley College, Cornell University, by Mr. P. P. Dodge, President of the Merganthaler Linotype Co. of New York city. The Paige machine was the invention of a mechanic in Hartford, Conn., and while it was a marvel of mechanical ingenuity, it was so complicated and of such delicate and intricate and expensive construction that it never had a chance of commercial success. The patent upon the machine is one of the most voluminous that was ever granted by the U. S. Patent Office, and it is said that the patient attorney who prepared the specification and claims was made insane by the work. Over $2,000,000 is said to have been sunk in developing the invention. The chief contributors were business men of Hartford, Conn., among them being Mr. Samuel L. Clemens (Mark Twain).

◆

THE THREE BATTLE SHIPS ordered by the last Congress were let on Sept. 14, one each to the Cramps, Newport News Shipbuilding Co., and to the Union Iron Works of San Francisco. These contracts call for ships of 12,500 tons displacement, a coal capacity of 2,000 tons and a speed of 18½ knots. Within the next few weeks contracts will be let by the Navy Department for four coast-defence monitors; 12 torpedo boats and 16 torpedo boat destroyers. Commodore Watson announced to the Navy Department that the Spanish cruiser "Maria Teresa," sunk at Santiago on July 3, will be floated. Ten 6-in. rapid-fire guns have already been removed from this vessel and placed on the collier "Leonidas."

◆

ANNUAL CONVENTION OF THE STREET RAILWAY ASSOCIATION OF THE STATE OF NEW YORK.

(Concluded from page 181.)

A paper, by Mr. D. F. Carver, Brooklyn Heights R. R., Brooklyn, N. Y., was the next on the list, and from it we have taken the following points of interest:

Track Construction.

The development of street surface railways from their operation by animal power to their operation by cable or by electric power has made many changes in track construction a necessity. The first essential of good track construction and good pavement is a good foundation. In a majority of cases this exists naturally at the depth at which ties are laid. If the natural foundation is not suitable, it can be made so by the use of broken stone or gravel. The ties should be of the best quality of yellow pine, sawed four sides, and of a size sufficient to give a bearing on foundation of not less than 4½ sq. ft. per tie. A very excellent and economical spacing has been found to be 24 ties to a 60-ft. rail. All ties should be thoroughly tamped near the rail, and the joint ties tamped throughout their lengths. The dirt under the base of the rail should also be thoroughly tamped, otherwise there will be a settlement which will allow the paving stones next the rail to be forced down.

The rail used should be of hard steel, and of a section that will give it great stiffness. The tread should be either level, or, as is becoming common practice, should bevel, so that the wheels will have a bearing for the width of the tread. This latter arrangement gives greater contact for traction and stoppages, and also causes less damage to wheels that are skidded in an emergency stop. As the lightest section of 9-in. rail is more than amply strong to stand the strain of carriage, provided, of course, that every tie has a first-class bearing, it has been found desirable to roll the web down to the thinnest section possible, and accept the small losses due to rails splitting along the web from the tension caused by the very unequal distribution of metal. The breakage above referred to has been found to be, throughout a year's work, about 0.25% of all rail laid.

The problem of the rail-joint has been a very trying one, but it is fast approaching a successful and satisfactory solution, the essential features of which are either a welded joint, which makes a rail practically one continuous mass, or the mechanical joint, which avails of the bearing surfaces beneath the head and tram, and beneath the base, and of the upper surface of the base of the rails which it connects. Either joint, to be entirely successful, however, must be laid with tight joints, so that passing wheels will have a continuous bearing.

This method of construction will, in time, force the track out of line, and where the line is curved to any extent will push the curve out of line; and also in renewing any portion of the track in warm weather, it will be found almost invariably impossible to put in new pieces of the same size as the old removed, because the great compression strain closes up the opening. Still, with all these objections, the added length of life of joints gained, is of decided advantage.

In paving the street, the portions outside the outside rail and between the tracks should be paved and thoroughly rammed before the sections between the rails are paved. This prevents the crowning of the stones between the rails from forcing the track out of gage.

A bed of concrete between ties has been tried to prevent the paving blocks from sinking, but such experience as the writer has had with this construction has not been very satisfactory, and as its first cost is great, and also as the interest on this extra investment is, in many cases, greatly in excess of the maintenance charges which it is intended to prevent, he is led to doubt very greatly its utility.

The question of track bonding was considered in a paper presented by Mr. R. P. Brown, Electrical Engineer, Brooklyn Heights R. R., Brooklyn, N. Y., which is abstracted as follows:

Track Bonding.

Several systems of track bonding have been tried upon the Brooklyn Heights R. R. since its operation by electricity. Originally the familiar supplementary ground wire with branches to the track and copper ground plates were employed, no dependence being placed upon the rails for returning the current.

The next step was to install return feeders with frequent taps to the supplemental wires. Increasing traffic caused an excessive return feeder outlay, and in 1895, when it became necessary to relay the tracks, it was decided to use the rails for at least part of the return circuit. The bond adopted was a short cast-copper plate (5 × 1-16-in.) the full width of the base of the rail, with about 12 sq. in. contact between the bond and the end of each rail.

The connecting piece of metal was curved so as to allow for expansion. To secure good connection, a re-enforcing plate of cast iron was placed underneath the area of contact and the bond pressed firmly against the rail by ½-in. bolts passing through the base of the rail. No machine work was necessary other than grinding the contact face on the bonds and removing the scale from the rail where the bond was to be applied by grinding with a portable emery wheel.

Recent tests show these bonds to be practically of the same resistance as when first installed, three years ago. The cost of these bonds was not greater than that of the No. 0000 bond going completely around the fish-plate, and having two or three times the electrical resistance of this connection. The difficulty of attaching a bond underneath the base of the rail, however, was considerable, requiring careful supervision to insure good results. This trouble led to further investigations, with the result that a bond electrically brazed to the rail was adopted the following year. This bond was somewhat cheaper than the plate bond and good work was more easily obtained on account of the better chance of inspection.

At present the bond which has been adopted as standard on all lines of the system having heavy traffic is made in two parts and brazed on the rails before they are removed from the yard. The shape of this bond depends on whether it is to be placed on the web of the rail, so as to come underneath the fish-plate, or as they are now applied, on the base and upper flange of the rail, outside of the joint plate. All forms of the bonds, however, are made up of 10 or 12 leaves of 1-64-in. soft copper, the carrying portion of the bond being 1¾ ins. wide, and the brazed contact having an area of about 1 sq. in. Soft spelter, with suitable flux, is used in brazing the copper to the steel rail. The bond is divided longitudinally into three parts, so as to give greater flexibility. When the rails are in position, the ends of these bond leaves are interlaced and fastened together by rivets and also by solder. The length of the bond between center of contacts is 5 ins., and its cross-section is equal to 350,000 circular mils.

On the lines having light traffic the short "horseshoe" bond has been placed underneath the fish-plate. These bonds are 3¼ ins. in length, of 0000 cross-section, and have ¾-in. diameter terminals. As a measure of safety, as well as to lower the resistance of the joints, all rails are double-bonded whether the brazed or horseshoe bonds are used. The holes for these bonds are drilled by the makers of the rail, and they are reamed out with emery paper to remove the rust that may have formed during shipment. If care is used in compressing the terminal of those bonds, there is no necessity for drilling or reaming of holes on the ground, as any slight irregularity in the drilling fills up when the soft copper is thoroughly upset.

Curved rail, switches and other special work are often difficult to bond satisfactorily in the yard, and the joint plates are of such section that the bond cannot be placed underneath. In such work long bonds going round the fish-plates are used. On account of the excessive wear on special work the joints are particularly liable to loosen, so that the bond must be extremely flexible.

It has been found that if a simple bond is used, it should be placed at the center of the web of the rail if sufficient contact can be obtained at that point. If contact is made at either the base or upper flange, the length of the circuit is increased by the height of the rail.

Contrary to the former practice of tinning the bonds and supplementary wire, the bonds and their exposed copper surfaces are carefully coated with an insulating paint, so that if there is any flow of the current in the track to the surrounding soil it must leave from the steel and not from the copper. This prevents the bonds being destroyed by electrolysis or other corrosive action.

To guard against imperfect workmanship, a system of testing bonds has been practiced. Usually only the joints on one line of rail are tested, though in sections of high current density, as in the vicinity of power houses, the resistance of each joint is obtained. The test is a simple comparison of the fall of potential across the joint and on a measured portion of an unbroken rail. Two Weston milli-voltmeters, with scales ranging from 0.001 to 0.3 volt are used; the readings being taken simultaneously. Contact is obtained by pressing hardened steel points on the surface of the rails. These points are set in wooden blocks and placed 6 ins. apart if used on the joints and 2 ft. apart for tests on solid rail. The distance on the rail is taken for 2 ft. instead of 1 ft., on account of the small amount of current flow in the rail on some of the lighter lines. These testing terminals are provided with handles of convenient length so that the person using them can stand upright and apply the necessary pressure with one foot. Two men can test joints very rapidly with this outfit. The current density of some of the rails was too low to give reliable readings with these instruments, so a portable resistance was arranged on a wagon and the necessary current readily obtained from the trolley wire. This resistance allowed about 300 amperes to flow from the line to the rail, and as it could be very quickly applied, rendered it a comparatively easy matter to test the joints in any section of the city.

Although the bonds are less than 6 ins., that length was selected for the distance between terminals of the voltmeter used in testing joints, because it gives a convenient fraction to subtract from the length of each rail in arriving at the total resistance in line of track. The drop on this 6 ins. was considered as increasing the length of the rail by an amount proportionate to the drop in the rail itself. From this the percentage that the rail of any line approached the conductivity of the solid steel rail could be easily determined.

The following results were obtained from different joints:

—Drop in volts.—			% of conductivity of solid rail.
Rail.	Joint.		
1 ft.	1 ft.	Falk Joint.	
0.00215	0.00355	(30-ft. rail)	98%
		(60-ft. rail)	99%
		Double Brazed Bond.	
0.00725	0.00758	(30-ft. rail)	99.8%
		(60-ft. rail)	99.9%
		Johnson Bond.	
2 ft.	6 ins.		
0.00364	0.00342	(30-ft. rail)	95.6%
		(60-ft. rail)	97.8%
		Plate Bond.	
0.0109	0.0233	(30-ft. rail)	89%
		(60-ft. rail)	94%

It will be seen by the foregoing that it is a comparatively easy matter to get a conductivity of over 90% of a continuous steel rail. As high as 600 amperes can be safely carried on any of the bonds mentioned, and the cost of double bonding in a satisfactory manner should not exceed 75 cts. per joint. The conductivity of steel varies with the amount of carbon in its composition, but, generally speaking, it is about ⅛ of the conductivity of commercial copper. Bearing these facts in mind, it will be readily seen that it is much cheaper to make the return circuit wholly of well-bonded steel rails, supplementing the track in the vicinity of the power house with worn-out rails carefully bonded.

Other papers of interest were read on "Individual Fare Boxes: Are They Practicable," T. J. Nicholl, Rochester, N. Y., and "The Relation Between the People and the Street Railways," J. T. Little, Jr., Metropolitan St. Ry. Co., New York.

After the close of the afternoon session, the visiting railway men were treated to a special exhibition of fireworks at 8 o'clock, which included several special features. Immediately afterward the banquet was held in the dining-room of the Manhattan Hotel, with Hon. Tom L. Johnson as toastmaster.

The morning session on Sept. 14 was devoted to the consideration of such topics as "The Repair Shop," "Municipal Ownership," "The Care of Dynamos," "General Track Construction," "The Use and Abuse of Transfers," "Pointers on Store-Room Accounts," "Long-Distance Power Transmission," "Pleasure Resorts: Are They Profitable?" "The Use of Air and Power Brakes on Street Cars."

At 11 o'clock, the members and visitors took trolley parlor cars at Sheepshead Bay bound for the navy yard, where some time was spent. Later, a steamer was taken, which left from the Bridge Dock and sailed down New York Harbor, up the Hudson, through Spuyten Duyvil and down East River to the Battery landing. On the way luncheon was served, and the following officers were elected to serve for the ensuing year: Pres., G. Tracy Rogers, Pres. Binghamton R. R. Co., Binghamton; First Vice-Pres., W. Caryl Ely, Pres. Buffalo & Niagara Falls Ry. Co., Buffalo; Second Vice-Pres., Albert L. Johnson, Pres. Nassau R. R. Co., Brooklyn; Secy. and Treas., Henry A. Robinson, Solicitor Metropolitan St. Ry. Co., New York; Members of Executive Committee, H. H. Vreeland, Pres. Metropolitan St. Ry. Co., New York; John W. McNamara, Treas. Albany Ry., Albany; Henry M. Watson, Pres. Buffalo Ry. Co., Buffalo; Clinton L. Rossiter, Pres. Brooklyn Heights R. R. Co., New York.

ANNUAL CONVENTION OF THE ROADMASTERS' ASSOCIATION OF AMERICA.

The sixteenth annual convention was held at Denver, Colo., Sept. 13, 14 and 15, the headquarters being at the St. James' Hotel. The meetings were held in the hall of the Chamber of Commerce, and the exhibits of the Road and Track Supply Association were in an adjoining building. It was a very successful meeting, and the attendance was exceptionally large. The opening session was called to order at 9 a. m. on Sept. 13, when the president, Mr. A. M. Hawkins (Norfolk & Southern R. R.) delivered a brief address. A few brief remarks were then made by Mr. Burnett, the founder of the association, after which the Secretary and Treasurer, Mr. J. B. Dickson (Chicago & Northwestern Ry.) read his report. The financial report showed the following summary: Receipts, $2,287; expenditures, $1,523; balance on hand, $764. The Hon. Alva Adams, Governor of the State of Colorado, then delivered a short address of welcome, in which he referred to the important relation of railways to the development of the country, and spoke of George Stephenson as having been the original "railway man," as he was at once a civil engineer, mechanical engineer, locomotive engineman, roadmaster and superintendent. Another short address by Hon. T. S. McMurray, Mayor of Denver, closed the formal part of the procedings.

The election of officers was next taken up and resulted as follows:

> President, T. Hickey, Michigan Central R. R.; First Vice-President, J. M. Meade, A., T. & S. F. Ry.; Second Vice-President, C. B. Teller, Denver, L. & G. Ry.; Secretary and Treasurer, J. B. Dickson, Ch. & Northwestern Ry.; Member of Ex. Com., C. E. Jones, C., B. & Q. R. R.

A paper on "Discipline, in Its Practical Application to Track Forces," by Mr. H. W. Church (Lake Shore & Michigan Southern Ry.), was then read by the Secretary. Its object was to advocate the so-called "Fall Brook" or "Brown" system. The paper was printed, slightly condensed, on page 173 of our last issue. In the discussion two or three members reported the system as in use in the track departments of their roads (including the Toledo & Ohio Central R. R.), taking in the roadmasters, supervisors and foremen. It was further stated that a roadmaster ought to try to educate his men and make something of them, instead of arbitrarily punishing them by suspension or dismissal.

The first business of the afternoon session was the discussion of a proposed amendment to the constitution changing the name of the association to the "Railway Maintenance of Way Association," but this amendment was lost by a vote of 24 to 45. Two minor amendments were adopted, one referring to the rights of honorary members and the other giving associate members (former members who have left railway service), the right to speak on the floor only by permission of the chair.

The report of the committee on "The Best Method of Preventing the Creeping of Rails," (p. 171 of the last issue of Eng. News), was then read, and brought out a little desultory discussion in which a few members presented their individual experience.

The next committee report taken up was a very long and elaborate discussion of the merits of tie-plates, and was, it may be remarked, one of the most complete studies of the subject that has appeared in engineering literature. We condense it as follows:

Tie Plates—Benefit and Results Obtained by Their Use.

This Committee was called upon to report on:

> Tie Plates; The Benefits and Results Obtained from Their Use; which is the best, most easily applied, and most effective; a tie-plate having a projection which runs parallel with the grain of the wood, or one which has a projection which cuts across the grain of the wood; and that as many plates of each kind as have been in use be obtained, and also a portion of the ties in use, be brought to the meeting for actual observation, not removing the tie from the plate.

We feel that this committee has been asked to decide upon too much; for, in connection with "tie-plates, the benefits and results obtained from their use, etc.," must be considered the conditions as to differences in the kind of ballast and of the tie, the weight and the size of the rails used, the number and effectiveness of track men to a certain section, the various climatic conditions; besides, also the amount and weight of traffic and the kind of motive power and rolling stock. All these different conditions and forces have to be taken into consideration in each case, both individually and severally, and in different parts of the country. It is thus clear that a large number of facts and conditions, in each case, must be collected, segregated and analyzed, to obtain the facts as to which is the best plate, and each case must then be considered in relation to the other cases under consideration, and as this entails a vast amount of labor and careful study it is clearly beyond the ability of any body of busy railroad men to so consider these cases in one year as to point out positively and definitely to one plate and say, "That is the best plate." This is made the more difficult also from the fact that through the experience gained by manufacturers in the use of their plates they are enabled from time to time to improve them, which necessarily means a constant change in the form and type of the tie-plate. However, considering the cases which have come under the personal observation of this committee in connection with the answers to inquiries which we have sent out to many experienced railroad men who have used the various types of tie-plates, we beg to submit recommendations as to the general construction and use of tie-plates, which we herewith submit, together with the facts and general information from which we have drawn these recommendations:

1. That tie-plates be used always in preference to rail braces for greater safety and higher economy.
2. That tie-plates be used on all ties where the life of the tie is limited by the cutting or sawing action of the rail.
3. That tie-plates be used on all ties whose life is limited on account of the destruction caused by spike killing.
4. That tie-plates with soft ties be used in preference to hard ties without any plates, when the natural life of the soft tie is equal to or greater than the natural life of the hard tie, cost being equal.
5. That the only plate used be one which becomes practically part of the tie.
6. That as a tie-plate is intended to prevent the cutting action of the rail flange across the wood fibers of the tie, the plate used should not itself cut such fibers and should prevent the rail from cutting them.
7. That a tie-plate having sufficient thickness to resist buckling, sand wear and rust, during the natural life of the tie, should be used.

General Considerations.—A tie-plate is a thin piece of metal placed beneath the rail and on top of the tie, with the object of preventing the latter being destroyed by the action caused by the movement of the former. It is not a rail chair, but is distinguished from the latter in being thin and light and often having a less bearing surface on the tie than the base of the rail would did it bear on the tie. The chair is a heavy piece of metal supporting the rail, and gives a greater bearing on the tie than the rail would if it rested on the tie.

In 1871 the first patent on a tie-plate proper was obtained. This was circular and had three teeth below it, but it did not come into extensive use. Several other patents were issued from time to time, but none of them, so far as we are aware, was ever put into practical use. In the '80's the first Servis tie-plate was invented and shortly afterwards put into use on a small scale.

This was abandoned for an improved one, and this latter was soon put into use on the Manhattan Elevated R. R., in New York, where such a device was badly needed to preserve the expensive ties in use and to economize the difficult tie renewals. Later came the C. A. C. Then the Goldie two-flanged. And shortly afterwards the Servis four-flanged, and the shoulder plate was put on the market. Then the Goldie claw, the Wolhaupter arch and girder tie-plate, and the Fox tie-plate were put into commercial use. Many patents have been secured on tie-plates, but the aforementioned plates are those which have been in use extensively, or are now in practical use.

The forces and strains to which plates are subjected are as follows:

1. As a wheel rolls over a rail each tie is loaded consecutively, and the ballast is compressed. The rail bends and takes an undulatory, wavy motion, or lever motion; the portion ahead and behind the wheel being higher than at the wheel. When the loads are heavy and the rails light, and ballast poor, the action is excessive.

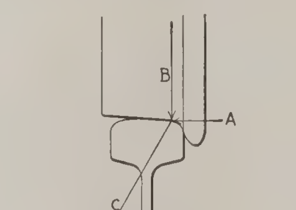

Fig. 1.

When the wheel is between two ties having plates on them, one edge of each plate is loaded. This has a tendency of raising or loosening the other edge of the plate, and at the same time causing the tie to churn—the wider the plate the greater this tendency is—and it is, therefore, apparent that a narrow plate is the best to resist these forces. This rising and falling of a light rail on a plate allows also small particles of sand to enter between the rail and the plate, which thus become an abradant, producing an injurious action on both rail and plate, if continued for any long period, and it would, therefore, appear that particularly where the rails are light some means should be provided for the excluding of this sand.

2. Another loading comes directly from the rail, and is of a compound nature, which is the chief source of tie destruction. This load is illustrated in Fig. 1.

The wheel flange is bearing sideways against the rail head, caused by the centrifugal force when it passes around a curve, or from the sway of the train. This force is shown by arrow marked A. The tread of the wheel is also bearing vertically down upon the head, shown by arrow marked B, and these two forces applied to the head of the rail produce a resultant force, shown by arrow marked C, through the rail which strikes the plate at a point marked D, near the outer edge of the rail flange. At D it is resolved into its two components again, with the result that there is a lateral force equal to A tending to slide the rail on the plate and widen gage, and with the vertical force B tending to press the plate into the tie and crush the fibers. This vertical force, B, will be found to be always much greater than the lateral force A.

Considering now the relative merits of a tie-plate and a rail brace to withstand these forces on a curve, it will be seen that in the case of the rail brace the small lateral force against the head is resisted by the upper portion of the rail brace and is taken care of by it, but as the vertical force is applied near the edge of the outer flange of the rail, this flange soon cuts into the wood and abrades it and allows the outer flange to become lower than the inner one and carries down with it the upper edge of the rail brace, tilting up the outer end, as shown in Fig. 2. It will be, therefore, seen that while a rail brace may take care of a small lateral force, it does not take care of the greater vertical force applied near the edge of the outer flange of the rail.

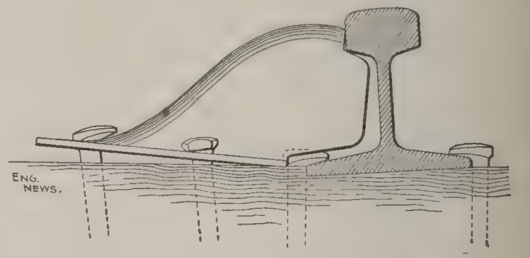

Fig. 2.

Considering now a properly designed tie-plate in place of a rail brace, we find that the great vertical force applied near the edge of the outer flange of the rail is taken care of by the plate and distributed over the tie beneath the plate and prevents the outer flange from cutting into the tie and canting the rail; but it is clear that to properly distribute this loading from the edge of the outer flange there should be more metal in the plate beyond the outer flange than beyond the inner one. The small lateral force causes the rail to slide outwardly on the plate, but this is prevented by the spike or shoulder outside of the rail, and as the plate ties the inside spike to the outer one the inside spike therefore also resists this tendency of the rail to widen gage; consequently, if there are as many spikes through the tie-plate as there would be through the rail brace, the tie-plate will prevent this lateral motion of the rail just as thoroughly as the rail brace would; but, as shown above, it also prevents the rail canting, which the rail brace cannot do. It is, therefore, very clear that a tie-plate is much better than a rail brace, and a tie-plate with more metal beyond the outer flange than beyond the inner one, is better than one which is equal at both ends. It is evident, of course, that the more metal, or shoulder, there is placed on top of the plate outside the outer flange of the rail the longer such metal will resist the wear from the lateral force, and as a continuous flange from edge to edge of the plate will give the most metal, such a flange would appear to be the most desirable, other things being equal, than a single spike, or even two spikes, particularly where the lateral force is extreme. However, there are many millions of plates in use, doing excellent service, without any shoulder, and there are difficulties, also, in shimming such shoulder plates in winter.

The above excellent features of a tie-plate on a curve also exist on tangents, but to a smaller degree. On tangents there is not only the great vertical force from the wheel, but there is more or less lateral force produced by the swaying of the train, trucks skewed out of level, etc., so that the tendency of all rails on tangents is to take an outward cant as well as on curves. This outward cant means widening of gage. This again means increased sway of the train, which again reacts upon the rail. If rail braces are used the tie must be constantly adzed to bring the rail to the perpendicular, thus destroying the tie and destroying the compact bed of the ballast. The rail brace must be removed and again respiked, thus spike-killing the tie, and all necessitating the spending of a great deal of time and labor.

Reports from Practical Experience.—In order to obtain, as far as possible, reports from practical experience, of the comparative merits of the different tie-plate used side by side in track, as well as the general experience with the use of any one kind of tie-plate, a circular letter was sent out to a large number of roadmasters and supervisors of our important railways in different portions of the country.

The following were the questions asked and answered:

> 1. Kind of tie-plate in use? 2. How long in use? 3. How do you apply them? 4. What is the average cost of applying a plate? 5. Have you the different kinds of plates under nearly the same traffic? 6. Kind of tie used? 7. Do you use them on curves only; if so, give the minimum of curvature? 8. Do you use them on every tie? What is your practice in regard to this? 9. Do they move longitudinally; if so, under what conditions? 10. What kind lengthens the life of the tie the most? Remarks.—Under this head state the amount of labor saved in respiking and other work incident to cutting ties, including any other information of interest.

We received a report from only one supervisor who had all o fthe different types of plates in use, but as this supervisor has nearly three-fourths of a million plates of the different kinds in use, about half of them having flanges across the grain of the wood and the other half with flanges parallel with the grain of the wood, and "has been using plates for the last six years," and as he has been studying them with care, his report is of great value. These plates were used on "yellow pine, chestnut and cedar ties," and he "drives them home with a heavy sledge," and says the cost of application varies from ⅜ to 9-16 ct. per plate. The plates are all used under the same kind of traffic and on curves "from two degrees up," and on "every tie on curves." They do not move longitudinally. His experience is that the plate which lengthens the life of the tie most "is the one with longitudinal flanges." Under "remarks" he states that at some curves where it was necessary to roll the rail and regage the track each year, "since plates have been put on these curves they have been kept in perfect gage and it has not been necessary to roll the rail in the last two years, and the rail lays perfect at the present time." "I have just as good results without a shoulder as with one. A plate with a longitudinal flange adheres to a tie better than one which cuts across the grain." In addition to this report he writes further as follows:

> I have had experience with the plates for the last six years under almost all conditions and have found that most of the talk about the spike shearing when it is not protected with a shoulder, is all nonsense. I find that if you keep the rails level so that they conform to the wheel base there will be no spread track, with or without shoulders. I have found that a tie-plate will lengthen the life of yellow pine ties from two to three years, and cedar and chestnut from three to five years. On curves where fast and slow trains are run the tie-plate will double the life of any kind of a tie, and when plates are properly applied they will stop the rolling of the rail, thus saving the adzing of ties to roll rail to gage and level. The plate should be so formed that the track can be shimmed without removing the plate. It should not be removed until the tie or rail is changed. I find that the plate with longitudinal flange adheres to the tie better than plates which cut across the grain. It should be formed so that it will adhere to the tie and become part of the same without injuring the fibers of the wood, and when once applied should not become loose and rattle. At the present time I have found none but the ones with long longitudinal flanges would adhere closely to the tie after they have been in track for a few years. The others will adhere to the tie for a short time, but will soon become loose and rattle.

He also writes relative to plates used in a heavy switch yard:

> These plates have been in track for eight months and have saved one set of ties. Before we used plates on this track it was necessary to renew the ties once every year, and some of them every six months. The cause of ties cutting out so fast is on account of the yard being damp and quite a lot of sand being used. Since tie-plates have been used in this track the ties are good for three or four years. This is one of the cases where plates pay if they wear out every six months, but the longer they last the better they pay.

2. A division engineer who has used some of the Servis, Wolhaupter and Goldie plates, writes as follows relative to his experience with thes different styles: He used them on every tie on curves of 6° and over, and at road crossings, and they are under the same kind of traffic. The ties are white oak and he applies them by "pulling the spike and raising the track high enough to allow adzing of tie level. Place plate under rail and spike to gage. Put plates into tie by striking lightly on edge of plates. After a few trains have passed over, tighten down spikes." In this manner it costs him between 1¼ and 2 cts. to apply these plates, and he finds they do not move longitudinally and "he has not noticed any difference to amount to anything," as to which kind lengthens the life of the tie most.

3. A roadmaster who is using Servis and Goldie tie-plates reports as follows: He uses them on white oak bridge ties only, and drives them into the wood with a 12-lb. sledge, which costs "about 1 ct. per plate." They are used "on every bridge tie," and "do not move longitudinally." He finds that the labor saved is about 50%, and says that he considers the Goldie lengthens the life of the tie most and gives better service than the Servis. The latter buckles.

4. An old, experienced roadmaster, who has about 70,000 Servis plates in track, reports as follows: He has used them on "2½° curves with oak, on cedar switch sets, and on center joint ties, where three ties are used." He applies them "by the aid of Ware's tie-plate surfacer and gage," and cost of applying is ½-ct. in ties out of track and less than 1 ct. when ties are in track. Oak ties used in both cases. He uses them on every tie, and finds they do not move longitudinally, and does not know which plate lengthens the life of the tie most. Under "remarks" he says:

> Having had 45,000 in use since 1892, on oak ties and on curves of 5° to 7½°, have not had to regage any part of it, and as the surface of the plates has not gone below the surface of the tie, and work of surfacing and regaging, caused by the rail cutting into the ties, has been entirely eliminated by their use. As an element of safety they are invaluable.

5. A division roadmaster, who is using the Wolhaupter and Servis plates, reports as follows: He has used these plates on white oak ties, on curves, since 1893-4, and he applies them by "pulling the spikes on every other tie, adzing the tie, and then driving the plate under the rail, which partly beds the plate in the tie. After a few trains pass over I then go back and apply them on the other ties." He says the average cost of applying them is "about 1 ct. per tie-plate." He uses them on curves "only 5° the minimum; under same traffic over both kinds of plates." He says, "I have had no trouble with them moving longitudinally." As to which lengthens the life of the tie most, he says, "The Wolhaupter Arch and Girder will give the best satisfaction. The Servis plates I have in use buckle; that is, turn up at sides of the rail." Under "remarks," he says: "I have used the plates on 5° to 10° curves. Before I put plates on these curves I had to adze the ties and regage the track once a year. Cost of doing this work, about 2 cts. per tie. I have had tie-plates on part of these curves for the last four or five years, and have not had to regage the track since the plates were put in. Before using the plates on these curves the ties would last four to five years, but by using plates we can get the full life of the tie, eight and nine years."

An engineer who has a large number of Servis and less than 100, each, of Wolhaupter and Goldie plates, says he uses the plates under the same kind of traffic and on oak and cedar, and merely "lays them on the tie." The cost of application is "practically nil." He uses them on both curves and tangent, on curves up to 18°. As to longitudinal movement, "under light rails and heavy traffic they move."

7. A railroad man who has a few of both Goldie and Servis plates in use on oak and pine ties, on joints only, states that they do not move longitudinally; that he prefers the Goldie, and that he finds considerable labor saved in the course of a year in re-spiking, adzing, etc.

8. Another roadmaster who is using a few of the Goldie and quite a number of the Servis, says he uses them on every tie, white oak, and on curves from 3° to 7°; that he applies them by "adzing to true gage, put heavy plate on top of tie-plate and sledge to close." The average cost to apply, "about 4 cts. per tie, when we have twenty to thirty trains in working hours, for the Servis, and about half that price for the Goldie." They do not move longitudinally "until the life of the tie is about gone." As to lengthening the life of the tie, "both kinds on a curve give longer life to a tie, neither kind will lengthen the life of a white oak tie on tangent." Under "remarks" he says, "The Goldie is a good, strong tie-plate, but will get loose on the tie sooner than the Servis, but the life of the Goldie will be much longer than the Servis. On a 3° curve and over, one-third labor is saved when the curve is well plated and the curve is safe. Our trains make 60 miles per hour on these curves. We use them under 80-lb. rails; 5-in. base. Have used Servis plates seven years. Like the last style of pattern best; it has a good outside lug that saves track spike and do not crack, but all plates will buckle when placed on poor ties."

9. An engineer of maintenance of way of a large traffic line, which has been one of the most extensive users of tie-plates for years, writes: "We have been using Servis tie-plates for several years past," and says, "that a great saving in the cost of tie renewals, and consequently in the expense of track maintenance, will be secured by their use. The kind of ties particularly used by us are redwood, the natural life of which (under heavy traffic) is seven years. With the use of tie-plates we hope to at least double this period."

10. A superintendent, who has had extensive experience with the use of different kinds of tie-plates, writes: "I am of the impression, however, that the Wolhaupter plates and well treated ties, with chloride or zinc solution, should give at least 30% of increase in life."

11. A superintendent of a road which uses plates extensively writes: "We believe that tie-plates materially lengthen the life of the ties, where ties are destroyed by the cutting of the rail, or by frequent spiking to maintain gage. With ties of soft wood, such as pine and chestnut, tie-plates are essential to secure the full life of the timber, and are especially so for bridge ties or switch ties. The gage is maintained easier and better when tie-plates are used, and we can maintain much firmer bearings between rails and ties than would be possible without the use of tie-plates. Tie-plates practically eliminate the labor of regaging or adzing to turn rail. Where sand is used freely the particular damage is due to softening of the wood, caused by the moisture held by the sand around the ties at the rails. In order to get the full benefit of the plate at such places it is important that the sand be kept below the base of the rail and the top of the tie be kept dry"

It might be well, before closing this report, to state in general the benefits to be obtained from the use of tie-plates:

(1) They prevent the tie from being cut by the rail and thus preserve the tie. a. Renewals in ties are reduced. b. Level of track is maintained. c. Adzing to maintain rail vertical is avoided. d. Cost of track labor is reduced.

(2) The rail is held vertical, and thus—a. Safety of operation is increased. b. Gage is maintained.

(3) The inside spikes help to maintain gage in addition to the outside spikes. a. They dispense with rail braces. b. Prevent the rail rolling. c. Maintain gage by preventing the rail rolling.

Thus, in general, it will be seen that a properly constructed tie-plate maintains good track and thus makes a large saving in the labor of track maintenance and in the cost of repairs to rolling stock through the more perfect track which it produces. It increases the life of the tie and thus decreases the cost of tie renewals. It saves in the cost of operating, through the possibility of carrying heavier loads with the same amount of motive power.

W. J. Prindle, J. L. Single, Henry Ware, Edward Marshall, committee.

In previous years the tie-plate report has provoked much discussion; but this year the report was received with little objection, and the seven recommendations of the committee, given above, were formally approved by the association.

In the afternoon and evening there were trips to the Elitch Gardens, a pleasure resort, where a theatrical entertainment was provided.

The morning session on Wednesday was called to order at 9.30 a. m. There was no report from the Committee on Rail Joints, but Mr. Hickey exhibited a model of the joint with an inverted piece of rail for a base support, invented by Mr. A. Torrey, Chief Engineer of the Michigan Central R. R., and recently described in our columns.

Two reports were presented by the committee on "The Advisability of Increasing the Length of Rails, and the Advantages to be Derived from the Use of Rails with Miter Cut Ends." Both the majority and minority report were printed on p. 172 of our last issue. The discussion turned largely on the expansion and contraction of light and heavy, long and short rails, and the opinion was expressed that heavy long rails take up more of this movement in themselves by internal stresses, while they take longer to heat up to high temperatures. Both reports were accepted as information, on the ground that comparatively few roadmasters have had experience with long rails or miter joints, and cannot therefore vote intelligently upon their wants. The report of the committee on "Widening Gage on Curves" was then read and was probably the report of greatest practical value read at the convention. We print it substantially in full as follows:

Widening Gage on Curves.

The question of widening gage on curves naturally divides itself into two heads: First, the reason, if any, for widening; and, second, the proper amount that the gage should be widened. There is no question but that the majority of roads in the past have widened the gage on curves too much, and without any thought of the reasons for doing so. The present method of gaging wheels gives a clearance of from ⅝ to ⅞-in. on tangent, and it is evident that no good reason whatever can be assigned for widening the gage on the curve, so long as there is sufficient clearance between the flange of the wheel and the rail to permit of the wheel taking a natural position in going around a curve. In other words, so long as the wheel is not forced out of normal position by the rail, or so long as the rails are not disturbed or forced out of their position by the wheels of the truck in passing around. If this be the case, then the second part of the question is simply to find out at what degree of curvature this play would be absorbed by reason of the sharpness of the curve. As in all questions of this nature, there are two factions who do not agree upon the fundamental principles involved in a mathematical discussion. The only two authors who have ever discussed this question thoroughly are Trautwine and Searles. Trautwine's discussion of the problem is based upon the theory brought out by the late A. M. Wellington, whose experiments upon a kindred subject involving the action of trucks in passing around curves, are very elaborate, being made with large-sized models and full-sized trucks. The theory deduced by him from these experiments upon the action of a truck in passing around a curve would be expressed as follows: In any truck system the flange of the forward wheel is invariably pressed hard against the outer rail, all the other wheels standing away from the rail and the rear axle always being normal to the curve except when forced out of that position by the rear inner wheel coming in contact with the inside rail, as shown in Figs. 1 and 2.

The followers of Mr. William H. Searles oppose the Wellington theory and hold his proposition is not proven. Mr. Searles takes the position that when a truck is passing around a curve, the flange of the forward wheel is invariably pressed hard against the outer rail and that the other wheels ordinarily stand away from the rail, and that the rear axle may or may not assume a normal position. Various positions are shown in Figs. 1, 2, 4, 5 and 6. When a truck has but four wheels the other three flanges are not usually in contact with the rails, the rear wheels dividing the play between in some unknown ratio. The sharper the curve the nearer the flange will approach the inner rail, and when by reason of the sharpness of the degree of the curve the rear inner wheel comes in contact with the rail, then the middle ordinate to twice the wheelbase will be just equal to the play allowed in setting the flanges. The rear axle will then be normal to the curve at the point of contact with the rear wheel. The sharpening of the degree of the curve beyond this point will force the rear axle into a position as shown in Fig. 2, and the flange of the rear inner wheel will then be grinding against the inner rail. In a six-wheeled truck, all flanged and with equidistant axles, the same is true as in the four-wheeled truck, up to the time that the rear inner wheel comes in contact with the rail, as shown in Fig. 4. If the curvature is then sharpened, the track will finally assume the position shown in Fig. 5, and the truck will then be wedged tight in the track, the points of contact being the outer front and rear wheel and the middle inner wheel. This happens when the middle ordinate to the chord of the wheelbase equals the play originally allowed in setting the wheel, and of course would indicate the limit of curvature of track at which the truck would go around without spreading the rails. This limit of curvature is expressed by the following formula propounded by Mr. Searles:

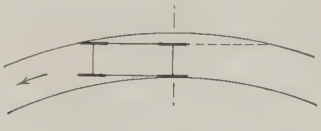

Fig. 1.

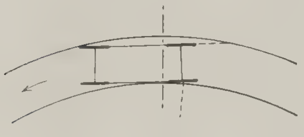

Fig. 2.

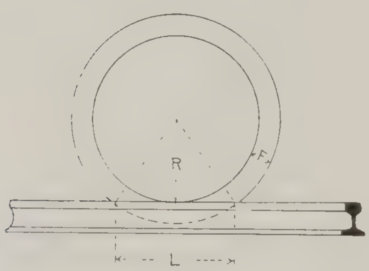

Fig. 3.

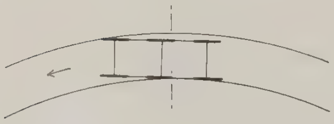

Fig. 4.

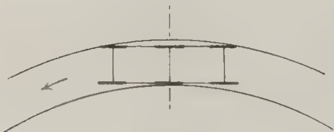

Fig. 5.

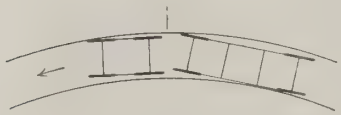

Fig. 6.

$$D = \frac{3825\ p}{I^2}, \qquad (1)$$

in which D = the degree of curve sought, p = the original flange play in inches, and I = the rigid wheelbase in feet.

If the middle axle is not equidistant from the others, let the distances be expressed by a and b in feet, then the formula becomes:

$$D = \frac{956\ p}{a\ b}. \qquad (2)$$

This is a general formula and applies to trucks of eight wheels, all flanged, as well as six wheels or more, and consequently is true for rigid locomotive wheelbases. Applying this formula to an engine with ⅝-in. clearance and maximum rigid wheelbase of 22 ft. 6 ins., the point at which gage should be widened is 5° 30′ curve; but if the swiveling device in the leading truck of locomotive is to be called into play in passing around a curve, Mr. Searles proposes the following equation:

$$D = \frac{956}{a\ b}\left(p + \frac{b\ s}{a + b},\right) \qquad (3)$$

in which b is the driving wheelbase, a the distance from the center of the forward driving axle to the center pin of the pilot truck, s the side motion of the center pin in inches, and p the play allowed by the flanges in inches, D the same as in the other equations. Use coefficient 955 up to 16°. For D = 20° use 960; for D = 30° use 966, and intermediate degrees in proportion.

This formula is based on the conditions that the center pin has exhausted its full side motion. The forward flange driving wheel is in flange contact with the inner rail, and the rear driving flange is in contact with the outer rail. Taking the same example as in the preceding problem, and supposing that the leading truck has a side motion of 1¾ ins., that the distance a is 7 ft., then b would be 15½ ft., and applying the equation (3) we find that D is equal to 16° 12′. With all the conditions assumed in this problem then, the gage would not have to be widened for such an engine up to a curve a fraction over 16°. If it were wished to determine how much a given sharper curve should be widened, it is only necessary to solve equation (3) for p, but write P to indicate the total clearance required, and then

$$P = \frac{D\ a\ b}{956} - \frac{b\ s}{a + b}, \qquad (4)$$

which, if the original clearance is subtracted, will give the amount that the gage should be widened for a given wheelbase.

A question which Mr. Searles has not taken into consideration is that the point of the flange where the wheel would come in contact with the rail in passing around a sharp curve is not vertically under the center of the wheel, as he assumed, but is a point on the wheel flange which is $\sqrt{(R+F)^2 - R^2}$ distant from the vertical through the center of the wheel. This, of course, for small wheels, could be ignored, but for large drivers on sharp curves it becomes an important factor.

Experiments having been made by your committee, they find that curves up to 6° can be laid to gage. Also, that allowance has to be made for the swiveling device on the pilot truck, owing to the fact that in a great many cases the full play is not secured. From tests this should be taken at one-half the amount. Owing to the great variety of wheel gages which pass over a road, allowance has to be made in gaging the track, consequently your committee does not recommend taking up the entire amount of clearance on curves, but rather of allowing one-half inch for any variation. Therefore, your committee would modify the Searles formula and recommend formula (3), modified as follows:

$$D = \frac{956}{a + b}\left((P - \tfrac{1}{2}) + \frac{\tfrac{1}{2}\ b\ s}{a + b}\right) \qquad (5)$$

and in place of formula (4) the following:

$$P = \left(\frac{D\ a\ b}{956} - \frac{\tfrac{1}{2}\ b\ s}{a + b}\right) - \tfrac{1}{2}. \qquad (6)$$

In view of the fact that allowance has been made for variations of wheel gage, your committee does not consider it necessary to take into account the formula

$$\sqrt{(R + F)^2 - R^2}.$$

The limit of widening the gage, in the committee's opinion, should be 1 in.

As the various roads have different clearances and a variety of wheelbases, it is impossible to give a table which would be applicable everywhere; but by substitution in the formula given, a series of tables could be gotten up by the different roads which would meet all their requirements.

As an example, in the use of formulas 5 and 6, a New York, New Haven & Hartford consolidation locomotive is taken, of which the following are the figures to be used:

Wheelbase equals 22½ ft., of which 7½ ft. is the distance from the center of the forward driving axle to the center pin of the pilot truck, and equals a in the formula. The rigid wheelbase is 15 ft., and equals b. The side motion of the center pin in inches equals 1¾ and is represented by s. The play allowed by the flanges in inches equals ⅝, and is represented by p. D equals degree of curve after which widening should begin. Substituting in formula (5), we have:

$$D = \frac{956}{7.5 \times 15}\left((\tfrac{5}{8} - \tfrac{1}{2}) + \frac{\tfrac{1}{2} \times 15 \times 1\tfrac{3}{4}}{7.5 + 15}\right)$$

$$D = \frac{956}{112.5}\left(\tfrac{1}{8} + \frac{13.125}{22.5}\right) = 8.5\ (\tfrac{1}{8} + .583).$$

$$D = 8.5\ (.708) = 6.018 = 6°\ 1'.$$

or widening should begin on curves of over 6°.

Substituting in formula (6) and calculating for a 16° curve,

$$P = \left[\frac{16 \times 7.5 \times 15}{956} - \frac{\tfrac{1}{2} \times 15 \times 1\tfrac{3}{4}}{7.5 \times 15}\right] - \tfrac{1}{2} =$$

$$\left[\frac{1{,}800}{956} - \frac{13.125}{22.5}\right] - \tfrac{1}{2} = (1.883 - .583) - \tfrac{1}{2} =$$

1.3 — .5 = .8-in., or, for all practical purposes, P = ¾-in. In other words, from 6° to 16° the widening will be ¾-in., for the example in question.

If D equals 18° 30′, we have by substitution in formula (6),

$$P = \left[\frac{18.5 \times 7.5 \times 15}{958} - .583\right] - \tfrac{1}{2}$$

$$\left[\frac{2{,}081.25}{958} - .583\right] - \tfrac{1}{2} =$$

(2.172 — .583) — ½ = 1.589 — .5 = 1.089 ins., or, for practical working, P = 1-in.

As previously stated, it is impossible to give one table which would cover all roads; but your committee would suggest for use on those having engines about of the type mentioned in the examples, a table which is practically taken from the above results:

Degree of curve.	Amount of widening, ins.	Gage of curve, ft.	ins.	Degree of curve.	Amount of widening, ins.	Gage of curve, ft.	ins.
1	0	4	8½	10	¼	4	8¾
2	0	4	8½	11	⅜	4	8⅞
3	0	4	8½	12	½	4	9
4	0	4	8½	13	½	4	9
5	0	4	8½	14	⅝	4	9⅛
6	0	4	8½	15	¾	4	9¼
7	⅛	4	8⅝	16	¾	4	9¼
8	⅛	4	8⅝	17	⅞	4	9⅜
9	¼	4	8¾	18	1	4	9½

Therefore for types of engines as mentioned, the widening of the gage should begin on curves of over 6°, and increases 1-12-in. for each degree of curvature over 6°.

F. R. Coates, A. S. Westin, R. P. Collins, J. W. Shanks,
H. B. Dick, Committee.

In the afternoon of Wednesday the concluding session was held. The last report presented was that of the committee on "The Latest Improvements in Frogs and Switches" (Eng. News, Sept. 15, p. 173). There was but little discussion and the report was accepted.

The vote on the place for holding the next convention resulted in the selection of Detroit. After this, resolutions of thanks to local committees, etc., were passed, and the new officers were installed.

During the afternoon there was an electric railway trip of some 20 miles for the ladies, and in the evening Mr. C. M. Hobbs, of the Denver & Rio Grande R. R., delivered a lecture on "Switzerland and Colorado," illustrated by beautiful stereopticon views.

On Thursday there was a trip over the narrow gage Union Pacific, Denver & Gulf Ry. to Georgetown and around the famous "Loop" to Silver Plume, where the railway winds up both sides of the valley, crossing from side to side, and rises 700 ft. in four miles.

On Friday the party left Denver at 7.30 a. m. for Colorado Springs and Manitou, visiting the Garden of the Gods and ascending Pike's Peak by the Abt rack railway. The night was spent at Manitou, and on Saturday there was a trip over the Denver & Rio Grande R. R. to the Royal Gorge, returning to Pueblo for dinner. In the afternoon the party visited the works of the Colorado Coal & Iron Co., after which they returned to Denver.

The Road and Track Supply Association, made up of the supply men in attendance upon the convention, elected officers as follows: President, Wm. Goldie (Dilworth & Porter Co.); Vice-President, J. A. Ingalls (Buda Foundry & Mfg. Co.); Secretary J. A. Brown (Pocket List Publishing Co.); members of the Executive Committee, Messrs. Bray and Fisher.

ANNUAL MEETING OF THE TRAVELING ENGINEERS' ASSOCIATION.

The sixth annual meeting of the Traveling Engineers' Association was held at Buffalo, Sept. 13 to 16. President D. R. McBain, in his address, said that the competition of electric railways must be met by greater economy in locomotive operation. He believed hard steaming locomotives to be the most fruitful source of waste in the motive power department.

The report of the Secretary showed a total membership of 235 railway companies. The receipts were $1,246 and the expenses $1,196. The first committee report was on the question:

What Is the Best Method to Be Pursued by Traveling Engineers in Giving Air Brake Instructions While on the Road?

The report was a very long and detailed one. Space permits an abstract of only a few points touched upon. Holding the brake set too long on passenger trains at the instant of stopping gives a disagreeable surge to the train, and may throw passengers off their feet.

When coupling an air brake engine to her train, the auxiliary pressure on engine and tender can be held down close to the train pipe pressure on the train by not charging auxiliaries up to the full pressure after each release of the engine brake, till hose is coupled ready for air to pass back to train. This will allow you to move the engine if it is necessary to do so to make any more couplings in the train. Do not test the brake until you have the standard pressure. Then make the reductions for a station stop; the first one just hard enough to be sure that all the leakage grooves are covered, and successive light ones afterward, till the train line pressure is reduced 20 to 25 lbs. On no account make an emergency reduction when testing the brake unless it is especially called for after the first test.

Take up the matter of listening for the length of the train pipe exhaust so as to judge of the number of car lengths of train pipe attached to the brake valve, and thus be able to judge whether they have all the angle cocks open. A partially closed angle cock can be detected by the intermittent flow of air from the train pipe discharged at the first reduction. A partially closed angle cock will allow the brakes behind it to set with a service application, but unless all the triples are in good order, some of them will be sure to release slow enough to jerk the train or stick altogether.

In coupling up hose, the angle cock next engine should be opened first so that the hose will be filled with air from the engine instead of from train pipe of the rear cars. Never open the angle cocks suddenly when the train pipe and auxiliaries are charged with air. It is certain to set all the brakes on that side of the empty hose with the emergency action. If the cocks are opened gradually so air will fill into hose and empty the train pipe, it is only a few seconds before it will equalize with the air in the already charged cars, and then the angle cock can be opened full. Show the trainmen how to couple onto an uncharged car or cars in a siding, and at the same time leave brakes on head end of train free, so that they can at once pull out to couple on the train and utilize the time while moving out of the side track to charge up the empty cars. In the majority of cases the last cars taken on will be fully charged by the time the stop is made for coupling on, and the test of brakes may be made then.

Take up with the trainmen the proper method of using the hand brakes in connection with the air brakes on a partially equipped train. Show them that the hand brakes should be set on the cars immediately behind the air braked cars, as that is the place where the slack in the train can be most easily taken care of, whether air or hand brakes are set or released. When releasing air brakes after hand brakes have been set on rear cars of train, it is absolutely necessary to have hand brakes next the air let off last of all. When backing out of a siding, show that hand brakes should be set on rear cars to hold the slack.

A very important point to take up with the engineers is the wasting of air in the auxiliaries by repeated applications and releases, and the still greater waste by setting the brake full on and then still further reducing the train pipe pressure below the proper amount. On a long train this may become criminal carelessness and cause a wreck by getting out of air on a bad hill.

If an engine is fitted with independent driver brakes, do not tolerate using this for bunching slack in train prior to use of train brakes, especially with all or nearly all air braked cars. These independent engine brakes should only be used independently when releasing the train brakes at slow speeds (when handling freight trains) or in bunching slack in train when going over uneven roads, "hog backs" and sags in track.

The use of pressure retaining valves on driver brakes of freight engines avoids lots of rough handling and prevents breaking in two. When stops are made for stations, water tanks and coal chutes, should the engineer see that he is going to stop too soon, and has to release the brakes, he turns up the pressure retaining valve before doing so, and thus holds the train bunched, as the retaining valve prevents the engine and front cars from running ahead. When the second application is made, there is very little chance of breaking the train in two and very little shock is felt at the rear end.

How Can the Traveling Engineer Best Instruct and Assist the Fireman in the Economical Firing of the Locomotive?

In this report stress was laid on the selection of men of some intelligence and ambition for firemen. In endeavoring to secure economy of fuel, it must not be allowed to interfere with the requirement that the engine shall hold its load and make its time. Good results can be secured by giving firemen elementary treatises on combustion, and seeing that they study and understand them. It is absolutely necessary to economy of fuel that the engine runner and the fireman should work in harmony, and the Traveling Engineer should have authority in the making up of engine crews to see that this is effected.

The Uniformity of Cab Fittings and Their Arrangement with a View of Accessibility and Utility.

The great variety in locomotives which now exists makes uniformity impossible; but whatever the type of locomotive, no pains should be spared to arrange the cab fittings where they will be most convenient for the engineer. A combination stand or turret supplied from a dry pipe in the dome, and fitted with an inside closing valve, was favored. The convenient location of the brake valve is the most important matter. It should not be so close to the boiler that the heat will injure the gaskets, and the handle should be where the engineer can reach it when he has his head out of the window looking for signals. The grouping of gages is an excellent plan, and uniformity in the diameter and graduation of the same gages on different locomotives in the same "pool" is much to be desired.

Lubrication of Locomotives; the Best Method of Reducing Hot Bearings to a Minimum with the Least Amount of Oil.

The report on this subject gave a large number of practical hints of much value, including answers to a long list of questions sent out by the committee.

The Use of Water on Hot Bearings of Engines and Tenders. Is it Advisable, and to What Extent Used? In Using Water for Hot Driving or Engine Truck Boxes, is it Used on Top or Side of Boxes?

It appeared from the report of this committee that on heavy locomotives in fast passenger service it has become quite common to fix pipes from the tender or injector pipe connections so that water can be turned on tender or engine truck journals or the driving boxes if they get hot on the road. On some roads, it is stated, that the fastest trains are only able to keep to their schedule by this means. One member stated that, besides his locomotive experience, he had been eight years in marine service, and had been in vessels where engines ran without stopping for 30 days with nothing but water as a lubricant in some of the heavier bearings.

Does the Location of Track and Station Signals in Any Way Affect the Safe and Economical Operation of Locomotives?

The following is an extract taken form the report of this committee:

> Every time a train is stopped or its speed reduced, there is not only more fuel used, but there is also more strain on the machinery of the locomotive, and on the draft rigging of cars getting the train into speed again, than there would have been had the speed of trains not been checked. This means not only increased cost of fuel, but also greater cost for repairs. Track and station signals are intended to indicate to engine and trainmen whether the track ahead is clear or blocked. They should be so located that engine and trainmen can distinguish them at a sufficient distance without having to reduce speed if the track is clear or be in danger of overrunning the signal if the track is blocked. Signals located where they cannot readily be seen or distinguished, or placed where their meaning may be wrongly interpreted, are neither safe nor economical. They require every train that passes them to slacken speed and the extra expense this causes in the course of a year is a large item. In addition to this expense, there is also an element of danger connected with such signals that should not be overlooked. With the high speed at which trains are run, and the heavy tonnage hauled, engineers are compelled to take every advantage possible to keep their trains on time. With signals properly located they have no difficulty in doing this; but where signals are located obscurely, it is often a question with him whether he will reduce speed to a safe limit, or take chances on the signal showing clear track. He may do this for a number of times with safety, but sooner or later the inevitable will happen and the wrecking crew will be needed.

In addition to the reports abstracted above, the following report of a special committee appointed at the meeting met with general approval:

The bearing at the back end of main rods is a very important and often a very troublesome one, and it is necessary that the brasses of these bearings be carefully fitted—that is, filed so as to be free of bearing at the joints of brasses and for a distance not less than a ½-in. from that point. The fitting of brasses to back end of main rods should be done so as to leave them free from the pin at all points. The size of the oil hole in all rod brasses should be as large as the oil hole in the strap. When the temperature of a brass bearing has been sufficiently raised to cause a discoloration it will ever afterwards be found unreliable.

With proper mechanical conditions existing, engine oil is the proper lubricant for all rod bearings. In the event of a pin becoming heated, valve oil (owing to its higher fire test) should be used. Engine oil should also be used for the lubrication of eccentrics. These should be supplied through a cup similar to that used on rod bearings. There should be a cellar in eccentric straps, oil cups on rocker boxes, also packing in link block oil holes. A link motion judiciously oiled can safely be run from 75 to 100 miles with one oiling. Oil cups which can be shut off at the end of each trip should be used for the guides. Oil applied by hand is wasted.

It will be found a valuable aid towards keeping cylinders, pistons, piston rod packing, valves, valve seats and valve stems in good condition to keep the main throttle valve slightly open when going into stations or down long grades, as it overcomes the vacuum forming tendency of the main pistons and prevents the drawing into the cylinders and steam chests of the smoke-box gases.

It is a good practice to groove the face of the piston packing rings, with the object of reducing the area of the surface of the ring in contact with the cylinder surface, as well as forming a partial balance to the piston and a receptacle for oil. The best point to have oil reach the driving and engine truck journals will be found to be as near the horizontal center of the journals as is possible. The use of a driving box cellar which will permit of the inspection or renewal of the packing without taking the cellar down is advisable. Enginemen should be instructed not to stir up the packing on the top of driving boxes, as it has been found to result in the heating of those journals, owing to the dirt which accumulates there being carried with the oil into the oil holes and onto the journals.

It is a necessary requisite for engine or car oils to be of such a consistency as will permit a free flow at atmospheric temperature. Tender truck journals should be lubricated by roundhousemen, who should be instructed to inspect these parts each trip to see that the packing is saturated with oil and kept in close contact with the journals. The best results are obtained by assigning this work to special men. Where engines are not equipped with a device which assures a constant feed of oil to the valves and cylinders of high pressure engines at all times, the enginemen should be instructed to vary the main throttle opening at intervals to permit the oil which has lodged in the oil pipes to flow into the steam chests.

Officers for the ensuing year were elected as follows: Pres., D. R. McBain (Mich. Cent.), Jackson, Mich.; First Vice-Pres., P. H. Stack (U. P.), Council Bluffs, Ia.; Second Vice-Pres., Charles Davies (Erie), Buffalo, N. Y.; Third Vice-Pres., C. P. Cass (St. L. & S. F.), Monett, Mo.; Secy., W. O. Thompson (L. S. & M. S.), Elkhart, Ind.; Treas., C. A. Crane (A. T. & S. Fe), Fort Madison, Ia. Executive Committee, J. R. Belton (C. & O.), Covington, Ky.; C. B. Conger (C. & N. W.), Grand Rapids, Mich.; I. A. Brown (C. & O.), Covington, Ky.

The next meeting will be held in Cincinnati, O., the 3d Tuesday in September, 1899.

Any of our readers desiring to secure the complete reports above abstracted should address Mr. W. O. Thompson, Elkhart, Ind., the Secretary of the Association.

ANNUAL MEETING OF THE NEW ENGLAND WATER-WORKS ASSOCIATION.

The seventeenth annual convention of the association was held at the Hotel Wentworth, Portsmouth, N. H., Sept. 14 to 16, inclusive. Mr. Willard Kent, President of the association, delivered an address after the usual opening exercises. He stated that the membership of the association had increased from 27 at its organization to 570 on June 1, 1898. During the past year the average attendance at the winter meetings was 84, the minimum having been 75. The report of the Treasurer showed a balance of $2,937, a gain of about $200 during the year. The Secretary stated that the 570 members were divided as follows: Active, 488; honorary, 5; associate, 77. The gain in membership during the year was 21.

Method for the Determination of Color and the Relations of Color to the Character of the Water.

The first paper read had the title given above, and was by Mr. Frederick S. Hollis, Biologist, Metropolitan Water Board, Boston. The author stated that the color of surface water varies with the amount of carbonaceous matter present. In unpolluted surface waters there is a pretty close agreement between the amount of color and the oxygen consumed, loss on ignition and albuminoid ammonia in solution. In contaminated waters there is no direct relation between the color and the chemical constituents. The color of water increases with stagnation. At the deepest part of Lake Cochituate the color at the surface has been observed to be 0.22, against 1.20 at the bottom. After standing, however, the color of the bottom sample increased to 3.70, by the oxidation of iron. The high color of this sample is no indication of the character of the whole lake, as the deep place from which the sample was taken has only a limited area. Much of the color of water is due to peaty materials, and much of that of surface water is caused by leaves. The author concluded his paper by describing the various color standards in use, including the Neslerized ammonia of Leeds, the platinum-cobalt of Hazen and the device designed by FitzGerald and Force.

Some Things that Should be Done in Constructing a Distributing System of Water-Works.

This paper was by Mr. Wm. R. Hill, M. Am. Soc. C. E., Chief Engineer and Superintendent of the Water-Works of Syracuse, N. Y. Attention was first called to the necessity of rigid inspection of pipe during its manufacture, including both material and workmanship. The joining of three or four lengths of pipe before lowering into the trench may be a little cheaper, but there is liability of injuring the joints. A block of masonry should be built back of all bends, hydrants and ends of all lines more than 6 ins. in diameter, to take up the pressure. The pipe should be tested after it is laid, to a pressure at least 100 lbs. in excess of the ordinary pressure the pipe is to withstand in service. Good castings for corporation and curb cocks may be made from a mixture of 88 parts refined copper, 6 parts tin, 3 parts lead and 3 parts zinc, but the zinc should be omitted if there is alkali or salt in the soil, or corrosion will result. Regarding service pipes and the use of fire hydrants for filling sprinkling carts, Mr. Hill may be quoted in full, as follows.

> Service pipes should be laid in straight lines at right angles to the axis of the street so that at a time of a leak the location of the corporation cock could be easily determined from the position of the curb cock. This, together with the fact that the main is laid at a fixed distance from the center of the street, will enable the repair to be made with the least possible disturbance to the pavement. If the service pipe is of lead all the solder joints between the main and curb should be made in a shop, as better work can be done there than in a trench. To one end of the pipe the tail piece of the corporation is soldered, while to the other end is the curb cock and a piece of pipe about a foot long is attached. The pipe is then coiled up and taken to the trench where it is to be used. The tail piece is attached to the corporation and the service is complete to a point one foot beyond the curb cock, where the joint connecting with the service to the building is made. None but the best of solder for the purpose should be used. The service pipe between the main and the curb should be made of one piece, and no unnecessary joints should be permitted. All short

pieces of lead pipe can be melted up and used for calking joints in cast-iron pipe. A service pipe should not be laid in the same trench or close to a sewer. It would be hard to discover a leak should one occur in such a service, as the water would not appear on the surface of the ground, but would find its way to the sewer. Where a sewer or other trench is excavated crossing under a lead service pipe, the pipe should be properly supported, as when the trench settles it would carry the pipe with it and would be apt to cause a leak at the nearest joint.

Fire hydrants should not be used as fixtures to fill sprinkling carts with water, unless they are provided with a special valve and nozzle for that purpose. Such a valve and nozzle can be made in the dome or cap of the hydrant. During the season when sprinkling is done the drip is closed and main valve in the hydrant is slightly opened, so that there is a constant supply of water in the barrel of the hydrant. The men who sprinkle cannot interfere with the main valve or nozzles, as their wrench will not fit them. To use these hydrants for fire purposes the firemen first close the main valve with three turns of the valve rod. They cannot make a mistake and take off the upper nozzle, as that requires a smaller wrench. No one but a fireman or an employee of the water department should be permitted to have a wrench that will open the main valve. These special hydrants should be placed at points convenient for the purpose of sprinkling. In the city of Syracuse, N. Y., there are 200 that have been in use two years, and have been very satisfactory, both to the water and fire departments. A frequent cause of trouble with hydrants is because they are not properly drained to a sewer. If this connection were made with a lead or wrought-iron pipe there should be no liability of the hydrant becoming frozen.

In answer to questions Mr. Hill stated that the special nozzles for filling sprinkling carts, described above, are on Eddy hydrants. He liked to see the lead driven ⅛-in. inside the bell. If that is done and the pipe tested to 100 lbs. above what it is to bear, he felt safe. On the Skaneateles Lake pipe line, at Syracuse, no leaks have been discovered since the pipe was put in use, some four years ago, and it is patrolled daily.

Mr. Fuller stated that on some systems under heavy pressure he had used cast lugs and rods to hold hydrant in place, instead of masonry supports.

Mr. Crandall expressed the opinion, with which several members afterwards agreed, that very poor coating had been put on cast-iron pipe of late, and that, in general, the pipe has been of poorer quality since the fall in prices. Mr. Coffin thought one cause for the poor coating is that the pipe is not left long enough in the bath, owing, perhaps, to rush of work at the foundries. He had been considering the advisability of lining cast-iron pipe with cement. Theoretically, a 6-in. cast-iron pipe reduced to 5¼ ins. by a cement lining would discharge as much water after 15 years as a 6-in. cast-iron pipe at the end of that period. Mr. Richards thought it would be cheaper to make the cast-iron pipe larger at the start.

The Water-Works of Portsmouth, N. H.

An informal talk on these works was given by the Superintendent, Mr. Ayers. They were built in 1798, by a company, and sold to the city in 1890. The first supply was by gravity from a spring which is still in use, delivering 300,000 to 400,000 gallons a day. In 1798 there were 127 water takers, paying a total of about $700 a year for water. In 1840 there were 459 takers, paying $3,800, and in 1890, when the city took the works, some 1,900 takers paid $23,000 a year.

The last of the wooden logs laid in 1798 were taken up in the 70's, when it was found that the 5-in. bore had increased to 8 ins., save for projecting knots, and the interior was polished as smooth as mahogany. All sorts of service pipes have been used during the last hundred years, including 1½-in. cast-iron pipe lined with ½-in. glass tubes, and wrought-iron pipe, enameled inside and outside with glass.

The Occurrence of Cristatella in the Storage Reservoir at Henderson, N. C.

This paper was presented by Mr. Robt. S. Weston, C. E., of Brockton, Mass., who was called to Henderson last July to ascertain the cause of a bad odor in the water furnished by the Henderson Water Co. The source of supply for these works is from spring-fed brooks, impounded in a shallow reservoir having a maximum depth of 10 ft., while most of it is only 4 ft. deep. The drainage area is 2.32 sq. miles, composed mostly of arable and pasture land, with some swamps and peaty matter. There is a population of 509 in the drainage area, or about 220 per sq. mile. There are 87 privies in the drainage area, but none are within less than 100 ft. of any stream, and the soil is so sandy that all the water is subjected to natural filtration, except during freshets. The cristatella develops in the reservoir every year, between July 1 and Sept. 15, giving rise to an odor like heaps of old oyster shells. The organism is a polyzoan, or moss-like animal, which attaches itself to the sides and bottom of the reservoirs, grows only in the light, and spreads by a budding process. It occurs at Henderson in greatest numbers when the temperature of the water is at the maximum, which was 85° F. this year. The temperature of the water in the feeders was lower, and few or none of the organisms developed there. They grew in greatest numbers near the intake, where the water was shallow and the temperature highest. If the reservoir was deeper, so the temperature would not rise so high, doubtless there would be no trouble. To remove the odor, as well as the turbidity which occurs at times, Mr. Weston recommended aeration, with subsequent filtration through a Warren filter. The aerator is placed over a small settling tank. Water passes upward to and through a ball nozzle, above which is a hood which deflects the water downwards over four steps, or weirs, one above another, pyrimidal in form, the lower step being 5 ft. sq. The daily capacity of the plant is to be 300,000 gallons. The daily consumption averages about 75,000 gallons. The plant is now being built. Questions put to Mr. Weston by members brought out the statement that he believed mechanical filtration to be cheaper than slow sand filtration in this case, since for taking out these comparatively large organisms a higher rate of filtration was permissible than where bacteria are to be removed.

The Water-Works of Monson, Mass.

A description of these works was read by Mr. F. L. Fuller, M. Am. Soc. C. E., of Boston. The plant was built in 1894-5, with Mr. Fuller as engineer and Mr. E. E. Eglee, of Flushing, N. Y., as contractor. The supply is taken from a large well located near a stream with a drainage area of about 6 sq. miles above the location of the well. The well is over 300 ft. above the village, thus giving a good gravity pressure, a very unusual thing for a ground water supply. The well has an inside diameter of 73 ft. at the top and 69 ft. at the bottom, the water generally being 19 ft. deep. Its storage capacity is about 675,000 gallons. The wall is of dry rubble, packed on the outside with broken stone, which gives some additional storage capacity. An iron roof covers the well. About 19 acres of land surrounding the well have been bought by the town.

Since these works were built the state of Massachusetts has built an extension of them to supply the Hospital for Epileptics, located in Monson. The chief feature of the extension is a distributing reservoir, 41 ft. in diameter at the top and 39 ft. at the bottom, having a concrete roof. A band of soft steel encircles the outer wall of the reservoir, to take up the thrust of the roof. The roof has a 4-ft. rise, and the concrete is 10 ins. thick at the springing line and 8 ins. at the top, the whole being covered with earth. The concrete is composed of 1 part Alsen's Portland cement, 2½ parts clean, sharp sand, and 4½ parts broken stone, not exceeding 2 ins. in size. Centering was placed for the whole roof, instead of for section after section. This method Mr. Fuller prefers for circular roofs. The reservoir has a concrete bottom 1 ft. thick, beneath which are drain tiles laid in broken stone, to prevent an upward thrust of the ground water on the bottom of the reservoir. In the driest weather there is some flow from the drains. Two small pipes extend up through the bottom of the reservoir. These are for the admission of ground water, in case of excessive pressure, and are provided with check valves to prevent loss of water from the reservoir.

Man's Imitation of Nature in the Purification of Water.

A paper with the above-named title was read by Dr. Gardner T. Swarts, Secretary of the Rhode Island State Board of Health, Providence, R. I. Slow sand filtration, the use of coagulants and subsiding reservoirs, the author showed, all have their prototypes in nature. These various systems were described by the author in an entertaining manner. Special inquiries addressed to health officers seemed to him to disprove the assertions sometimes made that the alum used in mechanical filtration is injurious to the human systems. Of 40 cities responding to his inquiries the health officers of only three or four stated that alum had been found in the filtrate. The amount of alum used in the various cities ranged from 0.1 to 7.0 grains per gallon of water. Dr. Swarts stated that slow sand and mechanical filtration may each be relied upon to give satisfactory bacterial results, but his remarks showed that he prefers mechanical filtration. Speaking of ordinary dug surface wells and of cemeteries located near sources of water supply, he said he thought the dangers from these had been overrated. Excavations near old cesspools and graves showed a discoloration of the soil for but a few inches from their limits. If the adjacent material had fissures the danger might be greatly increased.

Mr. Robt. Weston, having been asked to give some information regarding the Louisville experiments on water purification, said that the problem there, at times, was to remove 40,000 bacteria per cu. cm. and from 40 to 100 tons of mud from each day's supply. At New Albany, which is across the river from Louisville, and takes its supply from the same source, the Ohio River, the benefits of sedimentation are apparent. Although the water for New Albany receives the sewage of Louisville, which the Louisville supply does not, New Albany has only about 30 deaths from typhoid fever per 100,000, while Louisville has from 70 to 80. The New Albany water has about 30 days' sedimentation. Bids have already been received at Louisville for a filter house and clear water basin beneath it, but not for the filters themselves.

Results of Tube Well Experiments in Lowell, Mass.

These results, as set forth by Mr. Geo. Bowers, City Engineer of Lowell, are three driven well plants, with a combined normal capacity of about 10,000,000 gallons a day. The water is of good quality, and the quantity seems ample in view of the fact that the average daily consumption in 1897 was 6,594,000 gallons, and the average for January, the month of maximum consumption, less than 7,500,000 gallons. The third plant, recently completed by B. F. Smith & Bro., of Boston, as contractors, has a capacity of about 450,000 gallons a day. It includes 169 driven wells, each 2½ ins. in diameter and from 28 to 42 ft. deep, depending upon the thickness of the water-bearing stratum, the top of which is uniformly about 25 ft. below the surface of the ground. Lead pipe is used to connect the individual wells with the suction mains, as it can be made to conform more readily to the inevitable slight differences in elevation of the well tubing. The suction main and branches were tested with air in the field, and leaks were discovered where none were apparent on the water test. An air receiver is provided on the suction main, and there has been little trouble with air in the pipes thus far. The cost of the three plants has been about $265,000, or $26,500 per 1,000,000 gallons per day. Generally only two of the driven well plants are in operation, leaving one for emergency use or repairs.

Surface Water Supplies.

This paper was presented by Mr. John C. Haskell, of Lynn. It was devoted to the sanitary phases of the subject, calling attention to the dangers from typhoid fever due to sewage pollution and disagreeable tastes and odors caused by the lower forms of organic life in the water. Assuming that 400 microscopic organisms per cu. cm. will give rise to offensive tastes and odors, Mr. Haskell showed by figures from the report of the Massachusetts State Board of Health for 1896 that most of the surface supplies of the state were unsatisfactory during one-fourth of the year. The Laurence experiments show that surface waters may be made satisfactory in every respect by slow sand filtration; supplemented by aeration if necessary. A proper system of filtration, the author believed, is as necessary for surface supplies as are storage reservoirs. In conclusion, he expressed the belief that the surface waters of Massachusetts are as good as those of any other state, and with filtration may be made superior to underground waters.

Mr. Clark said he, agreed with Mr. Haskell regarding the advisability of filtering surface supplies, but even then they do not always have as good a color as ground waters. Regarding the Lowell well system, previously described at this meeting,no one knows how long it will be ample to meet the demands of increasing consumption, nor when iron will develop. He believed Lowell would eventually have to put in a filter plant, either to supplement the well supply from another source, or to remove iron from the water.

Mr. Richards pointed out the difference between disagreeable and dangerous waters. He thought it unfair to say that all surface supplies ought to be filtered, believing that some water from sparsely settled drainage areas was perfectly safe in its natural condition.

The Separate High Pressure Fire Service System of Providence, R. I.

In the absence of the author, Mr. Edmund B. Weston, M. Am. Soc. C. E., this paper was read by Mr. D. V. French, of Boston. In an appendix to the paper the author described a service used for thawing the ground to a depth of 12 to 24 ins. for trenching over 4,000 ft. in winter, the street being macadamized. Wooden boxes without bottoms were used, having a length of 72 ft. and a combined width of 4 ft. Steam from a boiler was admitted to the boxes. The boxes cost less than $20 and the thawing cost only 6.7 cts. per lin. ft. 4 ft. wide.

Mr. French said, in discussing the paper, that it was of great interest to insurance men, who were in favor of gravity supplies. A pressure of 100 lbs. is sufficient and preferable, except for high buildings. The proprietors of locks and canals at Lowell recently dug up some 12-in. uncoated cast iron pipe laid in 1849. It was so badly corroded that tests showed its carrying capacity to be no greater than that of a clean 8-in. main.

Tests of a Pumping Engine at Indianapolis, Ind.

A communication from Mr. F. A. W. Davis, of Indianapolis, was received and ordered printed, giving the results of a test of a Snow pumping engine. The test was made by Prof. W. F. M. Goss, and showed a duty of 150,000,000 lbs. on the British thermal units basis.

Closing Business.

The constitution was amended, without opposition, so as to permit meetings to be held outside of New England. There is a large membership in other sections of the country. An invitation to hold the next annual meeting at Syracuse, N. Y., was received from Mr. Wm. R. Hill, M. Am. Soc. C. E., of that city, and referred to the executive committee. The following are the principal officers elected for the ensuing year, all but the president being re-elected: President, F. F. Forbes, Brookline, Mass.; Secretary, J. C. Whitney, Newton, Mass.; Treasurer, Geo. E. Batchelder, Worcester, Mass.; Editors of the Journal, Jos. E. Beals, Middleboro, Mass., and Wm. H. Richards, New London, Conn.

Excursions.

On Thursday afternoon a boat ride was taken to the Portsmouth Navy Yard and around the harbor. On Friday, after the morning session, there was a drive about Portsmouth and vicinity.

Exhibits.

The exhibits by associate members were in charge of Mr. H. F. Jenks, of Pawtucket, R. I. A list of them is given under Industrial Notes.

THE LARGEST SINGLE CONTRACT ever let for an open-hearth steel furnace plant was closed on Sept. 24 between the Riter-Conley Co., of Pittsburg, Pa., and the Alabama Steel and Shipbuilding Co., Ensley, Ala. The contract calls for ten 50-ton "Wellman" rolling furnaces; the general dimensions being approximately 21 ft. wide, 37 ft. 6 ins. long, with a total height above foundations of about 22 ft. The contract embraces everything complete above foundations, including steel castings, hydraulic cylinders, and all plate and structural work for casings, bindings, pedestals, etc. The work requires approximately 400 tons of steel castings alone, while the total tonnage of steel work and all is nearly 2,000 tons. The work is to be erected complete at the new steel works at Ensley, the foundations being already finished. A gas producer house and a storage bin, 18 ft. wide by 343 ft. long, both of steel construction, are also included in the contract. The work was all designed by the Wellman-Seaver Engineering Co., Cleveland, O.

◆

A VERY LARGE ENGINE SHAFT is being constructed by the Bethlehem Iron Co., of South Bethlehem, Pa., for the Corliss Steam Engine Co., of Providence, R. I. This shaft will be 27 ft. 10 ins. long, with a maximum diameter of 37 ins., a bearing diameter of 34 ins., and a diameter of 32 ins., where the crank-disks fit on. Throughout its length is a 17½-in. hole. It is estimated that the finished shaft will weigh about 63,000 lbs. The specifications call for an elastic limit not less than 50,000 lbs. per sq. in., and an elongation of 18% in a round test piece 1×10 ins.

◆

A NEW PLANT FOR MAKING LARGE GUNS is about to be erected by the Carnegie Steel Co., at Homestead, Pa., according to a press despatch. A plot of ground of 35 acres on the Monongahela, within half a mile of the armor-plate mill has been purchased, and four buildings will be erected with a capacity for employing 2,000 hands. The new plant will probably contain only turning and other finishing machinery, as the open-hearth plant and hydraulic forging machinery now at the Homestead works are well adapted to produce gun forgings.

◆

THE NEW 12-IN. GUN FOR THE NAVY is intended to take the place of the old 13-in. gun. With this object in view, it has been increased in weight from 46 to 52 tons; but the 13-in. weighed 61 tons. The new 12-in. is designed to use a powder charge giving a velocity of 3,000 ft. per second to its projectile, says the Washington correspondent of the New York "Sun," as compared with 2,000 ft. for the old 13-in. gun.

◆

A 12-IN. KRUPP PROCESS ARMOR-PLATE, made by the Carnegie Co., was tested at Indian Head on Sept. 12. A 6-in. plate had previously been tested by a 6-in. shell with surprising results, and the government demanded the thicker plate now tried. The new plate was slightly under 12 ins. in thickness, and was substantially bolted to braces and backed by about 7 ft. of wood. The gun used was a new navy 12-in. gun, at 300 ft. range. Three shots were fired with armor-piercing projectiles. The first had behind it 380 lbs. of powder, imparting a velocity of 1,833 ft. per second; this projectile penetrated 8½ ins. and remained imbedded, with signs of being badly distorted at the point; but there were no radial or other cracks in the plate. The second shot had 417 lbs. of powder, giving a velocity of 2,022 ft. per second; as expected, this shot passed clear through the plate and backing, but what was found of the shell was badly broken and distorted. With the third shot only 370 lbs. of powder were used, with a velocity of 1,720 ft. per second; this shell penetrated about 5 ins. and stuck in the armor. But at the end there were no opening cracks in the plate, such as would be expected under so severe a test. The experts estimated that this plate had as much resisting power as a 13½-in. plate treated by the ordinary Harvey process. The test was so satisfactory that the Krupp process will probably be used for the armor on the new warships now contracted for. The maximum thickness of armor will probably be 15 ins., instead of 18 ins.

◆

A 35.2-KNOT SPEED, for the torpedo-boat destroyer "Hai Lung," is claimed by the "Kolnische Zeitung." This boat was built at Elbing, Germany, for the Chinese government by the Schichau Co., and the trial runs were made in the open sea over a 19-knot course, with a fresh wind and considerable sea. The boat traversed this course several times, the average time being 32 m. 28 s.; or the equivalent of a speed of 68 kilometers, 35.2 knots, or 40.8 statute miles. This is claimed to be in excess of any speed heretofore made on the water, surpassing that of the "Turbinia."

◆

THE SPANISH ARMORED CRUISER "INFANTA Maria Teresa," sunk at Santiago on July 3, has been finally raised and towed into the harbor of Guantanamo, Cuba. This ship was built at Bilboa in 1890, and is a twin-screw steel vessel, 364 ft. long over all; 65 ft. 2 ins. beam; 21 ft. 6 ins. mean draft; with a displacement of 6,890 tons. She has two sets of vertical, triple-expansion engines, and under natural draft these engines developed 9,500 I. HP., giving a speed of 18½ knots; under forced draft the power developed was 13,700 I. HP., with 20.2 knots speed. She will carry 1,050 tons of coal, giving her a steaming radius of 9,700 miles at 10 knots. Her water-line steel armor belt is 5½ ft. deep, 315 ft. long, and from 10 to 12 ins. thick. Her two turrets have 9-in. armor; the conning tower is 12 ins. thick, and the protective deck is from 2 to 3 ins. thick. Each turret contains one 11-in. Hontoria gun; and she had ten 5.5-in. Hontoria rapid-fire guns, eight 6-pdr. and ten 1-pdr. rapid-fire guns, with eight Nordenfeldt and two Maxim machine guns, and eight torpedo tubes. Her complement of officers and men was 484. The work of raising the "Infanta Maria Teresa" was performed by the Merritt-Chapman Wrecking Co., under the direction of Naval Constructor Hobson.

THE FOUR COAST DEFENCE MONITORS for which bids will be received this week, are already named the "Arkansas," "Connecticut," "Florida" and "Wyoming." These monitors are limited in cost to $1,500,000 each, and the general plan includes a single, balanced Hichborn turret on the center-line forward, armed with two high-power 12-in. rifles for smokeless powder, and four 4-in. rapid-fire guns will be mounted on a raised superstructure aft of the turret. There will also be a secondary battery of three 6-pdr. and four 1-pdr, automatic rifles. The length of the monitor on the load water line will be 225 ft.; extreme beam on the water line, 50 ft.; mean draft at normal displacement, 12 ft. 2 ins.; normal displacement, about 2,700 tons; total coal capacity, loose stowage, 200 tons. The hull will be unsheathed steel, with double-bottom and water-tight subdivision; there will be one military mast. The side armor belt will have a maximum thickness of 11 ins., tapering to 5 ins., with a depth of 5 ft. The barbette will be 10 ins. thick, and the turret will have 10-in. inclined front plates at an angle of 42°, with side plates 9 ins. thick. Two vertical, triple-expansion engines, with 17.26¼ and 40-in. cylinders and 24-in. stroke, will drive twin screws. Four water-tube boilers will furnish steam at a working pressure of 250 lbs. The speed called for is only 12 knots.

◆

SMOKELESS POWDER for the navy is to be made in a government factory now being established within two miles of the proving grounds at Indian Head. The factory is being built under an appropriation of $97,000 made by the last Congress, and the work of construction will be under the charge of Lieutenant Bernadou, U. S. N., an expert in the development of smokeless powder. The plans call for a plant capable of making from 3,000 to 5,000 lbs. of powder per day, and to this must be added the Newport government plant, with a capacity of 1,000 lbs. per day. The Duponts and the California Powder Co. are now each under contract to furnish 500,000 lbs. of smokeless powder.

◆

U. S. NAVAL ESTIMATES for the coming fiscal year aggregate about $20,000,000 in four bureaus alone. The Ordnance Bureau asks for $6,475,358, to meet ordinary expenses and the amount necessary to pay for guns and armor on ships under construction or contracted for. An additional sum will be required for the torpedo boats and destroyers soon to be contracted for. The Bureau of Construction and Repair wants $6,000,000 for vessels building, and $3,500,000 to make necessary repairs on ships in service. The Bureau of Steam Engineering asks for $1,000,000 for repairs to the machinery of ships. The Bureau of Yards and Docks wants $1,500,000 for a large dry dock at the Norfolk Navy Yard; $612,000 for the Brooklyn Navy Yard; $306,000 for Portsmouth; $367,000 for Boston; $755,000 for League Island; $2,000,000 in total for Norfolk; $25,000 for New London; $148,000 for Port Royal; $112,000 for Key West; $871,000 for Mare Island, and $53,000 for Puget Sound.

◆

THE POST-GRADUATE COURSE IN NAVAL ARCHITecture, commenced at Annapolis last year, under Naval Constructor Hobson, is abandoned by order of the Secretary of the Navy, on the recommendation of Chief Constructor Hichborn. The latter does not deem it practicable for the student to receive from one instructor the advantages or attention necessary for a thorough training. After examining the leading technical schools of the country, he recommends that the cadets selected each year for this post-graduate course be sent to the Massachusetts Institute of Technology, at Boston. This eminently sensible plan has been approved and eight cadets have been ordered to report there on Oct. 1 for a course covering three years. This includes practical instruction during the summer at shipyards and naval stations. The present class will be the largest ever instructed in naval architecture at one time. The practice, for the last 15 years, has been to select the three cadets graduating with highest honors each; and, until recently, these were sent for two years to leading technical schools in England and France. For the first five years the American cadets were educated at the Royal School at Greenwich; but this privilege was later refused by the British government. It will cost the government about $800 per year for the education of each cadet, exclusive of their pay.

SEGMENTAL WIRE GUNS, to the number of 50, and costing $500,000, have been ordered by the War Department from the Brown Segmental Gun Co., of Reading, Pa. They include 25 5-in. and 25 6-in. guns. "The Army and Navy Journal" says that army ordnance officers protested against the contract on the ground that "there never had been a successful test of this gun." The Brown Segmental Gun Co. answers this charge by saying that a 5-in. segmental tube wire gun, 44 caliber long, was some years ago turned over to Gen. Flagler for test. Though the contract called for a maximum chamber pressure of 50,000 lbs. per sq. in., 192 rounds were fired from this gun, with 43 rounds at pressures from 50,000 to 60,000 lbs., and six rounds with pressures ranging from 60,000 to 82,850 lbs. per sq. in. The gun survived this severe treatment, though the lining tube finally yielded; and this tube was only considered good for 150 rounds at 50,000 lbs. pressure, instead of 192 shots. The company considers this a very successful and thorough test of the qualities of the wire-wound gun.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred Sept. 22 on the Wisconsin Central R. R., close to White River, a small station near Ashland, Wis. A freight train broke in two while going down grade and the rear portion ran into the forward cars, killing one man and seriously injuring another.

◆

A CYCLONE passed over the strip of land between Lakes Ontario and Erie on Sept. 26, almost parallel to the Welland canal. In its progress a swath, about 300 ft. wide, was swept over and a branch took in a portion of Tonawanda, N. Y. Six persons were killed and 9 are reported seriously injured.

◆

A GRAIN DUST EXPLOSION, on Sept. 23, wrecked the granary of the Eastern Distilling Co., at Blissville, Long Island, caused the death of one man and injured four others. The granary was three stories high, built of brick and timber, with wooden partitions covered with corrugated iron. The force of the explosion blew parts of the building 100 ft. into the air, and buried part of the Long Island track with wreckage and twisted machinery, and flames spread like a flash through the steam grain conveyor connecting the granary with the docks.

THE PLANT OF THE PENCOYD IRON WORKS, PENCOYD, PA.

(With double-page plate.)

The Pencoyd Iron Works is one of the best-known of the several plants in this country which combine the design and construction of steel bridges and buildings with the manufacture of commercial steel in the form of castings, forgings, bridge steel and structural shapes of all kinds. The works were started in 1852 by Algernon and Percival Roberts, and until 1887 they manufactured puddled iron. In that year the product was changed from iron to open-hearth steel, a change which, of course, necessitated a complete modification of the plant and of the methods of handling and manipulating the metal in all of its stages of manufacture. Since first starting work as a steel plant, many improvements and extensions have been made in all departments until the works have reached their present great size and complete equipment.

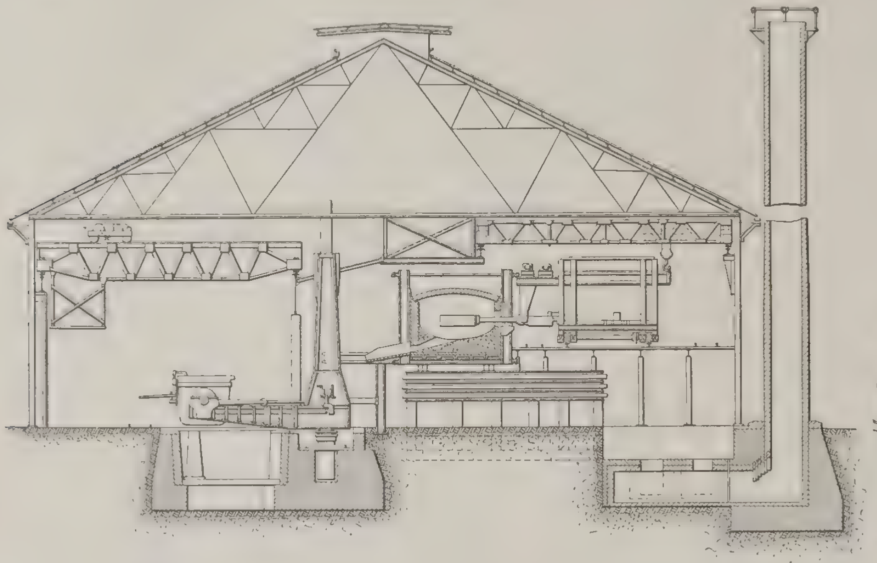

FIG. 3.—SECTION OF STEEL MILL SHOWING INGOT-CASTING PIT.

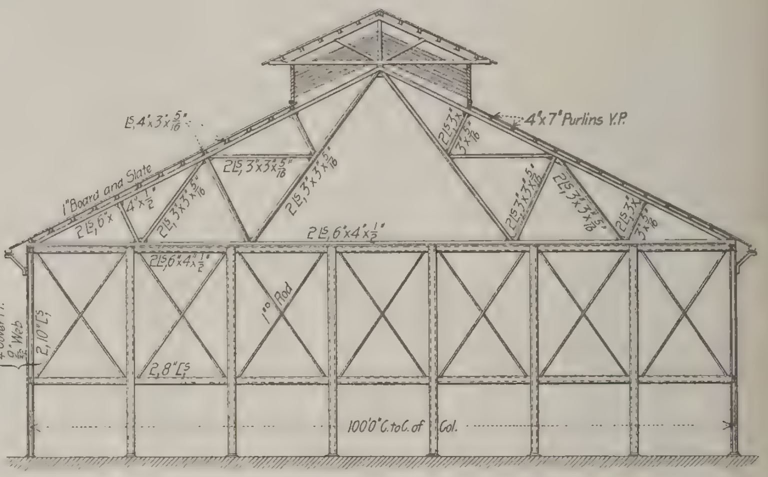

FIG. 5.—SECTION OF MILL BUILDING.

Before commencing the detailed description of the plant as it now exists, however, a brief explanation of the drawings which are shown herewith and on our inset sheet will be advantageous. The works are located on the west bank of the Schuylkill River, a few miles north of the business center of the city of Philadelphia, Pa., and occupy a narrow strip of land between the tracks of the Philadelphia & Reading R. R. and the river bank. Figs. 1 and 2 show the arrangement of the shops to fit this narrow tract. The material is delivered by rail at the south end of the works, and at the north end is located the foundry building. The other mills and shops are arranged between these two in the manner shown. It will be noted that the plans of the different buildings show the location of the furnaces, roll trains, hot beds, and all the various larger stationary machinery and tools with which they are equipped. Figs. 3, 4 and 5 show the arrangement for handling the metal at the furnaces and typical sections of the mill building and bridge shop. The half-tone views of special tools and machines which comprise the remainder of the illustrations are explained by the captions underneath each. With this explanation the various drawings and other illustrations can be studied intelligently in connection with the descripton which follows.

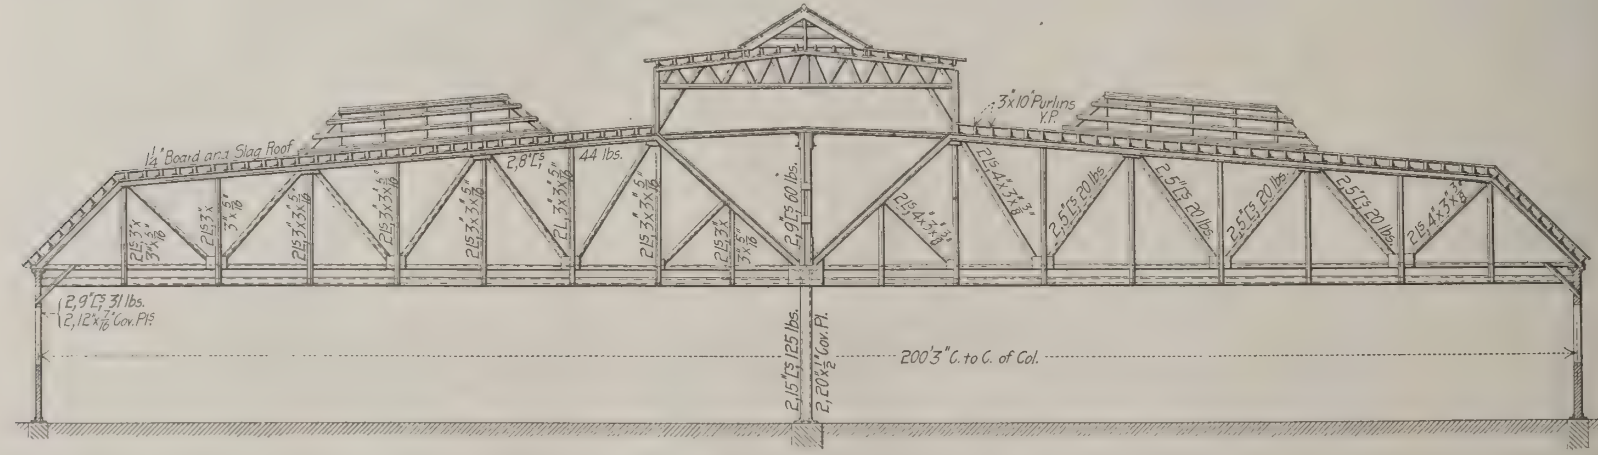

FIG. 4.—SECTION OF BRIDGE SHOP.

Shortly after beginning the manufacture of steel it was foreseen that open-hearth steel would be demanded in structural work, and the Pencoyd works, escaping the difficulties which were encountered by some of their contemporaries who put in Bessemer converters, adhered exclusively to the open-hearth process for their steel product. There are now nine 30-ton furnaces in operation, each producing about 450 tons per week, and a tilting furnace of 75 tons capacity is under construction. All of these furnaces are basic lined. The general arrangements for handling the metal are shown by Fig. 3, which is a section in elevation of the open-hearth works.

The raw material, pig iron, scrap and basic additions used, are placed in boxes in the yards, and shifted on cars to the furnace floor, where they are handled by a Wellman electric charging machine The molten steel is handled over the pits in ladles supported in radial hydraulic cranes, each furnace having its own ladle crane. The ingots are stripped and delivered by electric traveling cranes and cars to the pit furnaces of the blooming mill (Fig. 1), thence being reduced by the blooming mill to blooms and billets of the various sizes required by the finishing mills.

The blooming mill is a 36-in., two-high reversing mill, driven by a pair of 40-in. × 60-in. engines geared two to one to the mill. These engines have piston valves and a Marshall reversing gear operated by a hydraulic ram. The spur gear is 7½ ins. pitch and 30 ins. face and is cut from solid steel. The tables of this mill are equipped with hydraulic manipulators, so that all the operations are directed from a central station. The mill and engine are surmounted by a 30-ton electric traveling crane, and provided with a floor carriage for changing the rolls. This mill is fed by four vertical pit furnaces of the regenerative type, fired with producer gas. The products of the blooming mill supply three finishing mills and the axle forge. The principal part of the product goes to the beam mill, which is supplied with hot blooms. All the other mills receive their charges cold.

Beam Mill.—The beam mill is placed in the line of delivery of the blooming mill and is served with three regenerative heating furnaces for restoring full working temperature to the blooms on their passage from the blooming mill. Each of these furnaces is of very large capacity, being capable of receiving about 30 tons of steel blooms and is worked continuously, being charged and drawn at the same time. The mill furnaces are served with electric charging machines (Fig. 6), receiving current from an overhead trolley and operated by two motors, one for the traveling truck, the other for the longitudinal motion of the billet. This movement being effected by frictional contact of a heavy ram on moving rollers gives a desirable working freedom to the machine. This machine is so arranged that the billets pass over it and are pushed into the furnace by the ram, and also withdrawn by the same action by tongs, the billets passing directly over the table.

The beam mill consists of two distinct mills, for roughing and for finishing. The roughing mill is a 28-in. two-high reversing mill with a single pair of rolls, and the finishing mill is a 23-in. three-high mill with two stands of rolls. A notable feature is the absence of a flywheel from the three-high mill which allows of instantaneous stoppage or reversal in the case of accidents and places the mill under full control of the operator, thus avoiding those annoying accidents which have heretofore been so common in rolling mill practice. The engines are fitted with the Marshall reversing gear, the reversing levers being controlled by a hydraulic ram. The valves are double-ported balanced slide valves. The engines are of very substantial construction and have run at a piston speed of 1,500 ft. per minute without difficulty.

A roll changing house is located in the line of the mill, and the whole area is covered with a 40-ton traveling crane, which lifts a complete stand of rolls and fixtures, and permits the adjustment of rolls to be made while the mill is in operation.

The roughing mill is served with reversing tables and hydraulic manipulators, while the three-high finishing mill has traveling tables which have also a lifting movement operated by a hydraulic ram which raises or lowers the end of the table next to the mill, the opposite end being hinged. These tables are each operated by a single attendant. the horizontal movements are effected electrically under the Ward-Leonard system of control. The mill handles with ease the heaviest sections of structural steel up to and including 24-in. I-beams.

Not the least advantage of having the rolling mill equipped with tables is that much higher speed can be maintained and longer lengths can be handled than is otherwise practicable. In this mill the material is delivered at a speed approximating 1,000 ft. per minute and is regularly rolled in 150-ft. lengths and can be rolled much longer. The product of the finishing mill is delivered by live rollers to the saws or at the end of the tables to a shear (Fig. 7) for cutting up small billets and similar work. The finished material is transferred to cooling beds in the usual manner and then passed through straightening machines and suitable shears for cutting to lengths. Angles and similar sections are all straightened by roller straightening machines (Fig. 8), while gag presses are used for beam straightening.

The receiving yard for finished material at the end of the mill is covered by four parallel electric traveling cranes, each of 6 tons capacity. The floor of this stock yard is fitted with tables of live rollers, electrically driven, and with devices for transverse movement of the material.

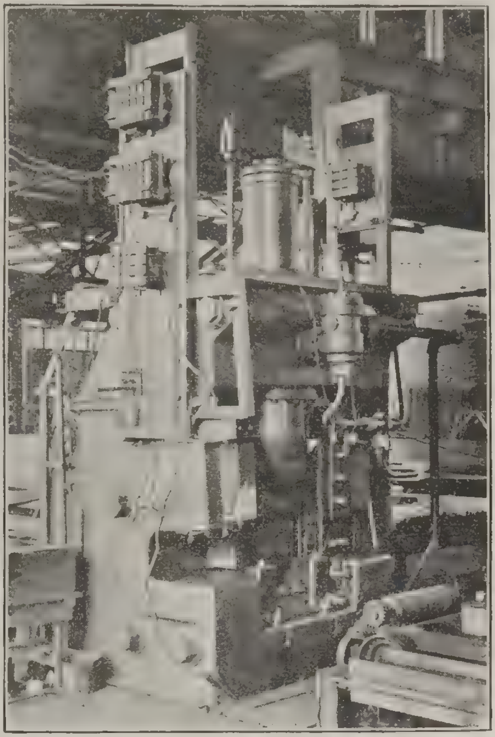

FIG. 7.—HYDRAULIC BILLET SHEARS.

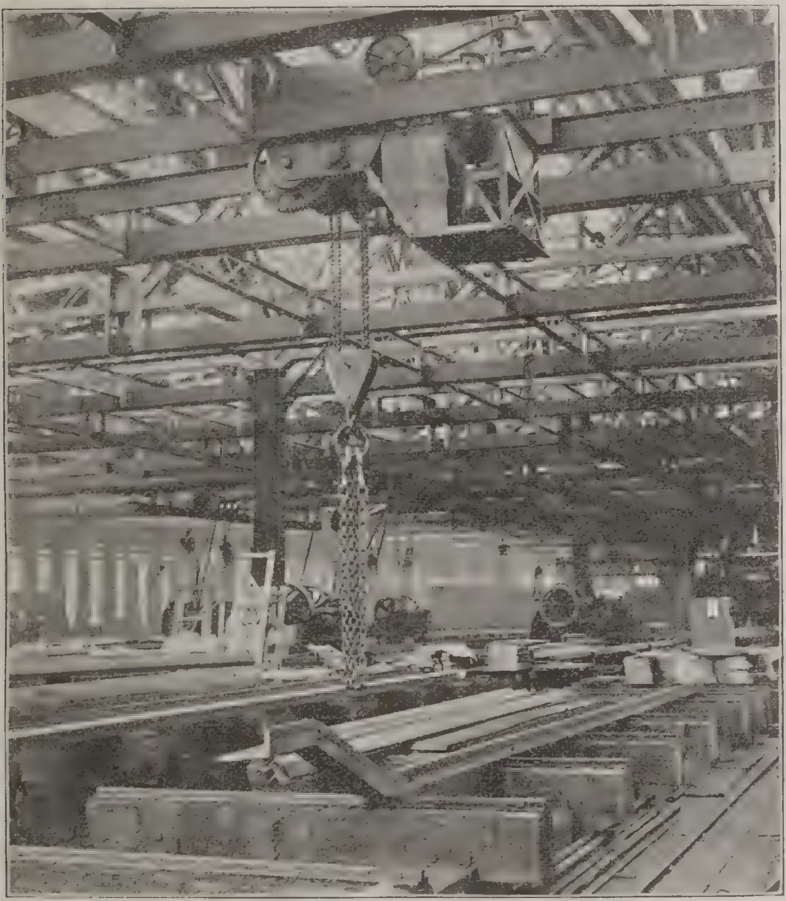

FIG. 9.—TEN-TON ELECTRIC TRAVELING HOIST, BRIDGE SHOP.

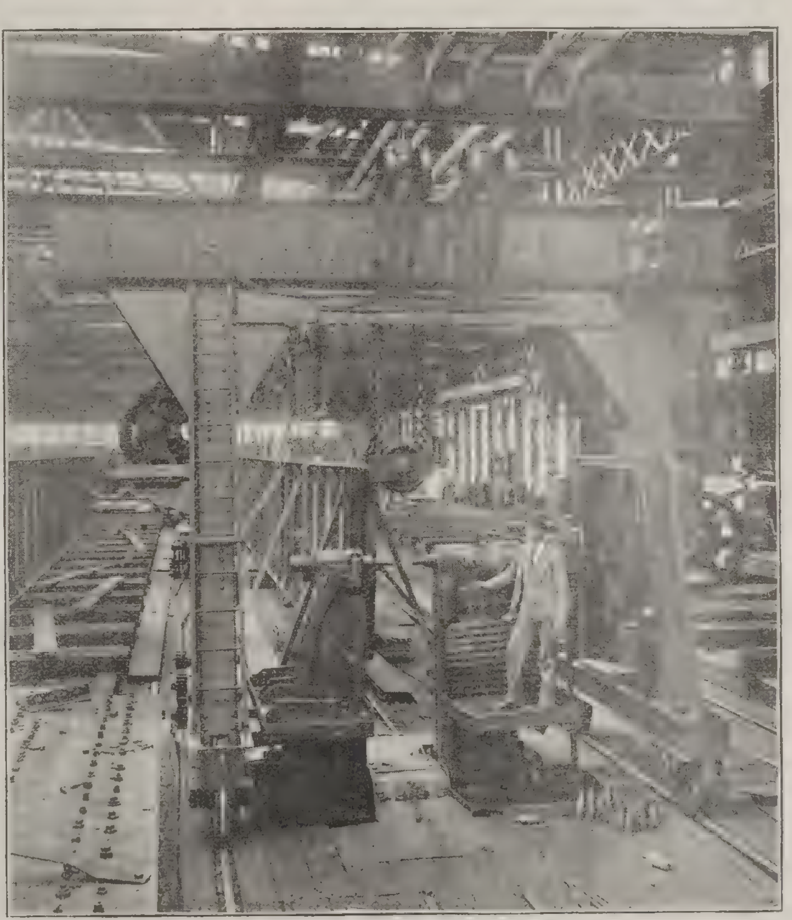

FIG. 11.—HYDRAULIC RIVETER WITH ELECTRIC TRAVELING GANTRY, BRIDGE SHOP.

Axle Shop.—At the lower end of the blooming mill building is located the axle-forge and shop. This contains a 20-ton steam hammer with a stroke of 8 ft., served with two hydraulic, fixed mast cranes, each of 20 tons capacity and two gas furnaces. This hammer, which was originally used for blooming, is now used for miscellaneous forge purposes. Three steam hammers are used for forging car axles. The steel billets for axles are delivered from the blooming mill about 6½ ins. square in the rough, and are finished at a single heat, into car axles. The axles as forged are delivered to the axle shop on the east side of the building, where they are cut, centered, turned and finished, as required. This department uses 14 lathes and turns out about 2,000 axles per week. Immediately outside this building are two drop-testing machines. In both machines the drop weighs 1,640 lbs., and the anvils upon which the axles are placed are 3 ft. between centers. The first has a maximum drop of 31 ft. and the anvil is on a solid foundation, while the second anvil weighs 17,500 lbs. and is supported on springs to conform to the specifications of the Pennsylvania R. R. Co. This fixes the inertia of the anvil and renders it independent of the foundation. It may be noted in passing that the specifications for axles are now more definite and the inspection more rigid than formerly. The chemical and physical requirements are insisted upon without much latitude for variation, the general tendency being to require a higher carbon limit and all other components lower than previously.

Steam Boiler Plant.—There are at present three principal steam boiler plants at the works. Boiler house No. 2 consists of twelve 156-HP. Babcock & Wilcox boilers; boiler house No. 3 contains four 250-HP., four 140-HP. and four 156-HP. Babcock & Wilcox boilers equipped with mechanical stokers; boiler house No. 2 is also being equipped with mechanical stokers. Bituminous coal is used throughout the works. The use of the mechanical stoker, especially when supplemented by coal and ash handling appliances, results in some economy of labor in extensive boiler plants and an abatement of smoke. An extensive series of tests run at the works indicate little economy other than that mentioned over hand firing.

Boiler houses Nos. 2 and 3 are connected by a 16-in. steam pipe and supply steam for all parts of the works, excepting the bridge department. There is a main trunk line for exhaust steam throughout the works, which collects the exhaust steam and conveys it to feed water heaters or for heating purposes in winter. The principal engines of the works, however, are supplied with condensers.

Boiler house No. 4 has one 250-HP., and two 156-HP. Babcock & Wilcox boilers. These are furnished with the chain grate stokers of the Babcock & Wilcox Co. and with the ash and coal conveyors of the Link Belt Engineering Co. Their operation is shown by the drawings Figs. 1 and 2. The coal is dumped from the cars between a pair of crushing rolls. These deliver to the conveyors which carry the coal to bins above the boilers, from which it falls to the stoker hoppers. The ashes are conveyed from ash pits to a bin over a car track and are dumped into empty cars run under the bin. This boiler plant supplies all steam used for power purposes at the bridge department, the prominent uses being that demanded by air compressors and hydraulic pumps.

The water supply for the steam boilers is largely obtained from dams constructed in the adjoining hills which collect the surface drainage and spring water and yield a supply well suited for boiler use.

Office and Machine Shop.—Fronting on the river are located the main office and the machine shop. The machine shop building is 35 ft. × 230 ft., and is equipped with tools for construction and repairs. Machinery and tools of special design are continually under construction as the development of the work requires. The upper part of the machine shop has a second floor which is used for a tool-room, the remainder being a templet shop. The templet and pattern shop proper is a three-story building located just west of boiler house No. 3 and across the railway tracks from it. These shops are thoroughly equipped with the necessary wood-working machinery. Material is laid out in the shops—both to templet, and also by mechanical spacing—according to the character of the work.

Bridge Shop.—The stock yard for the bridge works is located between the rolling mills and the bridge shop. Its whole area is covered by a system of traveling cranes, each of 6 tons capacity. In the yard are several bending and straightening machines for preparing the material for the shops.

The bridge shop proper is a building of steel skeleton construction 200 ft. wide and 460 ft. long. The walls, excepting where the windows, which form a large part of the sides, are located, are filled with concrete (Fig. 4). The plan of the building consists of a system of central longitudinal girders resting on posts 80 ft. apart. These girders sustain the interior ends of the roof trusses of 100 ft. span, thus leaving a clear transverse opening of 200 ft. wide, except where the few central posts occur. In addition to the usual wall lights, this building is well lighted in its center by a liberal provision of skylights in the roof. Each roof truss is designed to carry a rolling load of 10 tons. There is a complete system of electric traveling hoists suspended on runways, from the roof trusses. Some of these travel the entire width of the shop (Fig. 9), while others travel longitudinally. These hoists are of various designs, adapted to their intended uses, ranging from the light active machine, capable of handling 1 ton, up to one handling a 100-ft. girder weighing 60 tons. The shop contains 16 punches, six shearing machines, and a complete equipment of drills. Notable among these latter are three gantries, each carrying eight radial drills (Fig. 10). These gantries travel longitudinally through the shop, passing over the work operated on. There are also in use numerous portable pneumatic reaming machines and chippers, a hydraulic riveter, two fixed pneumatic riveters and twelve portable air riveters. Two of the riveters are mounted on hydraulic rams which allow a vertical movement of 6 ft. The work is carried through the riveter on an electric traveling gantry (Fig. 11). Besides the compression riveters referred to, there are also several impact air riveters used in places where it is impossible to use the compression riveter. The rivets are heated by petroleum furnaces operated by compressed air.

Planers and milling machines for finishing edges and ends of material are located at convenient points, also boring machines for finishing chords and posts. A pair of rotary planers, each with a 5-ft. cutter head mounted on a bed-plate 70 ft. long, are used to surface both ends of bridge members simultaneously (Fig. 12). The equipment in the bridge shop has been still further perfected by the addition of a multiple beam punch and a spacing punch (Figs. 13 and 14). The beam punch (Fig. 13) carries clusters of punches which at a single stroke perforates for the standard spacing for beam attachments and has also outside punches for the flange punching. The spacing punch is designed especially for punching plates and angles, punching up to ten holes at a stroke and automatically spacing by sixteenths of an inch up to 8 ins.

Electric motors are used for power transmission throughout this shop, the motors in some cases being a unit with the tool driven and in other instances the motor is bolted to a group of tools. The shop is heated in winter by exhaust steam in radiator pipes suspended from roof trusses. The circulation of the steam is promoted by an exhausting pump which draws out all the water of condensation and returns it to the boilers.

The average capacity of the bridge shop is about 5,000 tons per month, requiring 120,000 holes to be punched and 30,000 rivets to be driven per day. The storage yard for finished work is at the upper end of the bridge shop. The material is inspected and painted here. This yard is covered by two traveling cranes of 60 ft. span, each of about 40 tons capacity. These cranes pass over the tracks of both the Pennsylvania R. R. Co. and the Philadelphia & Reading R. R. Co.

Electrical Plant.—The electric motor has acquired an extensive application in the modern steel works. Considering the severity of the work, and the exposed situations in which the electrical appliances must necessarily be placed, as well as the delicacy of the electrical mechanism, the successful adaptation of this method of distributing power is somewhat surprising. These electric motors run successfully close to heated or molten steel, and in the dust and grime of the mill. A class of locomotive machinery has come into service which would be almost impracticable without the aid of electric power.

The general plan of the electrical system consists of a 220-volt distribution used for power purposes, for incandescent and enclosed arc lights, and a constant current system used in the series arc lighting. The electrical generating plant is located just west of the template shop and contains one 200-K-W., 220-volt. generator direct-connected to a 12 × 22 × 42 ins. tandem compound condensing Greene engine, and two 100-K-W., 220-volt generators, each direct-connected to a cross compound condensing vertical engine 10 × 19 × 16 ins. The series arc lighting lamps are of 2,000 c. p. (nominal), and are supplied with current by three 50-light and one 35-light General Electric dynamos belted from Westinghouse engines. The present power plant is being enlarged by the addition of a 500-K-W. generator and direct-connected engine.

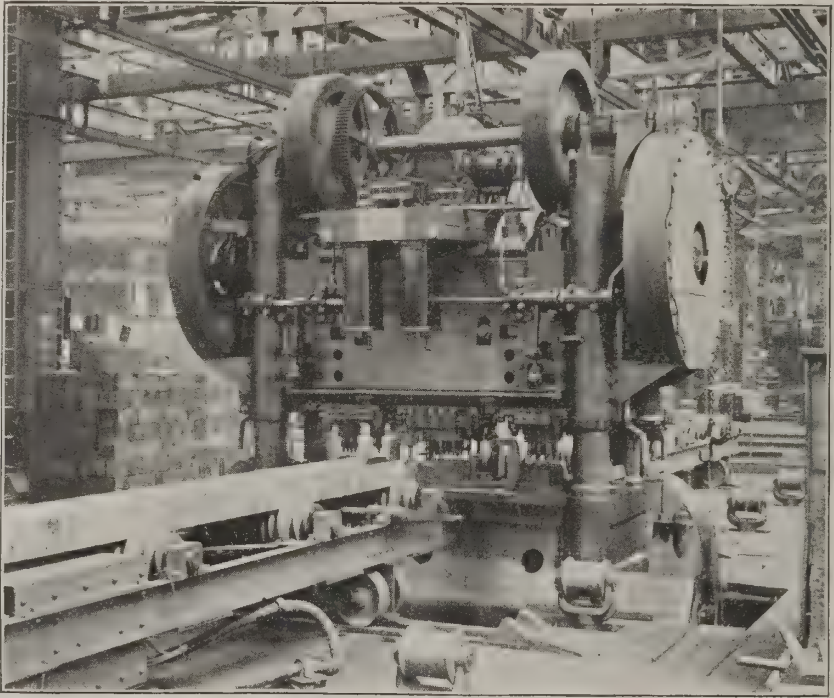

FIG 13.—MULTIPLE BEAM PUNCH, BRIDGE SHOP.

The switch-board contains the usual complement of instruments and a recording watt-meter. From the switch-board bus-bars there are 5 distinct circuits running as follows: One to the bridge shop, one to the beam mill, one to the beam mill yard, one to the steel mill, and one to the 20-in. mill. Each circuit and each generator has a separate automatic circuit breaker. In order still further to localize faults as much as possible, automatic circuit breakers are extensively distributed around the principal machines. On these circuits there are over 200 motors aggregating 2,500 HP., and distributed as follows:

	No. of motor.	Total HP.
Electrical repair shop	1	5
Boiler house	1	10
Blooming mill	4	35
Laboratory	3	5
Steel mill	27	355
Bridge shop	74*	860
20-in. mill	16	155
Beam mill	65	930
Two generators	..	50

*32 of these are on cranes.

The two generators last mentioned are driven by an 80-HP. motor and form the Ward Leonard system previously referred to as controlling the tables of the 23-in. mill. The gantry in the bridge shop carrying the work through the 100-ton riveter is also similarly controlled. There are numerous other small motors throughout the works which are not enumerated. At the stock yards at the extreme upper portion of the works there is a 15-K-W. generator, and on the circuit with it are five motors aggregating 35 HP.

The incandescent and inclosed arc system of lighting is run on the power circuit and requires 1,000 incandescent lamps run two in series and about 40 220-volt inclosed arc lamps. The tendency is to increase the incandescent arc system in the central area of the works, partly owing to the better diffusion of light from the inclosed lamp and also because this lamp allows the use of constant voltage current from the power system. In the outlying areas the series arc lamps continue in use, but it is proposed to drive their generating dynamos from direct-connected motors, the current for the latter being derived from the central power generating system, thus making the power generators a unit for electrical distribution for all purposes.

Air and Hydraulic Systems.—Above the storage yard are the air compressors and pumps supplying the air and hydraulic pressure required at this part of the works. There are two supplies of compressed air, one of 10 lbs. pressure used in oil furnaces, and the other of 80 lbs. pressure for riveters, chippers and reamers in the bridge shop. The air is compressed by a number of piston engines of various makes. The Norwalk machines are used for the high pressure and have both steam and air systems compounded.

The hydraulic power is also supplied at two pressures of 600 lbs. and 1,300 lbs., respectively. Where required at the individual machines intensifiers which increase the pressure to any desired amount are used. The pumps are all of the duplex Worthington type, with compound condensing steam cylinders.

The hydraulic pressure required at the lower portion of the works is obtained from the pump-house marked "K," Figs. 1 and 2. This system works at about 500 lbs., and requires two pumps. These are both compound duplex pumps and have two, 18 ins. x 10 ft. accumulators. From this station the pressure is taken down the river to the steel mill, where the ladle cranes, furnace doors, and the gas and air reversing valves are operated by it, and up the river through the blooming mill, beam mill and stock yards, where it actuates furnace doors, manipulators, transfer tables, turntable, screws on mill boxes, shears, etc.

The billet shear at the end of the blooming mill table, where great rapidity of action is essential, is worked by a steam driver. The steam cylinder is 50 ins. in diameter, the ram 8 ins. in diameter, and the stroke is 9 ft. 4 ins. The steam cylinder has the cut-off controlled by the operator.

Eye-bar Shop.—The eye-bar shop adjoins the bridge shop stock yards and the Compressor and Pump House. It has at present facilities for upsetting 8-in. bars to heads of 18½ ins. diameter, and a new machine is under construction capable of upsetting 14-in. eye-bars with heads of 33 ins. diameter.

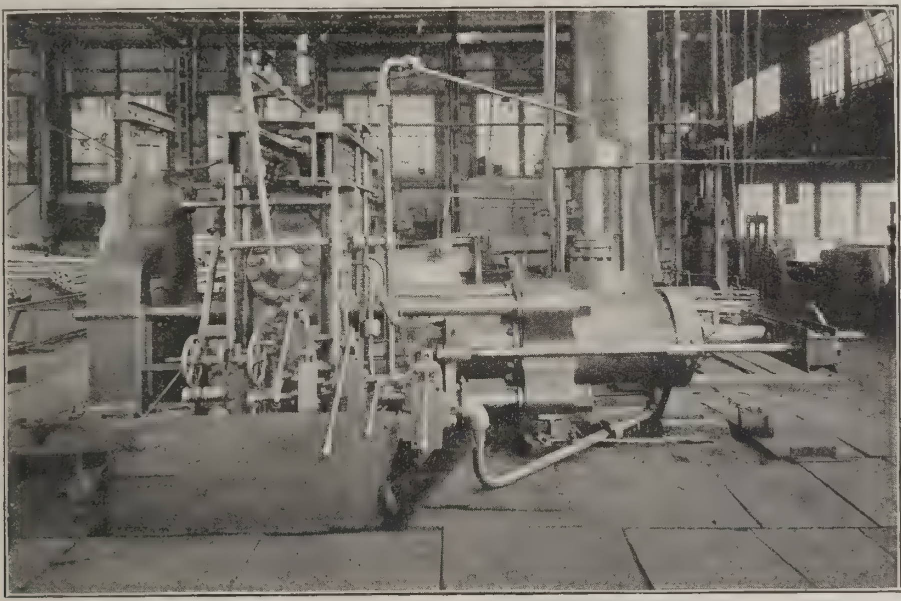

FIG. 15.—HYDRAULIC EYE-BAR UPSETTING MACHINE, EYE-BAR PLANT.

The shop contains four oil furnaces, one heavy hydraulic shear for cutting bars to length, five hydraulic radial cranes, one hydraulic punch for punching eyes, one set of rolls run by hydraulic power for flattening heads after being upset, two boring mills set on the same bed 70 ft. long and used to bore both eyes of a bar at the same time, and an annealing pit of sufficient length to take in the longest eye-bars and having the temperature controlled by oil-burners. A larger annealing furnace and muffle is contemplated in connection with the new eye-bar machine. The present eye-bar machine (Fig. 15) consists of a hydraulic grip which clamps the bar in position in the machine, a second press which lowers and holds the dies in place over the bar, and a third massive press which pushes in the rear die and upsets the bar. An intensifier is used on this machine, which increases the hydraulic pressure from 1,300 to 3,000 lbs. per sq. in. There is also a hydraulic press used for straightening bars.

In this shop is also the hydraulic crimping and forming press (Fig. 16). This is used in crimping angle stiffeners and in bending or curving. It consists of a vertical press carrying a clamping die and a horizontal press containing the crimping or forming die. This machine is coupled to a multiple intensifier, by means of which the pressure is graduated for light or heavy work.

Testing Laboratories.—The chemical laboratory is located near the steel mill. All the analyses of ores, metals, coals and gases for the works are made here. When making soft steel, samples are taken from the furnace before tapping. The samples are forged and fractured and from the appearance of the fracture the melter judges if the phosphorus is as low as required. When the metal is cast a sample is taken, and before the metal is rolled a chemical analysis is made and the carbon, sulphur manganese and phosphorus determined. When hard steels are made, samples are taken and analyzed for carbon before the furnace is tapped. In all cases complete records are kept of the charge, duration of heat, product, analysis and melter. All ingots are given a number which locates the furnace and heat, and these numbers are marked on the finished product.

The physical tests are made in the same laboratory. The apparatus for testing the steel consists of a 150-ton Olsen testing machine and two smaller machines. The material tested is taken from the finished product, pieces 18 ins. long being cut from the webs of channels and beams, the legs of angles and tees and the flanges of Z-bars. The cross-section of these test bars run from ½-in. to 1 in. square, excepting the following sections, which are tested full size: Flats up to 3 ins. in width, rounds up to 2½ ins. in diameter, and squares of 2 ins.

A section of this department is equipped with apparatus for making experimental investigations throughout the works. These comprise boiler and engine tests, electrical measurements, the quality of supplied material, etc., and are made periodically to aid in maintaining a high standard of efficiency.

Bolt and Forge Shop.—Above the eye-bar shop is the bolt and forge shop. All the bolts and rivets required by the works, also sleeve nuts and clevises are made in this shop. Small forgings required for bridge work are also made here. A notable feature of modern smithery is the absence of welding which is becoming a lost art. Clevises, sleeve nuts and similar connections are now made from solid steel.

The shop contains two steam hammers, two acme rivet machines, one bolt machine, one triple acme screw cutter, one machine for upsetting clevises, five smith's fires, two spring pointing machines, two hydraulic benders, one power shear, one air compressor furnishing air for the oil furnaces, several drills, lathes and shapers, and a Westinghouse engine driving the shop. The product of this shop is entirely consumed by the bridge shop and amounts to 9 tons of rivets and 4,000 bolts per day.

Stock Yards, etc.—At the extreme upper end of the works is located the iron foundry, now being rebuilt on a more comprehensive scale. On the side near the river lies the mill stock yard and store house for lumber, erectors' material, and finished patterns. In the stock yards are located the saws and shears for cutting material to lengths. The sections are handled throughout the yard by locomotive cranes.

The various departments of the works have a complete telephonic communication through a central station, and the works have communication with the main office and the various branch offices by long distance telephones.

For the information from which this article has been prepared we are indebted to the A. & P. Roberts Co., Philadelphia, Pa., the proprietors of the Pencoyd Iron Works.

THE FRENCH SOCIETY OF CIVIL ENGINEERS.

The French Society of Civil Engineers, according to a long illustrated article in "Engineering," was founded in 1848, by some of the graduates of the Ecole Centrale. The purposes of the society were to throw light upon obscure questions in civil engineering; to assist in developing the applied sciences; to extend professional teaching among workmen and shop-foremen; to insure closer relationship among members; to conduct an employment bureau for members, and to establish a benevolent fund in case of necessity.

The beginning of the society was very modest, and for 22 years a hall capable of seating only 60 persons answered all the purposes of the meetings. In 1872, however, the society numbered 1,000 members, and it built its own house with a lecture room large enough for 200 persons. This house, in the Rue Rougemont, cost about $52,000 for land, building and fittings. The annual revenue of the society, in 1887, was $20,600, with expenditures of $14,520 per year. In 1897 the treasurer reported secured investments of $17,200; balance on hand, $1,200; $12,800 of various debts; $2,000 in literary account; $1,300 in furniture and $208,800 invested in the new house; against this was a loan of $103,000 on the building.

The growth in membership may be summarized as follows: In 1848 there were 134 members; in 1860, 525; in 1872, 1,038; in 1882, 1,984, and in 1897, 3,054. The published transactions and minutes now form 65 volumes, containing more than 800 papers with discussions. The society library numbers 18,000 volumes; and the "Bulletin" of the society is published monthly, with full "Minutes" issued every two weeks.

The first meeting in the present society building was held on Dec. 17, 1896, and it was officially opened in January, 1897. The general arrangement of the house is simple. The basement contains the heating and lighting appliances and vaults for the archives of the society; the ground floor is occupied by the vestibule, the main lecture room and some small rooms; and the main hall was placed on this floor, entering directly from the street, as it is the practice to rent it for concerts and other meetings. In the entresole is a suite of rooms used as a member's club; on the first floor, or the one over the entresole, are the offices and principal committee room, and the second floor is entirely devoted to the library. On a third floor are the living apartments of the secretary.

THE JACQUES PROCESS FOR CONVERTING HEAT INTO ELECTRICITY.

In the summer of 1896 Dr. W. W. Jacques, of Boston, announced that he had solved the problem of the direct conversion of heat into electricity, and had made an apparatus which effected this conversion with the astonishing efficiency of 88%. The genuineness of the invention was said to be vouched for by such excellent authorities as Prof. Cross of the Massachusetts Institute of Technology, Prof. Rowland of Johns Hopkins, Messrs. Stone and Webster of Boston, and others. In an article in "Harper's Magazine" Dr. Jacques described his invention and assured his readers that its success was beyond doubt, and that henceforth power could be generated from coal by his process with vastly better economy than by the steam engine.

In our issue of May 21, 1896, we discussed Dr. Jacques' alleged invention and suggested that it would be a good plan to learn something more about the invention before passing judgment upon it. More than two years have elapsed, however, and the steam engine still turns round, nor is there any present indication that Dr. Jacques' "electricity-direct-from-coal" apparatus will supplant it.

Quite a number of experimenters have studied Jacques' apparatus, but the best explanation of its real character that has thus far appeared was given in a paper recently read by Prof. Langley, of the Case School of Applied Science, before the Electric Club of Cleveland. We abstract the paper as follows:

In its best form the Jacques battery consists of a closed cylindrical iron cell about 6 ins. in diameter and 2 ft. high, forming one terminal in which is suspended a carbon rod 3 ins. in diameter and some 20 ins. long, forming the other terminal. The intervening space between the sides of the cell and the carbon is filled with caustic soda or potash (NaOH or KOH) kept in a molten state by heat applied by some form of external furnace.

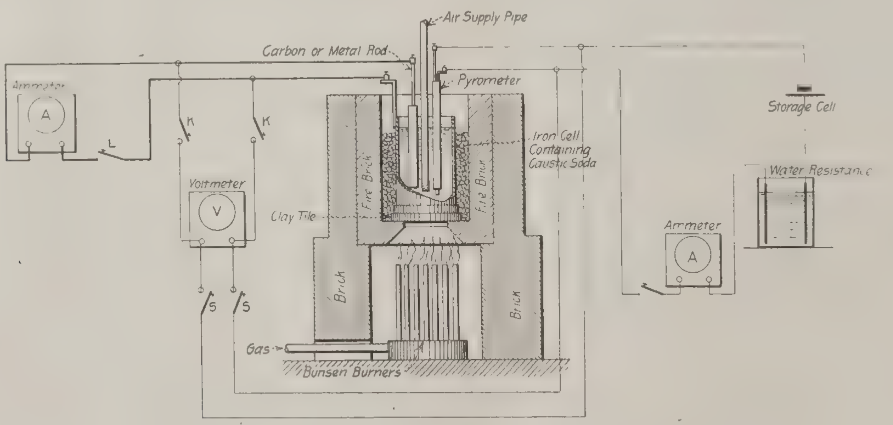
An iron pipe is run down below the surface of the molten potash, and terminates in a rose nozzle. Through this air is forced which rises in fine bubbles through the molten mass and comes in contact with the carbon rod. It was claimed by Dr. Jacques that chemical combination took place between the oxygen of the air and the carbon rod under these conditions resulting in the generation of a current of electricity. With this apparatus it is claimed that a current of 150 amperes at 1 volt was obtained, and the efficiency was about 32%, as compared with the present efficiency of about 9% as obtained in the ordinary way, using furnace, boiler, engine and dynamo. In a special test, in which 100 cells 12 ins. deep and 1½ ins. in diameter was employed, 30 16-c. p. lamps were lighted for 18¾ hours. During this time the average pressure was close to 90 volts, the current 16 amperes and about 8 lbs. of carbon were consumed in the cells. That is to say: 90 × 16 = 1,440 watts = 1.93 E. HP. were generated for 18.75 hours at an expense of 8 lbs. carbon or $\frac{8}{18.75} = 0.427$ lbs. per hour or 1 HP. hour was produced for 0.221 lbs. of carbon. Since in a perfect thermo-electric generator 1 HP. hour is produced by the combination of 0.175 lbs. of pure carbon, the efficiency may be given as

$$\frac{.175}{.221} = 79 + \%.$$

It will be noticed, however, that no account whatever is taken of the heat required to maintain the solution in a molten state.

The exact source of the electric current in the Jacques cell has been, as already stated, a mooted question, Dr. Jacques claiming that the chemical action between the oxygen of the air and the carbon of the rod formed carbonic acid and the electro-motive force obtained (1.04 volts) agreed with that theoretically obtainable when oxygen and carbon combined to form CO_2.

To determine the action taking place in the cell and thus afford a final settlement of the dispute a test was undertaken in which the specifications for the Jacques cell in the inventor's patent were followed exactly and the data obtained during a series of experiments forms the basis of a thesis presented by Messrs. H. S. Rosewater and W. H. Oldham, of the Case School. These experiments are described as follows:



APPARATUS USED TO TEST THE PRINCIPLE OF THE JACQUES' CARBON BATTERY.

A fire brick furnace was constructed to protect the gas flames used in heating the cell. This was 2 ft. 11 ins. × 2 ft. 6 ins. by 2 ft. 6 ins. deep. In the upper position was placed the cell made of a section of 4-in. iron pipe 12 ins. long, with a cap over the lower end. The carbon rod and pyrometer were suspended in this and later rods of other materials, such as copper, iron, etc., were substituted. The necessary heat was supplied by a special gas burner made by mounting 15 ordinary Bunsen burners on a circular base. Air was supplied through a piece of gas pipe, closed at its lower end and drilled full of holes, which was dipped into the solution. The blast was regulated by throttling until no splashing occurred. To measure the temperature of the solution a pyrometer was constructed and carefully calibrated. This consisted of a 24-in. piece of ¾-in. pipe, at the lower end of which was placed a coil of platinum wire wound upon a clay pipe stem arranged to project partly through the asbestos plug. By keeping the current constant a direct measure of temperature changes was given by the voltage of a circuit of which the coil was part. Calibration was done in an oil bath, using accurate mercury thermometers. The other instruments were a milli-ammeter, an ammeter reading to 5 amperes and a voltmeter reading to 5 volts.

The accompanying cut represents the apparatus used. In this it will be noticed that the voltmeter V is arranged to read either the electro-motive force of the cell or the difference of potential at the terminals of the pyrometer, the former obtained by opening S S and closing K K, the latter by opening K K and closing S S. The current flowing in the battery circuit when L was depressed was measured by the ammeter A, and that flowing in the pyrometer circuit was indicated by the ammeter A_1, the current being obtained from a storage cell and regulated to about 0.25 amperes by means of an acidulated water resistance.

The readings were taken in a regular order throughout the seven experiments, which were as follows: A copper rod suspended in the solution without air blast; same with air blast; an iron rod without blast and again with; a carbon rod with air blast, then without; and, lastly, a carbon rod without blast but with about an ounce of $NaNO_3$ added to the solution to accelerate the oxidization of the carbon.

Each experiment extended over a period of something over four hours. The figures resulting from these tests were plotted on cross-section paper with the time as abscissas and the temperature and voltage as ordinates, and a study of the curves thus obtained developed a number of interesting facts. In every instance the curves resembled thermal curves. At the start, with no air blast, when the solution is cold and the iron cell hot, the difference of potential between the cell and rod is greatest. As the heat is transmitted through the solution and the whole cell becomes nearer an average, but higher, temperature the difference of potential falls off. Toward the end of the run, when the heat was shut off, the curves show the opposite effect, the temperature of the cell being less than the solution, and at the same time the difference of potential again increases. In other words, the maximum difference of electrical potential occurs when the temperature difference is greatest. The addition of air, tending as it does to cool the solution and rod, would increase the difference of temperature and therefore the difference of electrical potential, a fact noticed in the experiments. The same effect would also be noticed with any gas. On the other hand, if the action were chemical or galvanic, as claimed by Jacques, and the oxygen present in the solution produced negative curves, it would be expected that the addition of oxygen by supplying air would make the curves still more negative. This, however, did not occur.

These conclusions are borne out by a paper read by Mr. C. J. Reed before the American Institute of Electrical Engineers, at its meeting on April 27, 1898. In this, what is termed thermo-electric battery is described, in which the elements are much the same as those used by Dr. Jacques, i. e., an iron cell using sodium or potassium hydrate (NaOH or KOH) and iron or carbon rods. Mr. Reed, however, uses two rods as the elements. In conclusion, Mr. Reed devoted considerable space to a series of curves, which are plotted from values obtained by Liebenow and Strasser,* in a series of experiments in which they used metal cups, iron and nickel, and alkali hydrates with carbon, iron, nickel, steel and silver rods. The results obtained were plotted in the form of curves. Unfortunately, Liebenow and Strasser did not perceive the full force of these experiments, and the relation between the curves of temperature and electro-motive force was not apparent because of their manner of plotting the data. Speaking of this, Mr. Reed says:

> When the intensity of the electromotive force is compared directly with the temperature, instead of inversely (as was done by Liebenow & Strasser), the relation becomes apparent and a diagram thus constructed shows decidedly that the electromotive force increases and decreases with the temperature of the electrolyte. From the nature and arrangement of the apparatus we know that the difference of temperature between the electrolyte and the rod will also increase and decrease with the temperature of the electrolyte. * * * * In the same paper the further statement is made, still considering the work of Liebenow and Strasser:
>
> A second group of most instructive experiments with metal rods substituted for the carbon rods demonstrate in an equally convincing manner that a change in the temperature of the electrolyte produces corresponding change in the electromotive force.

It appears to be quite clear from the foregoing that Dr. Jacques' electric generator, which was to revolutionize the art of obtaining power from coal is really an ordinary thermo-electric battery with an efficiency which is probably as low as that of most thermo-electric batteries. One wonders how the eminent men who vouched for the Jacques battery two years ago failed to discover this fact.

RAILWAY CROSSING COMPUTATION.

Several articles upon railway-crossing computation having recently appeared in this journal, our attention has been called, in this connection, to a short method proposed and used by Mr. L. K. Vial, late Chief Engineer of the Ajax Forge Works, of Chicago, and Prof. R. B. Ketchum, of the University of Illinois. The method is given in full in the "Technograph," for 1897-98, published by the engineering societies of the University of Illinois, but the following abstract will sufficiently explain the process proposed:

The three general cases considered are: (1) The crossing of two tangents; (2) the crossing of one tangent and one curve, and (3) the crossing of two curves. The solution requires the finding of the frog angles and the chord lengths between the frog points, with the angle of intersection of the center lines of the two tracks and the degree of curvature, or the radius, given. The basis of the advantages claimed for the new solution is embodied in the statement that: Any chord length equals the product of the gage and the cosecant of the mean of the adjacent frog angle. This is expressed algebraically, as follows:

$$\text{chord} = g \csc \frac{A + A'}{2}. \qquad (1)$$

Where g is the gage and A and A' are the frog angles adjacent to the chord. This equation is rigidly true for all chords in the crossing of two tangents, and the chords connecting the two tangents, in the second case; but is approximate only for the other chords of Case 2 and for all the chords in the crossing of two curves. The equations given are as follows:

Case I.—Crossing of Two Tangents.

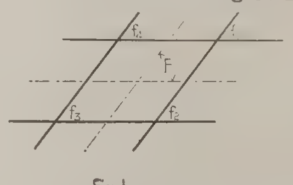


Fig. 1.

For the frog angles we have $F = f_1 = f_2' = f_3 = f_4$; for the "chord" lengths, we have $f_1 f_2 = g \csc F$; or, for sake of analogy to equation (1), $f_1 f_2 = g \csc \frac{f_1 + f_2}{2}$. Similarly for the other three chords.

---

*Zeitschrift fur Elektrochemie, Feb. 20, 1897.

Case II.—Crossing of One Tangent With One Curve.

For the frog angles we have, noting that $M = R \cos F$ and m_1, m_2, m_3 and $m_4 = M = \frac{1}{2} g$:

$$\cos f_1 = \frac{m_1}{r_1} \quad (2) \qquad \cos f_2 = \frac{m_2}{r_2} \quad (3)$$

$$\cos f_3 = \frac{m_3}{r_3} \quad (4) \qquad \cos f_4 = \frac{m_4}{r_4} \quad (5)$$

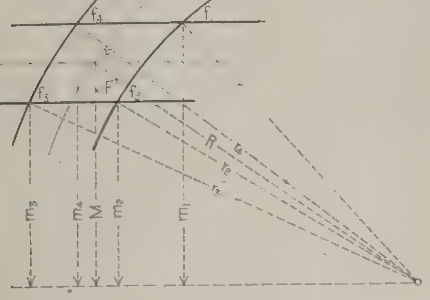

Fig. 2

For the chord lengths we have from equation (1),

$$f_1 f_2 = g \csc \frac{f_1 + f_2}{2},$$ and similarly for the other three chords.

Case III.—Crossing of Two Curves.

Frog Angles.—After solving triangle $OO^1 F$ for OO^1 (= D), we have from triangle $OO^1 f_1$,

$$\tan \frac{f_1}{2} = \frac{1}{S_1 - D} \sqrt{\frac{(S_1 - D)\ (S_1 - r_1)\ (S_1 - m_1)}{S_1}} \quad (6)$$

from triangle $OO^1 f_2$,

$$\tan \frac{f_2}{2} = \frac{1}{S_2 - D} \sqrt{\frac{(S_2 - D)\ (S_2 - r_2)\ (S_2 - m_2)}{S_2}} \quad (7)$$

from triangle $OO^1 f_3$,

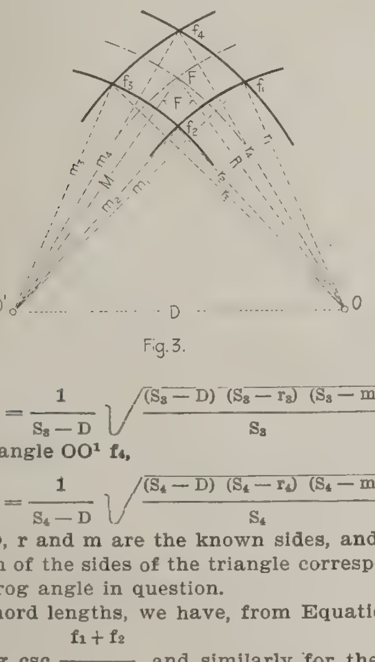

Fig. 3.

$$\tan \frac{f_3}{2} = \frac{1}{S_3 - D} \sqrt{\frac{(S_3 - D)\ (S_3 - r_3)\ (S_3 - m_3)}{S_3}} \quad (8)$$

from triangle $OO^1 f_4$,

$$\tan \frac{f_4}{2} = \frac{1}{S_4 - D} \sqrt{\frac{(S_4 - D)\ (S_4 - r_4)\ (S_4 - m_4)}{S_4}} \quad (9)$$

where D, r and m are the known sides, and S the half sum of the sides of the triangle corresponding to the frog angle in question.

For chord lengths, we have, from Equation (1),

$$f_1 f_2 = g \csc \frac{f_1 + f_2}{2},$$ and similarly for the other three chords.

The original article shows the degree of accuracy and the limitation of the application of Equation (1), and also gives two tables for corrections to be applied only in extreme cases. As a general statement, Equation (1) is practically correct in all cases where either or both curves have radii exceeding 700 ft., and it is practically universal in its application to general railway work.

◆

ARE HIGH STEAM PRESSURES ECONOMICAL FOR STATIONARY ENGINES?

In April last an interesting ceremony took place at the Bellevue Hotel, in Philadelphia, when a bust was unveiled of Chief Engineer B. F. Isherwood, U. S. N., in the presence of a large party of well-known engineers, including many who were formerly connected with the Navy. A complete report of the speeches made on this occasion was given in the "Journal of the American Society of Naval Engineers" for May. Among the speakers on that occasion was Dr. Chas. E. Emery, whose sudden death only two months later our readers will recall. Dr. Emery, in his address, gave some interesting reminiscences of his services under Chief Engineer Isherwood during the war, and then followed with a discussion of some of the principles which Isherwood's investigations first established, which is of much interest and deserves careful thought and consideration by all interested in steam-engine design. We quote this portion of Mr. Emery's address in full as follows:

> It appears probable that investigations, of the character early made by Mr. Isherwood, may reveal results in relation to our modern steam engineering somewhat similar to those he early established. He showed that, under the conditions obtaining in the engines he tested, it was most economical to limit the expansion of steam, and consequently the size of engines, more than had previously been the custom. We can now see that the proportions adapted for low pressures were not the most economical for higher pressures, but it is a grave question if any actual loss during average working resulted from this. We had in our practice for the first time boilers which would supply all the steam the engines could work off, consequently the maximum speed could be obtained at any time and continued indefinitely. This was something new for a steamship. It was something to be sought for and not readily found, even in the present. Undoubtedly the economy was not the maximum, when the machinery was forced to its utmost, but this occurred very rarely, probably not 1% of the time, whereas the engines were of proper size to secure the maximum economy possible during the long periods requiring moderate power, so the average results were as good and generally better than would have been obtained with any other adaptation of simple machinery using the steam pressure available.
>
> It is evident to me that the same principle can be applied in the proportions of our modern compound engines. Some have realized it, and it is not uncommon on the more noted of the transatlantic steamers to hear the safety valves blow for a short interval after changing watches and cleaning several fires, showing the close adaptation of the engines and boilers. On the contrary, I was on a yacht recently, designed to run with 200 lbs. of steam, which had engines so large that when linked up and running at full boiler power it was necessary to keep the throttles nearly closed. The advantage of keeping the engines rather small for the work and the boiler power ample, as in Mr. Isherwood's practice referred to, will be evident to all, on account of the very superior economy obtained in running during the greater part of the time at reduced power.
>
> Further than this, I believe that the limit of desirable steam pressure has been reached, and that possible economy in a scientific rather than a theoretical sense would be attained by not attempting the higher pressures now found practicable. I recently had occasion to investigate a number of compound engine plants operating factories in the East. The one that was most vaunted and claimed to be securing a horse-power for 1.3 lbs. of coal, required 2⅓ lbs. Several others required over 2 lbs., and in only one case did the cost fall as low as 1¾ lbs., and this was one of the earlier engines designed as the immediate results of the analysis I published of experiments with compound and non-compound engines, made, under the direction of Mr. Loring and myself, with engines of different kinds on revenue cutters, which I designed so as to make such a test practicable 24 years ago, and before the revival of the compound engine here and its application to vessels of the U. S. Navy. The proportions of the cylinders of the factory engine referred to were more nearly like those I had used for lower pressures and set forth in my analysis, and the water consumption for this long-stroke engine, small clearances and a steam pressure of 125 lbs., was 16 lbs., the chief economy being in the boilers, whereas the compound engine of the series I designed so long ago gave a horse-power for 18.4 lbs. of water per HP. per hour with only 70 lbs. steam pressure. It is certain that these modern engines with high steam pressures will, under experimental conditions, do 25% to 33% better than the figures stated, but it is equally certain that they do not do it under the conditions of ordinary practice. The same general results are shown on shipboard, notwithstanding there is the same talk about getting a horse-power for 1.3 lbs. The fact is that few steamers use less than 2 lbs. per HP., and the average is higher than that. In some cases, with particular provisions for securing economy from the boilers, better results have been obtained, but it is a question whether any special mechanism is proper for use on a naval vessel liable to the exigencies of war.
>
> Since the average cost of a horse-power is already considerably above 2 lbs., and as this is as true for engines carrying 200 lbs. of steam as for those carrying 125 lbs., the general result, independent of particular cases, is that it is not desirable to carry the higher pressures, with their attendant increase of radiation, liability to external leakage, and particularly the liability to large wastes by inconsiderable leaks in the cylinders and valves and the increased wear and friction of high-pressure packings. If this general proposition be true, another incidental advantage follows to which I have already called attention in the Journal, viz., the possibility of abandoning the intermediate cylinder of a triple-compound engine and the restoration of the 2 or 3-cylinder compound engines, properly proportioned to do the work economically. The triple-compound engines are particularly unfitted for variable powers. This is recognized in the Eastern mills, and compound engines are used exclusively to assist water-wheels even for pressures up to 180 lbs. The compound engine with pressures exceeding 150 lbs. would not be desirable on shipboard, as proper results could not be secured with a simple valve gear, but with lower pressures there would be no trouble whatever in using such engines even with simple lap-valve cut-offs, and the worst penalty to secure best economy would be an independent cut-off for the small cylinder, as in my design of 24 years ago. These suggestions are not criticisms of the policy of any-one. We desire to compliment the present management of the Bureau and express our love for its Chief, but only by suggestion, discussion and investigation can the truth be known. The suggestions are made here because they are in the line of Mr. Isherwood's earlier work, and a correct principle lives through all time.
>
> I have, however, thus far neglected to state that, although the high steam pressures do not give increased economy in practice, they have enabled the mean pressure, referred to the large cylinder, to be increased from 25 up to 40 lbs., and in small engines up to 50 lbs., which, with higher speeds, better material and closer design, has so greatly decreased the size and weight of steam machinery. This has been partially defeated in many cases by attempting with higher pressures greatly increased expansion, which, though economical on a test, is a blunder for variable power and long continued use where minor repairs cannot be promptly made. We must recognize that, in the suggested decrease of pressure, which can certainly be obtained without decreasing the economy in actual practice, we must not increase the size of engines so that, even without the intermediate cylinder, they will be heavier than those for which they are substituted. Just where the limit is, cannot be determined in a hasty discussion of this character. I only wish to call attention to the fact that apparently such a limit exists and that the efforts of thinking engineers can well be directed to its exact definition under particular conditions.

RATIONAL FORMULAS FOR THE STRENGTH OF COLUMNS.

A paper by Mr. Carl G. Barth, entitled "An Investigation into the Strength of Columns, Leading to Some New Formulas," read before the Engineers Club, of St. Louis, Mar. 16, 1898, and printed in the "Journal of the Association of Engineering Societies" for April, contains a long mathematical investigation of the subject, and presents some working formulas both for concentric and for eccentric loads. The basis upon which the work proceeds is stated as follows:

> Evidently all we can look for in a rational column formula is that it shall enable us to determine a load that will subject a fairly well-made and properly arranged column to no undue stress, even if that load should accidentally be applied at some reasonable distance out of center.
>
> The formula herein to be proposed is of that nature, and has been derived by considering all the uncertainties of a practical column (such as possible imperfections in its material and form, and any possible eccentric displacement of the load) as equivalent to a certain amount of initial eccentricity of the load on an otherwise ideally perfect column.

The author's final formula for concentric loading, reached after making some approximations for the purpose of simplifying a much longer formula, is:

$$p = \frac{f}{1 + \frac{9}{\pi^2} \frac{f}{E} \left[\frac{l}{r}\right]^2} = \frac{f}{1 + 0.912 \frac{f}{E} \left[\frac{l}{r}\right]^2},$$

in which p = permissible working load per square inch of cross-section of the column, f = permissible working stress per square inch of section of an exceedingly short practical column, E = modulus of elasticity of the material, l = length, and r = least radius of gyration, both in the same units.

For eccentrically loaded columns he obtains:

$$p = \frac{f}{1 + \frac{w\,a}{r^2} + 0.912 \frac{f}{E} \left[\frac{l}{r}\right]^2},$$

in which w = distance from the center at which the load is applied, and a = distance from the center of the section to its most remote fiber.

We cannot spare the space for even an abstract of the analysis by which the formulas are derived, but must refer those who are interested in the subject to the original paper.

This has been reprinted in a separate pamphlet, copies of which can be obtained, we presume, by addressing Mr. Barth, at 337 Harrison Ave., Scranton, Pa.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; 6 *months,* $2.50; 2 *months,* $1.00. *To all other countries in the Postal Union: Regular Edition, One Year,* $7.60 (31 *shillings*); *Thin Paper Edition, One Year,* $6.31 (26 *shillings*). *SINGLE COPIES of any number in current year,* 15 *cents.*

In ordering changes of mailing addresses, state BOTH old and new addresses; notice of change should reach us by Tuesday to be effective for the issue of the current week. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number 328 *means that subscription is paid to the* 32*d week (that is the issue of Aug.* 11) *of the year* 1898; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line. Want noticees special rates, see page* 18. *Rates for standing advertisements sent on request. Changes in standing advertisements must be received by Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

The entire success of the conduit electric railway system in New York city and in Washington is likely to lead to demands upon electrical railway companies in other cities to remove their poles and overhead wires and substitute the conduit system. As it happens, the franchises under which not a few street railway companies are operating, contain a provision that when any system of electric street railway operation is perfected and proved to be practicable which dispenses with the use of overhead wires, the company may be required by the municipal authorities to alter its lines to that system. The rigid enforcement of this requirement would generally be a serious thing for the street railway companies; and in many cases we believe the real interests of the city which has the right to require such action by its street railway companies can be better served by a more conservative course. It must be remembered that the cost per mile of the electric conduit construction is very high. It may be roughly estimated at about double the cost of the ordinary overhead trolley system. Many street railway companies would be forced into receivers' hands if required to duplicate their investment in their tracks, with no additional income resulting. It may be said, that that is no affair of the city authorities, their sole duty is to see that the railway does everything which it is obliged to do for the city by the terms of its franchise. This, however, we believe to be a narrow view of the question. If the size of a city and the volume of traffic on its street railways is sufficient to justify the conduit system, then it may be all right to compel the company to install it; where the city has the power. But to bankrupt a city's railway companies will in the long run injure the city and the patrons of its railways, as well as those who own the railways. The prejudice against the overhead trolley system has almost disappeared. The "deadly overhead wire," which was what the public feared most, has an astonishingly small record of accidents against it, as it is now installed in street railway practice. The trolley wires being located in the middle of the street are no such obstacle to the work of firemen as are the electric light, telephone and telegraph wires, which are strung on high poles next the curb. Really, except where streets are so narrow and crowded that the room taken up by the poles is a serious matter, the only objection to the overhead trolley system for street cars is the objection to the disfigurement of the streets. And this disfigurement is by no means so serious as is sometimes claimed. If the street railways were owned by the city, how many taxpayers would be in favor of expending an additional $25,000 per mile of track merely to improve the aesthetic appearance of the streets by dispensing with overhead trolley wires? Certainly the gain to the average citizen from the removal of the overhead construction would not compensate for the loss that will inevitably result from throwing the company into bankruptcy.

Suppose, however, that a company can well afford to introduce the conduit system. Even then we believe that in many instances something better can be done than to force the company to adopt it, where the city has the power. Concessions in the form of reduced fares, especially to school children and workmen, increased transfer privileges, extensions to outlying suburbs in need of better communication, or even increased cash payments to the city as rental for the use of the streets, would, in most cases, be of much more real value to the citizens than the removal of the poles and overhead wires.

Of course, we are not speaking now of the largest cities. In several of these, space, light and air in the streets have become so valuable that the substitution of the conduit in place of the overhead system ought to be made, and doubtless will be in the near future.

◆

The smoke nuisance, due to the use of soft coal, has reached Scranton, Pa., the chief center of the anthracite region. An ordinance has been adopted in the select council directing the city engineer, building inspector and plumbing inspector to "acquire a knowledge of methods and devices now in use for the purpose of reducing to a minimum the smoke and dust annoyances resulting from the use of bituminous coal, and report to councils at the earliest date possible." The burning of soft coal in Scranton is worse than "carrying coals to Newcastle." About two years ago the Scranton papers were full of claims that the anthracite culm piles in and near that city were a storehouse of the cheapest fuel in the country, that the culm could be made into gas, and the gas used to generate power at a cheaper rate than water power could be furnished at Niagara Falls. And now it appears that it is found cheaper, by some of the Scranton people at least, to burn soft coal obtained from a distance of say 200 miles, than to burn the culm which may be had in the city for 25 cts. a ton. We in New York city can sympathize with Scranton in this matter, for the use of soft coal here is increasing steadily, and complaints of the smoke nuisance have become quite common. One method of getting rid of the nuisance has occasionally been tried here with success, which may be commended to the attention of the Scranton officials who have been directed to "acquire a knowledge" of the subject. It is an ordinary suit in court brought by any individual who is aggrieved, praying for an injunction restraining the offender from using it in such a way that it will emit smoke and cause a nuisance. Such injunctions, we understand, have been granted on the ground of the common law respecting nuisances, that no man has a right to maintain a nuisance that injures his neighbor's property or destroys his comfort, and offenders have been compelled to abandon the use of soft coal and return to anthracite.

◆

PIONEER RAILWAY CONSTRUCTION IN NEW COUNTRIES.

The course of recent events appears to indicate that within a few years the great empire of China may offer a new field to the American engineer and merchant, and that the overthrow of Spanish misrule and medievalism in the West Indies and the "Far East" will also lead to possibilities of rapid development of American interests in these smaller fields. Development in such cases means, first of all, the introduction or extension of the railway. While the American engineer in his own country has shown his ability to build light and inexpensive railways for development purposes, and to improve these lines in proportion as the traffic increases, he has so far had but little opportunity to exercise this ability in other countries, with the exception of Mexico. It is true that he has built railways in the West Indies, in Central and South America, and in the Hawaiian Islands, and is building one in Korea, but most of these have been short lines, built to accommodate an existing traffic from mines, or along established routes of travel, rather than to serve as lines of general development. Already American engineers have been established as advisers in railway affairs in China, and should the recent war with Spain result in giving the United States a permanent foothold in what is termed in Europe "the East," there is little doubt but that American interests in China will experience considerable benefit. It seems appropriate at this time, therefore, to give some consideration to the general question of the construction of pioneer railways in new countries, and particularly in China.

For many years past there has been a great deal of energy expended in promoting railway schemes in China, most of which had practically no result. Every large European country has tried to force railways upon China, and there have been not a few American schemes for this purpose. For a long while the Chinese have stolidly and steadily rejected all propositions, and the most that has been done has been gradually and very slowly to build the lines now known as the Imperial Railways of North China, less than 300 miles in length, and extending from Tientsin to Pekin, and northeast to a point beyond Shan-Hai-Kwan. Two other short lines are also making slow progress.

Within very recent years, however, and especially since the war with Japan, there have been signs that the Chinese will eventually permit their country to be opened up by railways, and the result has been that renewed efforts have been made by professional promoters and by representatives of various foreign governments to obtain important concessions. At the present time a great number of lines are projected, but little is known as to the probabilities of their construction, although the appointment of an American consulting engineer to the Director General of Railways may be assumed to indicate that there is already some appreciation of American skill in railway construction.

In India, Australia, and Siberia, the railways have been introduced by one nation, and that the dominant nation, and the work has, therefore, not been subject to the interference of outside influences. The same is in the main true of Africa, although the number of petty states bordering upon the great territory held by the British have caused some political complications.

In China, however, the conditions will be very different. That nation will do none of the work itself; in fact it has no men competent or experienced enough to plan or direct such work, and it must, therefore, rely almost entirely upon foreigners for its railway system. As a result of this the Chinese government has already been subjected to severe pressure from various other nations, each of which will probably get some share in the distribution of concessions, and it is impossible that all these varied interests should work harmoniously together. Already a war cloud has been raised in Europe by differences over the diplomatic negotiations for railway concessions in China. The government apparently cannot foresee that which seems to outsiders to be the inevitable outcome of this sort of competition. It has evidently no determined policy on the railway question, and is seeking to play off the various Powers against each other, which is a dangerous practice.

In the various discussions upon this subject, one very important point seems to have been almost entirely ignored, and that is the relative character and competence of men of the different nationalities interested to build railways suitable to the conditions prevailing in China. It is essential that the lines should be made as cheaply as possible

[illegible]

with due regard to efficiency and safety, since the vast majority of the people are extremely poor, and most of the railways will be lines of development, the fundamental principle of which is that the greatest length of line should be built in the shortest time and with the least expenditure of money. It is, we think, not too much to say, that American engineers are pre-eminently qualified to undertake this character of construction, since they have shown by their works that they understand and can act upon this principle, avoiding, on the one hand, the Scylla of unnecessarily good lines built at large cost and great expenditure of time, and, on the other hand, the Charybdis of purely cheap lines, as speculative enterprises, which can hardly be included in the term engineering works.

The greatest amount of railway building in new countries has been done by English engineers, but while their work has been good, it has in very many cases been much more expensive than the existing conditions have warranted, and they have shown a tendency to build a limited mileage of first-class railway, rather than an extensive mileage of railway of a character more suited to the traffic. This matter was discussed in our issues of Aug. 4, 1892; Dec. 22, 1892; and April 6, 1893. For lines intended to develop and open up a new country this system is essentially wrong.

In India and Australia the policy of slowly building lines of the most substantial character, and with handsome and costly structures, was followed for several years. In this connection it is interesting to note that in the early days of railways in India, Col. Kennedy, a military engineer who was sent out to report on the introduction of railways, proposed that the Bombay, Baroda & Central India Ry. should cross the flat alluvial districts on its line by means of iron viaducts with 60-ft. spans of through Warren girders on screw-pile piers, each pier to consist of three vertical piles, with batter piles on one or both sides at the crossings of non-tidal or tidal rivers, respectively. This system has been much used in India, but the fact of its recommendation for the first lines in a new country, requiring the importation of thousands of tons of ironwork from England, seems to show that Col. Kennedy was not the right sort of engineer for pioneer lines. In fact, it was this gentleman who, in 1851, prepared a report in which he laid down a series of rules for railway construction in India, which is remarkable for its complete disregard of economical considerations. In this report he recommended that the new Indian railways should have maximum grades of 1 in 2,000 for main lines, and 1 in 330 for branch lines, with "impulsive planes" to assist the ascent. The consulting engineers, however, disapproved of "impulsive planes," and recognized the fact that such limitation of grades was uttterly impracticable, since it would often be far more economical to build a short line with heavy grades than a long line practically level, especially in mountainous districts.

In India some of the trunk lines were of very expensive and permanent construction, and some of the large flood areas are crossed by railways on high embankments with immense high level bridges and an extraordinary number of flood openings, entailing enormous cost. It must be remembered, however, that the conditions there existing differed very considerably from those of Australia, Japan and Africa. The military and strategic necessity for railways in India was a most important consideration, fully equal to that of their necessity for development purposes, and in many cases this fully warranted the enormous expenditures involved in the great works which were required to ensure uninterrupted communication. Still, there are many railways in India which have been built in an unnecessarily expensive manner. In fact, the type and cost of construction of the early railways in general, in that country, was far beyond what was necessary, and an enormous loss of life in the terrible famines has been attributed largely to the fact that the authorities devoted their attention to building short lengths of excellent and costly lines rather than to building a comprehensive system of lines of communication.

In Australia the special advantages of the construction of light and cheap railways for development purposes are being more generally recognized, and in 1893-97 Mr. M. C. Kernot, Engineer in Chief for the Government Railways of Victoria, had several such lines built in that colony at a cost of less than $10,000 per mile. These were in districts where the ordinary passenger and freight traffic was light, and the railways carried wheat and agricultural produce to the seaboard. Seven lines, aggregating 192 miles in length, showed a cost per mile ranging from $6,690 to $10,805, the average being $8,840 per mile. These were of the standard gage of the colony, 5 ft. 3 ins., and had 60-lb. T-rails on eucalyptus ties 9 × 4½ ins., 9 ft. long, lasting 25 years. The bridges and box culverts were of timber. Even this low cost could have been further reduced by the use of plows, scrapers and grading machines; but in order to furnish work for the unemployed of the large towns, all the grading was done by pick and shovel, wheelbarrows and teams. Small contracts were let to gangs of men, each gang appointing its own foreman, but the entire gang shared equally in the earnings. The work was mainly in level country with occasional sand hills and ridges. The annual rainfall of the district is but 14 ins., and the water is quickly absorbed by the sandy loam. As the question of floods did not enter into consideration, the line was built on low embankments, the earth being compacted by means of water-ballast rollers hauled by bullocks. In New South Wales, also, somewhat similar pioneer lines have been introduced, on which trains are run at low speed, and in order to save the expense of fencing it was determined to run trains only by day. On one line, however, this latter arrangement has been rendered unnecessary by the use of an electric headlight, this being done in order to allow of making certain connections with the main line trains.

It seems not improbable, in view of the actions of the Chinese in the past, that procrastination and obstruction will for many years be the great hindrance to railway construction and will of necessity greatly increase the cost of such construction. There will probably be special boards or commissions on railway affairs, composed of native officials who cannot be expected to understand their duties, or to be competent to direct or advise, all of which will tend to complicate matters and introduce delay and extra expense. These hindrances, too, will be increased materially by red tape methods similar to those which have tried the souls of professional engineers in India for the last fifty years. Sir Arthur T. Cotton, R. E., in his "Public Works in India," 1853, makes the following remarks upon the course of officialdom in that country:

> The motto hitherto has been: "Do nothing; have nothing done; let nobody do anything. Bear any loss, let the people die of famine, let millions be lost in revenue for want of water or roads, rather than do anything." It is not the loss of money that we mind, that is nothing. We can afford to lose millions every year for want of hydraulic works, and therefore to spend thousands on such works would, of course, be nothing. But nothing must be done.

The delays and contingencies due to government regulations and red tape are by no means the only hindrances to rapid and economical construction. The provincial and local authorities will all have more or less power for interference and will cause embarrassments which can only be dealt with by the expenditure of time and money. The character of the people, too, must be taken into consideration, and this is such as to undoubtedly lead them to put many practical obstructions in the way of the work and harass its execution.

While much of the projected work will be in flat and easy country, as on the Shansi and Hankow lines (Eng. News, Aug. 12, 1897, and March 31, 1898), yet, under the conditions already noted, no accurate estimate of cost can be made. Even supposing that a careful estimate is made, with a full knowledge of the character of the country, the style of construction, the labor conditions, and the cost of material, then liberal but indeterminate allowances must be made for contingencies incident to the difficulties of work in new countries, with little skilled labor, and with inadequate facilities for transportation or for replacing material lost or damaged in transit. Furthermore, the general evidence is to the effect that, in China at least, provision must be made for certain payments to a long list of officials. Under these circumstances, estimates based on the cost of construction in other countries are of little value.

The character of construction will, of course, depend largely on local conditions. In a new country the question of gage is one of the first considerations, but the cases are rare in which the standard gage of 4 ft. 8½ ins. will not be the most advantageous, for trunk lines at any rate. The troubles due to lack of uniformity in gage, which are so seriously felt in India and Australia, seem not unlikely to arise eventually in China. The lines now in operation are of the standard gage, as are the two short lines under construction, but the Manchurian railway, which is an extension of the Trans-Siberian Ry., will have the Russian gage of 5 ft. In China, as already stated, the country is largely flat or rolling, so that there will be but little reason for bringing up the stock arguments in favor of a narrow gage.

One important point, however, is that much of this flat country is subject to inundation, and that the railway must either be kept above the flood level by diverting it around on the higher ground and carrying it on viaducts and embankments with flood openings, or must be carried boldly across as a low-level line, traffic on which may be stopped occasionally during periods of high water. This is largely a question of expediency, but though it is a very important question, it is not unfrequently overlooked. For example, we may mention a treatise on "Pioneer Engineering," by Mr. Dobson, an English engineer, in which the question of the relative merits and expediency of high-level and low-level lines is not considered at all. In many cases it will probably be a wise plan to boldly cross the district by a low-level line, conforming as closely as possible to the surface of the ground, and allow traffic to be temporarily suspended during flood times. Of course, if the traffic is heavy enough to warrant the cost it may be better to keep the line as far as possible on high ground and to cross the flood district by trestles or viaducts. An interesting article in relation to the building of high-level or low-level railway lines across districts subject to inundation will be found on another page of this issue.

Under the conditions which prevail in China, it is practically impossible to lay out a system of railways suitable to the general development of the country, but the engineers will have to deal with individual lines along routes prescribed and limited by the concession for each line, and it is not at all improbable that some of these will conflict and be in competition, thus involving an expenditure of money and work which might better have been devoted to the extension of a complete system of railway.

To encourage traffic in a country where wages are so small, the rates must be extremely low, and the cost of construction and equipment must equally, therefore, be kept at a minimum. The improved facilities will undoubtedly induce travel on the part of merchants and others, and the social system is such that it will be impracticable to introduce the American system of uniform rates and accommodation. The increased intercourse, however, will tend to weaken the existing class distinctions, as has been the case in India.

One of the great economic purposes of railways in a new country, is to reduce the cost of transportation far below the enormous cost of slow transportation of small quantities in native wagons and on native roads. This aim can only be attained if the railway is built with a view to the lowest possible charges. Steam navigation on rivers and canals also tends to increase traffic and reduce the cost of transportation, and it is probable that China, like India, will offer a field for this system of transportation. In fact, in April last the Chinese government determined to abolish the restriction on the use of steam power, and to permit foreigners to use steam vessels to navigate the rivers and lakes instead of using only native boats. This will probably prove to be an important concession.

In the planning of a system of transportation, one of the prime considerations is the time in which the means of communication can be completed and put in operation, as the more rapidly it is built and extended the more rapidly will the traffic be developed. Any delay in completing the line will, on the other hand, be a cause of serious loss. Sir Arthur Cotton estimated that for the construction of 760 miles of development railways in India, there would be a saving of $75,000,000 in cost of transportation by building the line in 15 years at $50,000 per mile, rather than in 30 years at $25,000 per mile, the greater expense being allowed for difficulties in construction, and not for heavier works. In other words, if the cost of transit of the existing traffic, including what is brought to the line in consequence of the improved facilities which it offers, was $12,000 per mile, and could be reduced to one-fourth of that sum by a railway, there would be a loss to the country of $9,000 per mile for every year the opening of the line was delayed.

Train speed is a matter of very minor consideration, the traffic accommodation and capacity of the slowest railway being far and away beyond that of road transit. It will be evident that traffic can be better served and at far less cost by being handled on 500 miles of railway at 10 miles per hour, than on 100 miles on the railway cars at 30 miles an hour, and 400 miles on wagons at 3 miles an hour. What is needed, in the interests of the development of the country, is not speed in operation, but speed in construction, thus giving a system that will naturally reduce the cost of transportation over a larger area of country, rather than one requiring a large expenditure for a small extent of excellent communication. This has been the fundamental principle of railway construction in the United States, and when once the line of communication is completed it can be improved in accordance with the growth of the traffic.

Under such a system, districts having mineral or agricultural resources which are at present practically unavailable on account of the difficulties and cost of transportation, may be quickly developed, and bring a heavy traffic upon the line.

The eminent Indian engineer, Sir Arthur T. Cotton, R. E., who has already been referred to, strongly advocated the construction of cheap railways which could be built rapidly and carry traffic at low speed, the primary object being to open up communication. The following quotation sums up his principles in brief:

> Nothing can compensate for loss of time in opening up the country. What is most wanted is speed, not in traveling on the railways or canals when executed, but in executing them. What is the use of going a hundred miles at the rate of 34 miles an hour, if we must then go on at 3 miles an hour for thousands of miles. To throw open the country 20,000 miles of good common road, to be traveled at 7 miles an hour, and costing only $2,500 per mile, would be of immeasurably greater value than 800 miles of first-class railway at $60,000 a mile, with a speed of 34 miles per hour; since the former could give an average speed through the country more than double that of the latter. Speed is indeed what is wanted, but speed in forming communications, not speed in traveling upon them.

He opposed the government policy of building magnificent roads, and the railway policy of slowly building lines of first-class construction, but strongly advocated cheap railway construction, considering that in regard to the important point of completing a system of communication, such railways have an enormous advantage over common roads, and would cost but little more. The cost of works for a cheap railway, complete to subgrade, would be but about one-fifth that of a good road, and the work could be done in one-fifth of the time, while the laying of track would be done very rapidly. He claimed, and supported his claims by careful calculations, that the time saved in laying such a railway, as compared with making a road, would, on main lines, much more than pay for the railway, and held this up as an argument against going on with the construction of common roads on main lines of travel.

The conclusions arrived at fifty years ago in regard to India, seem to be very directly applicable to China at this time, and may be summarized as follows:

Cheap railways and good common roads will greatly reduce the present cost of transit. In a rich country already provided with a complete system of cheap transit, high speed of transit is a prime consideration, but in a very poor country, with no adequate means of transit at moderate cost, the prime consideration is to provide a general system of cheap transit. The great point, therefore, is to adopt a system of communication which will greatly reduce the cost of transit, and to execute this throughout a large extent of country in the shortest possible time, rather than to make the most perfect communication possible on a few hundred miles in the course of 20 or 30 years.

LETTERS TO THE EDITOR.

The Litigation Over Air Brake Triple-Valve Patents.

Sir: It is reported to us that a statement is being circulated to the effect that the decision of Judge Wallace, of the United States Circuit Court, in our suit against the New York Air Brake Co. for infringement in the manufacture and sale of its present form of triple valve, is a final one. Such a statement is utterly without foundation, as the case in question will not be finally decided until after it has been heard by the Court of Appeals. The hearing before the Court of Appeals is set down for the next term, which opens about the last of October, and the merits of our case are such that we have good reason to believe that the decision of the Court of Appeals will be favorable to us. Very truly yours,

The Westinghouse Air Brake Co.

Pittsburgh, Pa., Sept. 24, 1898.

◆

The Accident at the New York and Ottawa R. R. Bridge.

Sir: In your interesting account of the failure of the New York & Ottawa R. R. bridge over the St. Lawrence River, it is not clearly stated as to what depth, if any, the crib foundation was sunk below the natural bed of the river. From the description I take it that the crib simply rested on the bed of clay and boulders. If this is true, it would seem a most serious fault of design for so important a structure. The sinking of the crib would increase the erosive effect of the current to some extent and would lead one to expect quite possibly, if not probably, what apparently did actually happen.

I do not believe, and think most engineers will agree with me, that any material other than solid rock is to be trusted for a foundation for a bridge pier in a river having so great a velocity of current, unless excavated so far below the natural bed of the stream, or so thoroughly protected by riprap or otherwise, as to make the undermining of the structure by the scouring action of the current practically impossible. Yours respectfully,

E. W. Lewis.

Duluth, Minn., Sept. 20, 1898.

(Doubtless the engineers in charge of this piece of work considered that the bottom on which the crib rested was sufficiently stable to justify them in founding the crib directly upon it. They believed that the swift current of the river had in the course of centuries so scoured the bottom that no further erosion need be feared; and we are informed that the divers who went down inside the crib found the boulders on the bottom so firmly imbedded in the hard pan as to be very difficult of removal.

The protection of cribs by heavy rip-rap is always a good precaution, and the result in this case shows that it would have been wise to have made use of it; nevertheless, in fairness to those responsible for this structure, it should be said that rip-rap is frequently omitted on river bottoms of cobble-stones and boulders, where the engineer feels sure that the bottom will safely withstand the increased scour.—Ed.)

◆

Differentiation in Professorships of Civil Engineering.

Sir: It is taken for granted that the title "Professor" will always be used to officially designate the heads of collegiate departments of civil engineering, although in social life it may be considered more desirable and refined to use the simple prefix "Mr." The indiscriminate prodigality manifested in appropriating the title (extending even to the signboard "Virgil Greene, Professor of whitewashing," swinging in a Southern alley, or "Professor Gray, dyer and cleaner," insinuating an academical interest in collegiate clothing) may approach the humiliating until one remembers that the man graces the title—the title does not make the man. After all, there is no other word that will so thoroughly designate and describe the professional duties under consideration.

The universal title of professor may, then, be considered as fixed. It may also be held as perfectly settled that American custom has become too well defined to consider favorably the system of many technical schools of continental Europe, which give to each member of its faculty simply the general title of professor without combining in that title the designation of his particular branch of instruction. Where a college charges one man with the responsibility of all the civil engineering instruction, there can be no question but that he should be the "Professor of Civil Engineering." This term in its fundamental meaning covers the whole field of engineering, except military, and therefore is most fitting. It is where the institution has grown to require a differentiation of instruction in civil engineering that confusion follows. Its cause is partly of classification and partly of administration; but the results, as exemplified by present practice, it may be hoped, are, in some respects, only tentative.

One college has a "Professor of Mathematics, Surveying and Astronomy," and at the same time a "Professor of Civil Engineering, Mining and Metallurgy,' and another has its "Professor of Mathematics and Geodesy," while still having its "Professor of Civil Engineering." Other institutions, while combining in a title courses more closely allied, still display a combination of branches not the most intimate in character, or a prolixity of terms quite subversive of a simple directness; as the "Professor of Civil Engineering in charge of Railroad Engineering and Geodesy." Several universities have a professor of civil engineering, and also professors of branches universally understood to be embraced by the general term of civil engineering. One college has its professor of civil engineering and associate professors of several of the subsidiary branches. Two universities have abandoned the title of professor of civil engineering, and have their professorships differentiated by titles distinguished by engineering designations which the term civil engineering broadly includes.

When there comes a marked increase in the instructional force, should one still be a professor of civil engineering with all the others subordinated, should the stronger men of this force be designated as professors of differentiated branches of civil engineering while still retaining this general professorship also, or should the latter proposition be adopted, but dropping the professorship of civil engineering?

The first mentioned plan is one adopted by British colleges, which usually have a professor of civil engineering, lecturers, demonstrators, assistants and instructors. Apart from the fact that this would involve a change in the prevaling American tendency and practice, there remains the situation that this plan would be hardly applicable to our colleges where the system of apprenticeship has no part in engineering education, and which are often situated in the smaller cities where eminent lecturers cannot be readily called upon as occasion demands. With us such men must be on the permanent staff of the institution if their services are secured; and in expanding to cover the ever broadening field of instruction and to keep pace with the demands of active engineering practice, men of recognized ability could not be expected to be made subordinates.

Moreover, there remains the most important consideration of all, the close touch that exists, the intimacy that must be fostered between engineering practice and engineering education. Civil engineers have differentiated as mechanical engineers, mine engineers and electrical engineers, so that now in America these last are rarely thought of as civil engineers; specialization has further given us railroad engineers, hydraulic engineers, sanitary engineers, bridge engineers, municipal engineers, geodetic engineers, topographical engineers, structural engineers and irrigation engineers—terms scarcely less fixed and characteristic than the previous ones; and it has coined and is adopting more or less well-known designations of similar style.

Profiting from this practice, mindful of the spirit of the usage of the universities, and aiming to secure titles that will be at once definite, distinctive and terse, it would seem no very difficult task to formulate a system applicable to any situation. The keynote to such a plan would be the use of the more general and inclusive designations where the number interested is few; the application of the more restricted and specific terms where those concerned are greater in number; and the passing from the former class to the latter with the growth of the institution by adopting the latter character of titles while abandoning the use of the former as circumstances permit.

Suggestive of development under this plan may be considered the adoption of the titles "Professor of Railroad Engineering" and "Professor of Municipal Engineering" where there are established two professorships. The former designation is already considerably used, but the merits of the latter term seem to have been overlooked by all but one of our universities. "Municipal Engineering" characterizes the title most fittingly, particularly where there are but two or three co-ordinated professorships; in style it is direct, simple and expressive; in significance it carries undoubted distinction; in scope it includes a large proportion of the civil engineering branches, while still being sufficiently elastic in application to embrace allied branches, or not, as circumstances make advisable; moreover, the term signalizes a line of labor that engages the attention and interest of a large number of our engineering graduates. In a large measure the same reasoning applies to the other title already mentioned, and together they would comfortably cover the whole field. Or, if three responsible heads were deemed advisable, the third appellation might, for similar reasons, be found in "Professor of Structural Engineering." Other professorships would find their appropriate designation in the list of engineering specialties already given or implied, always tending from the more inclusive terms to the more specific as the field expands. In special situations certain titles would naturally be adopted earlier than in the general case; as, in the arid states, the universities would probably find the "Professor of Irrigation Engineering" of the first importance.

With co-ordinate professorships established to conform to the trend of engineering practice, with the covering of the field by these subsidiary titles, and with several correlated professors placed in responsible charge of the work, what reason remains for continuing the professorship of civil engineering? One who holds the latter title may readily object to assuming a less comprehensive one, or executive details may, in a certain case, interpose; but these will not permanently interfere with merging such a condition into the differentiating system of co-ordinate titles, and so giving free scope to a thorough education of the specializing engineer. As Mr. George S. Morison said in his Presidential address before the Am. Soc. C. E., 1895, "the civil engineer of the new epoch must be a specialist, . . . but his specialty must not be of a narrow kind; he must have that general knowledge and training that marks the liberally educated man."

The educational development of the immediate future involves specialization. Whether a thorough differentiation, meeting the needs and embodying the genius of the coming age will ultimately require (as sometimes with nations) the impulse of an all-embracing, supreme system, the future will disclose. If this occurs the professorship of civil engineering may well be reinstated, but with an enlarged significance. For it must follow differentiation to reunite all its branches, some of which are, in this country, already all but divorced, and others are in course of separation. Such an adjustment would mark the complete realization of the statement of the authority already quoted, that "it is a common error to think of civil engineering as a co-ordinate branch of a general profession with many other branches; to class it with mechanical engineering, with hydraulic engineering, with sanitary engineering, with mining engineering, with electrical engineering, or with any other specific branch. The name of every special branch of engineering has a distinctive meaning. . . . . Civil engineering, in its true meaning, embraces every special branch of engineering." However, our immediate concern is not affiliation, but differentiation. J. L. Van Ornum,

July, 1898.

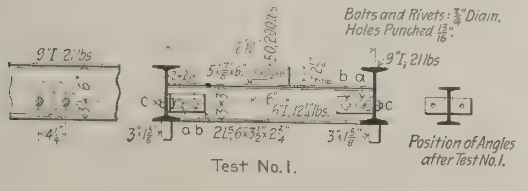
Erroneous Data in Manufacturers' Hand-Books Concerning Structural Beam Connections.

Sir: The letter of May 6, 1898, addressed to you by Mr. Henry S. Prichard, of Trenton, N. J., is duly noted. In this letter Mr. Prichard criticises the data relating to beam connections in hand-books issued by the Cambria Iron Co. and others. In order to ascertain the actual facts in this case we had tests made of our standard beam connections with the results shown below: The details of the arrangement of the beams for test are shown on the accompanying sketches:

Test No. 1.—Connection angles were riveted to the 6-in. I-beams and bolted to the 9-in. beams with rough ¾-in. bolts and the 6-in. I-beam was coped in our usual manner flush with the bottom of the 9-in. I-beams. The pressure of the testing machine was distributed over a space of 6 ins. at the middle of the 6-in. I-beam, as shown on sketch, and was applied by the downward pull of the moving head of the testing machine, which travels at the rate of about ¾-in. per minute. In this test the 9-in. I-beams were braced at both ends, as shown in the sketch. Pressure was applied up to 50,200 lbs., and the test was stopped as the 9-in. girder beams were bending outward and began to buckle. At the conclusion of the test the bolts, rivets and angles were found to be intact.



Test No. 1.

Fig. 1.—Test of 6-in. I-Beam With Riveted Angle Connections Bolted to 9-in. I-Beam Girders and Coped to Fit Bottom Flange.

Test No. 2.—This test was arranged in a manner similar to that used in test No. 1, the only exception being that the 6-in. beam was not coped, and was bolted to the 9-in. beams at the middle of their webs. At a pressure of 47,000 lbs. the connection angles began to spread and at 49,500 lbs. they had assumed the position shown in the sketch, when one bolt sheared at the connection with the 9-in. I-beam. The position which the angles assumed in this case was apparently due to the fact that the bolt holes in the connection angles were more than a quarter of an inch further apart than those in the 9-in. I-beam to which the angles were secured, and as the pressure was applied the slack was taken up with the result shown. This also caused a severe pressure to come upon the bolts, owing to the leverage or knuckle-joint action of the connection angles after they had assumed a position out of line. In this case the leg of the angle between the point of the connection to the 9-in. beam and the first rivet which secured it to the 6-in. beam was bent into a warped surface. After this test the rivets were intact.

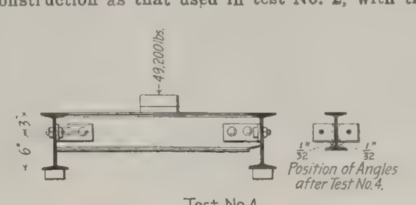
Tests Nos. 2 and 3.

Fig. 2.—Test of 6-in. I-Beam With Riveted Angle Connections Bolted to Middle of Web of 9-in. I-Beam Girders.

Test No. 3.—This test was made on a 6-in. I-beam of same construction as that used in test No. 2, with the exception that the 9-in. I-beams were not braced together at either end. The ultimate strength developed was 55,300 lbs. when the 6-in. I-beam bent and buckled. The test was continued until the load dropped to 40,000 lbs., when the I-beam was very badly distorted. At the end of the test the connection angles were spread at their lower edge about 1-16-in., as shown on the sketch, but the rivets were intact. The four connection bolts were slightly distorted by the shearing strain due to the spreading of the connection angles, but they did not shear.



Test No. 4.

Fig. 3.—Test of 6-in. I-Beam With Riveted Angle Connections Bolted to 9-in. I-Beam Girders and Coped to Fit Top Flange.

Test No. 4.—This test was made on a 6-in. 12¼-lb. I-beam, which connected to the 9-in. I-beam and coped flush on top. One of the ends of the 6-in. beam was also coped on the bottom, as shown in the sketch. In this test the 6-in. I-beams bent and buckled in the center at a maximum load of 49,200 lbs., and the connection angles did not bend away from the web of the beam more than 1-32-in. In this test also the rivets were intact, but the bolts were slightly distorted as in test No. 3.

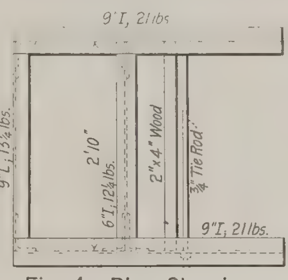


Fig. 4.—Plan Showing Arrangement Used for Making Tests Nos. 1 and 2.

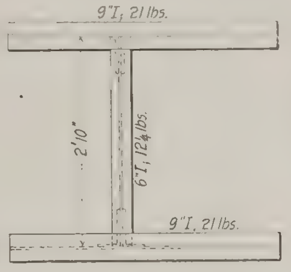

Fig. 5.—Plan Showing Arrangement Used for Making Tests Nos. 3 and 4.

The material of which the beams and connections were composed was ordinary medium Bessemer steel taken from stock without any selection, and the workmanship was of the ordinary commercial character.

Although Mr. Prichard's remarks relate to the strength of the beam connection under uniform load the arrangement of testing machine did not permit of the introduction of a load of this character, and in consequence the tests were made with a central load on a beam of about half the length of that to which Mr. Prichard refers, in order that the conditions might be similar as nearly as possible under these circumstances.

As stated on page 39 of the book entitled "Cambria Steel," the minimum span for which standard connection angles may be safely used with a 6-in. 12¼-lb. I-beam uniformly loaded to its full capacity in accordance with table of safe loads corresponding to a fiber stress of 16,000 lbs. per sq. in. is 5.7 ft., and the uniform load corresponding to this length is 13,600 lbs., as shown by table on page 74. The average ultimate load on the beams as shown in tests 2, 3 and 4 is 51,333 lbs., and these loads were approximately central, and if we assume a safety factor of four, this practically corresponds with the safe load, which is 13,600 lbs., as stated in the Cambria book. The load in test No. 1 did not come upon the connection angles, but was transmitted to the flange of the 9-in. beam. It should also be considered in all of these tests, with the exception of No. 1, that the full capacity of the connection was not reached, as the beam failed by bending and buckling without destroying the connection.

If we should carry Mr. Prichard's statements to their logical conclusion in view of the figures which he presents and the above tests, the shear on the rivet would be about 268,000 lbs. per sq. in., notwithstanding which the facts are that they did not fail, thus showing the entire fallacy of his reasoning, as no rivet could be expected to withstand any such stress.

The tests which were made on the 6-in. 12¼-lb. I-beams show that the strength of the connection for this size, as stated in the Cambria tables, is correct, but at the same time the strength of this same connection when used on heavier sections of 6-in. beams might not be sufficient for the short spans stated in the tables. Very short spans are not ordinarily used in building work, and if used are not likely to be loaded to the capacity of the beams. For the reason, however, that none of the tests (with the exception of test No. 2, which was not representative on account of the differences in spacing of the bolt holes), developed the strength of the connection, but bent and buckled the beams themselves, the actual ultimate strength of the connection was not fully demonstrated. The statements made by Mr. Prichard relating to the connections for 6-in. 12¼-lb. I-beams are fully disproved by the actual results of our tests. We must thank Mr. Prichard for giving us the opportunity of demonstrating the correctness of our figures with regard to the particular connection in question. Yours truly, Geo. E. Thackray.

Johnstown, Pa., June 3, 1898.

(When we received Mr. Thackray's letter, Mr. Prichard had already notified us that he proposed to reply to Mr. Christie's letter in our issue of July 21. In order that the whole remaining correspondence might be presented to our readers together, therefore, we furnished a proof of Mr. Thackray's letter to Mr. Prichard, enabling him to reply to both communications in one letter.—Ed.)

Sir: The replies of Mr. Christie, writing for the A. & P. Roberts Co., and Mr. Thackray, writing for the Cambria Iron Co., to my criticism of the table giving the strength claimed for standard beam connections (Eng. News, July 21), leaves the discussion of the point at issue in a condition which makes further discussion and investigation desirable.

As a preliminary, it is well to state the requirements for safe connections. At 16,000 lbs. extreme fiber stress, a steel beam has a factor of safety of about 2, as regards the beginning of failure, and about 4, as regards complete failure; supposing it to fail by bending. The factor of safety required for the connections should be equal to or greater than that required for the beams, both as regards the beginning of failure and complete failure. A table giving the strength of standard connections should state as the strength of each connection an amount no greater than should be used under the most unfavorable conditions to which the table can be reasonably understood to apply from a consideration of its title and the descriptive matter accompanying it.

The table criticised is based on uniformly distributed loads; but the tests of 6-in. and 8-in. beams, quoted by Mr. Christie, were made with concentrated loads applied at the middle of each span, the 6-in. beams being rolled-up sections having about 50% greater rivet bearing than the minimum size to which the table applies, and the 8-in. beams being of shorter span than called for in the table. The loads were, therefore, less than half what should have been used to test the accuracy of the table and the rule by which it was calculated.

In the tests made by both the A. & P. Roberts Co. and the Cambria Iron Co. the connection angles were riveted to the webs of the beams tested. This corresponds with the illustrations in the Roberts' hand-book, as they show the connections riveted and make no mention of bolts. In the Cambria book, however, and in the books of the other companies referred to in the criticism, the connections are shown with holes which are stated to be for either bolts or rivets. As bolts are generally conceded to be weaker than rivets, they should have been used by the Cambria Iron Co. in testing the accuracy of their table and the rule by which it is calculated.

Neither the A. & P. Roberts Co. nor the Cambria Iron Co., in the published reports of their tests, have noted the points at which failure of the connections began, and consequently they do not give full data from which to determine the safe loads. The data published, however, are sufficient to show a marked discrepancy between the results obtained and the amounts given as the safe loads by the method advocated in the criticism. In accounting for this discrepancy, Mr. Christie takes no exception to the reasoning employed in the criticism, but attributes it to the neglect of "two elements of resistance" in the premises on which the reasoning is based. Mr. Thackray, on the other hand, takes no exception to the premises in which three elements of resistance are neglected; to wit: the frictional resistance from the grip of the rivets, the partial fixedness of the ends, and another element hereinafter described, but claims that the discrepancy shows the entire fallacy of the reasoning. In view of this difference of opinion between the author's critics and the insufficiency of the published reports of the tests which they quote, some additional tests seemed desirable and have been made.

Six beams were tested, the ends in all cases being simply supported. The sizes and arrangement of the beams and connections are illustrated in the accompanying cuts. The outstanding legs of the connecting angles were riveted to the flat connecting each pair in all cases except No. 6, in which they were bolted. The connection angles were 6 × 4 × 7-16 ins. for Cases 1, 2 and 6, and 6 × 6 × 7-16 ins. for Cases 3, 4 and 5. The beams were 6-in., 12¼ lbs. per ft. with webs 0.23-in. thick for Cases 1, 2, 5 and 6, and were 6-in., 17¼ lbs. per ft. with webs 0.46-in. thick for Cases 3 and 4.

In Case 1 the connection angles were bolted to the beam with rough bolts, forced to a bearing before the test, and the nuts were screwed up to a gentle touch only. In Cases 2 and 4 the connection angles were riveted to the beams. In

Case 3 the connection angles were bolted to the beam with turned bolts, which fitted the holes, and the nuts were screwed up to a gentle touch only. In Case 5 the connection angles were riveted to the beam, but the holes in the beam were made ½-in. larger than the diameter of the rivets to prevent the rivets from getting any bearing on the beam, the object being to test the frictional resistance from the clamping power of the rivets. In case 6 the connection angles were bolted to the beam with rough bolts forced to a bearing before the test, and the nuts were screwed up tight so as to give all the frictional resistance practicable. The rivets and bolts were all ¾-in. in diameter, the rivets were machine driven, and the holes were punched 13-16-in. diameter, except those for the turned bolts and those in the web of the beam in Case 5.

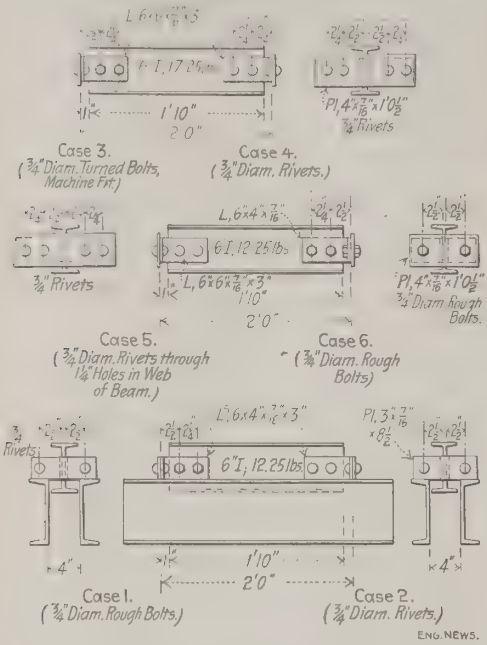

Fig. 1.—Diagrams Showing Sizes and Arrangement of Beams and Connections Tested by Mr. Henry S. Prichard, New Jersey Steel & Iron Co.

It was intended to test the connections only and not the beams, and to insure the beam from failing, distributing flats were placed between the top flange and the pressure edge of the testing machine. In Cases 1 and 2 the flats were not added till the beam began to fail.

The results of the tests are given in the table below, to which is added a comparison between the calculated safe loads for the connections and those indicated by each test separately considered.

In calculating the safe loads by the usual method (that on which the table criticised is based), the bearing value for both rivets and bolts was taken at 20,000 lbs. per sq. in. as stated in the tables criticised. In calculating by the writer's method, the bearing for bolts was taken at 18,000 lbs. per sq. in. and for rivets 21,600 lbs. per sq. in., to agree with the article on beam connections in Engineering News of May 16, 1895. In obtaining the safe load indicated by each test a factor of 2 was used with regard to the beginning of failure, and of 4 with regard to complete failure.

The point at which the connections began preceptibly to rotate with reference to the web of the beam was taken as the beginning of failure. In Case 5 it was possible to obtain this point easily and accurately because after the point was reached the pressure on the machine remained stationary for a few moments. In the other cases, however, it is probable that the results are a little high, as it is difficult to perceive by simple observation the very slight movement which accompanies the beginning of the crushing of the bearing surfaces.

In arranging for the tests the beams were first supported at the ends by resting the flats connecting the outstanding legs of the connection angles on a pair of channels. After the connection at one end of a beam had failed, a support was placed under the beam at that end.

The load was applied midway between supports in each case, and one-half the pressure indicated by the machine was taken as the load on a connection. In each case the connection angles rotated about an axis perpendicular to the web of the beam, as shown in the photograph, bringing pressures in opposite directions on the two bolts or rivets connecting the clips to the beam. That the pressure on the bolt or rivet nearest to the edge of the beam was much greater than on the other one was shown by the amount the holes enlarged and by the shearing of the bolts and rivets. The connection angles at each end of each beam also rotated in a plane perpendicular to the web of the beam, and in opposite directions, as shown in the photograph, so that their tops approached each other, producing a toggle joint action, and firmly clamped the beam. The effect of this was to weaken the connection of the outstanding legs to the flat and strengthen the connection to the web of the beam. The clamping pressure developed was in some cases so great that the webs of the beams were crushed a full 1-32-in., and a bearing thus secured at the upper edges of the clips. Mr. Thackray mentions a similar "knuckle-joint action," as he terms it, in one of his experiments, but he mentions it only as a source of weakness. The strength added to the connection to the web of the beam by this toggle-joint action was not mentioned by either Mr. Christie or Mr. Thackray, and was neglected in the writer's theory, but it appears to have been the chief element in causing the high ultimate strength which most of the connections developed. It is probable that it also added considerable strength to some of the connections before failure began. This is indicated by the fact that in Case 2, in which the chance for toggle-joint action was greater and the bearing surface of the rivets less than in Case 4, the point at which failure began was higher than in Case 4. The writer's theory also neglected the partial fixedness of the ends and the frictional resistance from the clamping effect of the rivets and bolts. If the ends were partially fixed it would have some indirect as well as direct effect on the strength of the connections by modifying the toggle-joint action, but the writer's experiments have not covered this point. The frictional resistance from the clamping power of the rivets and bolts amounted to 2,000 lbs. in Case 5. In Case 4, by comparison with Case 3, in which the nuts simply touched, it was probably about 3,000 lbs., and in Case 6, by comparison with Case 1, about 2,000 lbs.

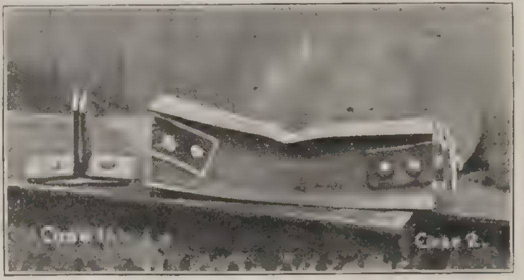

Fig. 2.—View of Angle Connections Showing Manner of Toggle Joint Action.

That the loads at which failure commenced in Cases 1 and 6 were small as compared with the other cases, is probably due to the fact that the bolts did not fill the holes and consequently had very little bearing at the start (theoretically only a line of bearing). As the bolts would get their full bearing before failure had progressed very far, the safe load indicated by the tests can hardly be regarded as a fair criterion. That Case 4, in which rivets were used to connect the clips to the beam, developed so much greater ultimate strength than Case 3, in which turned bolts were used, was due partly to the fact that the rivets were initially tight, while the bolts were not, partly to the fact that the rivets were steel while the bolts were iron, and partly to the fact that the greater strength of the rivets made them last longer and thus enabled a greater toggle action to be developed.

The most seemingly astonishing fact was that in Case 1 the ultimate strength was much greater than in Case 3, notwithstanding the fact that in Case 1 rough bolts were used, against turned bolts in Case 3, fewer rivets connected the outstanding legs of the clips to the flats, and the bearing surface of the bolts was 50% less. This fact is probably explained by the greater toggle-joint action permitted by the construction in Case 1.

Mr. Christie's, Mr. Thackray's and the writer's experiments, considered together, show conclusively that the strength of a connection cannot always be obtained by simply multiplying the nominal strength of one rivet (or bolt) by the number of rivets in the connection, as the authors of the table criticised assumed, and that the strength of a connection depends not only on the bearing and shearing strength of the rivets (or bolts), but also on a number of other elements. Whether or not it is good practice to rely at all on these other elements of strength is an open question. The authors of the table criticised do not appear to have thought that it was, because in the descriptive matter accompanying the table they claim that it is based on the bearing and shearing values of the rivets. If it is proper to rely on these other elements of strength, then the writer's theory gives results which in some cases err considerably on the side of safety. On the other hand, even if these elements of strength are relied on, the method of calculation on which the table criticised is founded gives results which in some cases are dangerously high.

Respectfully, Henry S. Prichard.
Trenton, N. J., Sept. 3, 1898.

Results of Tests for Strength of Standard Beam Connections.

Case.	Load at the beginning of failure, lbs.	Ultimate load, lbs.	Safe load: Indicated by test, lbs.	Safe load: Calculated by: Usual method, lbs.	Safe load: Calculated by: Writer's method, lbs.	Remarks.
1.	2,000	24,900	1,000	6,900	1,470	Beam split from hole "a" to edge at 22,800 lbs., after ultimate had been reached.
2.	13,000	......	6,500	6,900	1,765	Did not fail under load of 24,900 lbs.
3.	9,500	17,790	4,450	13,800	2,940	At 17,790 lbs. bolt "a" sheared off.
4.	12,500	40,310	6,250	13,800	3,530	At 35,000 lbs. cracking noise; cause not discovered. At 40,310 lbs. rivet "a" sheared off.
5.	2,000	.....	1,000	......	.....	Frictional resistance test, carried to slipping point only.
6.	4,000	24,700	2,000	6,900	1,470	At 22,000 lbs. one clip began to crack; at 24,700 lbs. bolt "a" sheared off.

◆

Notes and Queries.

In our issue of Sept. 1, p. 143, we published an abstract of a paper read before the American Association for the Advancement of Science, by Prof. L. G. Carpenter, of Fort Collins, Colo., on "The Energy received from the Sun." In this abstract the energy was given as "½ to ¼-HP. per sq. yd." These figures should have been 0.5 to 1.4 HP. The statement of the energy in calories (7 to 17) in the abstract was correct.

In the article on "Metal Trucks for Freight Cars," in our issue of Sept. 15, it was stated in reference to the Cloud truck that about 2,600 are now in use. The Cloud Steel Truck Co. now informs us that since furnishing us the figures used in the preparation of that article they have done a large amount of business. Up to the present time they have sold some 5,000 Cloud truck frames and 15,000 of the Bettendorf I-beam steel bolsters.

D. B. McK. asks if a beam or column whose cross-section is an equilateral triangle can be strengthened by cutting off a certain portion of each of the three corners? He says that the strength varies as $\frac{I}{c}$, (I) being the moment of inertia and (c) the distance of the farthest fiber from the neutral axis, and that while (I) is reduced by trimming the corners, (c) is diminished more than (I), and therefore the beam is really strengthened. This is correct, according to the accepted theory of flexure, and on page 180, of Wood's "Resistance of Materials" (second edition), will be found a solution of the problem. In the case of a triangular section, if one of the corners be taken off for 0.13 of its depth, the remaining trapezoidal beam will be 1.091 times as strong as the triangular beam. In other words, there will be a gain of 9%. It is also true that the other corners can be trimmed off slightly without causing any appreciable weakening.

◆

RAILWAY CONSTRUCTION IN DISTRICTS SUBJECT TO INUNDATION.

In describing the new railways to be built in the province of Shansi, China, in our issue of March 31, we mentioned that the crossing of the wide alluvial plains bordering upon the rivers presents a somewhat difficult problem, as these plains are subject to inundation during the rainy season, when the rivers overflow their banks. To build a high-level line would be costly, especially in view of the amount of waterway to be provided by bridges or trestles, and it is intended, therefore, to build a low-level line which will be covered during the floods, but will be left practically uninjured when the water subsides.

This same problem has been encountered in Australia, more especially in Queensland, where the economic value of the low-level system, in spite of a short interruption to traffic, appears to have been abundantly proved. In an interesting little book on "Pioneer Railways for Queensland," by Mr. George Phillips, a civil engineer who has had extensive railway experience in that colony, this particular subject is discussed, and the advantages of the low-level system of construction in that colony are shown by practical experience. The illustrations show some of the low-level river crossings during and after the floods, the latter showing that the small short bridges are practically uninjured, and only blocked by dirt and drift which can easily be cleared away. On the other hand, the views show that longer and more substantial bridges built on high-level lines in the same district have been practically wrecked, some of the costly metal spans having been carried away. The low-level system requires a minimum amount of expense for general construction and for bridging, while the bridges can usually be renewed promptly and at small expense if they should be washed out. The high-level system involves more expense in construction for embankments and waterways, while the bridges are larger and considerably more expensive, involving a much greater expenditure of money and time in renewal. With the low-level bridges, the higher the flood the less is the danger of damage by drift, etc., but with high-level bridges any rise in the water increases the danger.

An illustration of this is afforded by the experience with two bridges in Queensland. It is stated that the low-level deck bridge over the Burdekin River withstood several floods, the maximum depth of water being 50 ft. above the floor. The Logan River bridge, with two piers and three metal through spans, was built with its rail level 6 ft. above the level of the highest recorded flood, but in 1887 the flood rose 11 ft. above the rail level and the piers and spans were swept away.

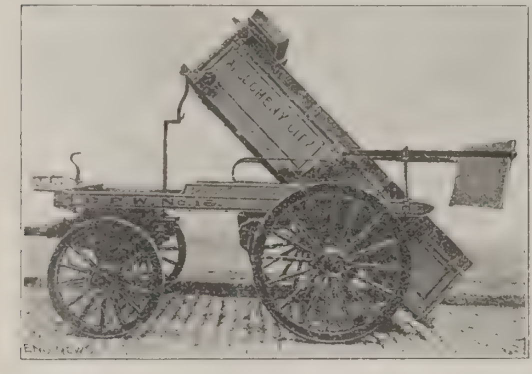
We have had occasion before to point out the expense which has attended the endeavors of European engineers to introduce European methods of practice in the colonies, and their failure fully to recognize economic considerations or the influence of local conditions. This conservatism and adherence to old-world customs naturally led to considerable opposition to Mr. Phillips' plans for low-level railways, economical in cost, but the practical results appear to have fully substantiated his claims. For about 90 miles the Normanton & Croydon Railway crosses black-soil plains, and here Mr. Phillips used timber and steel-trough ties, bedded to half their depth in the soil and with earth filled in round the ends. After the first heavy rains the road settled down uniformly, leaving the surface slightly higher than that of the surrounding country, but not enough to interfere with the natural drainage. After a flood the line was easily and quickly put in condition for traffic, even when the ground was for weeks too wet and boggy for wagon traffic. Subsequent attempts at improvement by other engineers who failed to grasp the principles of construction of this line, had unsatisfactory results. It was thought that even a pioneer line could not be permitted to exist on the surface of the ground, and, therefore, the track was raised above the ground level, with the result that the floods turned the dirt ballast into mud which washed out and left the line in bad condition. The remedy then suggested was to use stone ballast, which was not obtainable for a long distance. The Railway Commissioners feared that it would be only a "fine-weather" line, and that the cost of maintenance would be higher than for a road "properly ballasted and drained," but, as a matter of fact, the low cost of construction more than compensated for the slight interruptions to traffic, while the cost of maintenance was very much less than the average for the Queensland Government Railways, although wages were higher on this line.

Mr. Phillips quotes from the article on "English Railway Practice in India and the Colonies," in our issue of Aug. 4, 1892, and we give below some extracts from his discussion of the question of low-level lines:

> As a rule, natural drainage is only applicable to pioneer railways, and chiefly in even country within tropical or subtropical regions, where its adoption in lieu of the artificial method means all the difference between a high cost and a low cost road.
>
> In mountainous country there is practically no choice, and sufficient provision must be made for artificial drainage below the level of formation, but in uneven country very considerable economies can be safely practised by adopting in a modified form the principle of natural drainage at the crossings of the larger watercourses. The instances in which a high-level bridge will practically cost no more than a low-level bridge at the same place are comparatively rare, and only occur where the whole of the flood water is confined to one well-defined channel with banks of the same or very nearly the same height. Very frequently the broken portion of the channel of a river can be spanned in a few hundred feet, whereas in times of extreme flood the water may cover low-lying land on one or both sides of the main channel to a width of thousands of feet, or even of several miles. Now, these are precisely the places where a large expenditure may be incurred under the high-level or artificial system of drainage, or great economies may be effected under the low-level system, and it should be remembered that in the case of pioneer railways the value of the traffic to be carried in any one year will not be increased under the first system, nor diminished under the second system.
>
> The necessity for, or the adoption of, artificial drainage in even and uneven country, rules to a very great degree the selection of route, and determines the extent and cost of the work. No one who has not been professionally engaged in the selection of railway routes in new, uncharted, and thinly peopled countries, can form any idea of the extent to which the question of artificial drainage dominates almost every other consideration. The crossing of and the providing passage for, or the avoidance of water, are very frequently the chief items of expense, more especially in even country, where the surface of the ground offers every natural facility for the laying down of inexpensive pioneer railways, the cost of which need not greatly exceed the value of the rails, fastenings, and sleepers; but the difficulty of providing artificial drainage below the level of formation stands like a lion in the path of the engineer, who considers that artificial drainage is a necessity.
>
> Under the European, or high-level system, it not infrequently necessitates great detours to avoid low-lying and flooded areas, thus thrusting the lines back into broken and hilly country, when much easier gradients could often be secured at far less cost over the flooded flats, but the fear of injury to embankment or occasional delay in the running of trains is ever active with the engineer who is wedded to the high-level system.
>
> It seems almost incredible that while settlers may dwell, cultivate, and carry their produce to market on even country, which is occasionally inundated, it is deemed by some engineers that to lay inexpensive railways on the surface of such country, is so unprofessional as to be almost immoral, so that the very munificence of nature is regarded as sufficient reason for depriving the settlers of those modern facilities which alone can enable them to turn the bounty of nature to the fullest account.
>
> Until a more common sense system be generally adopted, the extension of railways in such countries as China. Africa, South America and Australia, will progress but slowly and intermittently.
>
> The European, or high-level method of building railways prescribes that all water crossing the route of a railway must be provided passage below formation. This may not be so serious a matter in Europe, where the rainfall is usually well distributed throughout the year, and in any case the extent of traffic to be served justifies expensive and high-class lines of communication.
>
> In the tropics, and regions adjacent thereto, the rainfall is usually confined to a period of a few weeks at certain seasons of the year, and the body of water to be provided passage for under the high-level system is sometimes enormous in volume and extent.
>
> In Australia, there are many rivers which occasionally overflow the banks of their usual channels, and cover areas of adjacent country to a width of from 1 to 20, and even 30 miles. These exceptional floods are not frequent, and in any given locality their periodicity is so uncertain that intervals of 5, 10, 15, and 20 years may, and sometimes do, elapse between them.
>
> In passing, I may say that while I have known several high-level bridges to be destroyed by floods, I do not know an instance in which a low-level railway bridge has been seriously injured from the same cause, although numbers of such bridges have been submerged time and again to depths ranging up to 50 ft. The reason for this immunity is that logs, trees, and floating debris are only brought down in any great quantity whilst floods are at or near their full height, so that the floating material is safely carried over the low-level bridges; on the other hand, should a flood rise a few feet higher than usual, or than is anticipated, the debris is apt to lodge against the girders of high-level bridges, and thus subject them to severe lateral stresses.
>
> I have not enjoyed the privilege of visiting China, but I have a theory that the conservative Chinese will not favor the construction of railways with high embankments over the even cultivable plains adjacent to their great river systems, as such embankments would necessarily derange their complicated system of boundary ditches by gathering the drainage of many ditches to a focus, and discharging the accumulated water at new and unaccustomed points. I feel confident that this is a question which engineers constructing railways in China would do well to take into serious consideration.
>
> There are many places in Australia where the raising of an embankment five or six feet in height across long stretches of even country, through interference with natural drainage, result in serious loss to the occupants of the adjacent country, whether they be engaged in pastoral or agricultural pursuits. I have taken sections across 15 or 20 miles of plains, bounded on either side by rivers, where the difference in level was very trifling throughout the entire length of the section, and it is not difficult to conceive that what would only be an inconvenience when the plains were covered with a few inches of surface water, might, under the retarding influence of a railway embankment, become a serious source of loss where sheep are pastured or valuable crops are grown.
>
> As an illustration, take the case of the railway from Sydney to the town of Bourke, in New South Wales. For several hundred miles this railway traverses even country very similar to that on the lower Flinders River in North Queensland; for the last 13 miles before entering Bourke the railway is within the high flood area of the Darling River, and is constructed on the high-level principle, with an embankment some 5 or 6 ft. in height, pierced by many flood openings. It should be observed that the railway does not cross the river, but merely intrudes upon the flooded area.
>
> In April, 1890, the last 13 miles were washed away during a high flood, so that communication with the town could only be maintained by boats. This portion of the railway probably cost $40,000 per mile, but I have no hesitation in saying that a surface line, costing not more than $10,000 per mile, would have proved equally serviceable, and would not have needed reconstruction after the flood subsided. In addition to this, it is evident that the embankment (despite the numerous flood openings) must to some extent have retarded the escape of the flood water, and thus have caused it to rise to a greater height in the town of Bourke, the inhabitants of which ineffectually attempted to protect their homes by means of a rampart of earth encircling the town and abutting in two places upon the railway embankment.
>
> When the railway engineer comes to deal with even country, more especially if he has been chiefly accustomed to construction in uneven country (as is almost invariably the case with European engineers), he is a good deal puzzled as to the best methods of procedure. If he consults the standard works on civil engineering he will learn that the approved method of crossing a great plain is to throw up an embankment from side-cuttings, which are ultimately intended to serve as ditches. Probably his author makes no comment upon the necessity for cross drainage through the embankment, or, even so, gives no clue as to the amount to be provided.
>
> The engineer looks with anxious eye upon the vast expanse of plain, which his levels tell him rises or falls on either side of the proposed line of railway, and he commences to wonder what the effect will be when those plains are submerged, 1, 2 or 3 ft. deep with water, and he realizes that the higher the embankment the deeper the accumulated water will be, and the greater the destruction if it should overflow the embankment.
>
> Evidently there are only two courses that can be wisely adopted. The first, and the most usual method, is to throw up an embankment of sufficient height, and at the same time provide sufficient openings to carry off the intercepted water before it has time to rise above the level of the formation. The second method (as advocated by me for pioneer railways in Queensland), is to keep the line right down on the surface and permit the water to follow the lines of natural drainage even if those lines take the water over and across the railway. An intermediate course is sometimes pursued by throwing up a low embankment from soil obtained from side ditches, supplemented by a few box-drains put in very much at haphazard. The fallacy of this method is generally demonstrated upon the first heavy rainfall sufficient to scour out the shallow formation and ballast, thus leaving the road in an impassable or dangerous condition.
>
> The first, or high-level method, if carried out in a scientific manner, entails a great deal of trouble and additional expense in the survey, as the areas to be drained must be ascertained, with approximate accuracy at all events, whilst the water sheds of even country cannot be easily defined, and they are often very remote from the railway.
>
> The following is an extract from "Engineering," London, Nov. 22, 1889:
>
> > From Amballa to the Sutlej River the line crosses an immense number of waterways, many of which are the so-called lost rivers, whose water ultimately disappear in the great Indian Desert. For some reason that is not quite evident, the former effluents of the Indus system that debouch from the hills to the eastward, do not now carry anything like the steady quantities of water they formerly did—although at times, with heavy rains in the foothills, they still come down in tremendous spates that last but a few hours, and bring with them, as all-hill torrents do, immense volumes of silt. At some point or other in the course of each such waterway a bar has silted up the defined channel, and just above it the water of a spate fans out and covers a wide tract of country. While it lasts this is a very profitable form of natural irrigation. But, unfortunately, each spate brings with it a share of debritus, and as it cannot force this over the bar, it necessarily deposits it higher up the channel, and thus the bar, which forms the root of the fan, is perpetually retreating upstream and nearer to the hills. Of late years the consequences of this action have been very disastrous for the railway line between the Jumna and the Sutlej, for the rivers, as they once were, with fairly defined and deep channels that were bridged 25 years ago with perfect success, now "spill" or fan out their waters over the lands above the line, and for several years past, in spite of the addition of immense lengths of flood openings, each recurring July and August has seen the railway breached and communication jeopardized, if not entirely cut off. As the cheapest and best way out of this class of catastrophe, Col. Conway Gordon, the present Director-General of Railways in India, has proposed to lower the level of the rails for, perhaps, miles together, till flush with the natural surface of the absurdly slight depressions that scarcely differentiate one "spill" from another.

A NEW DUMPING WAGON FOR HANDLING GARBAGE AND OTHER MATERIAL.

Two of the essentials of a good dumping wagon are that the load be well distributed over front and rear wheels, so as to haul easily, and that the dumping mechanism be strong and simple These qualities are both claimed for the wagon illustrated herewith. The load is carried well forward, while in transit, and is shifted backwards, when it is desired to dump, on rollers, running in guides, as shown in the view. The trunnion-plate is fastened to the body of the cart. The rolling motion is secured by pushing or pulling, or by means of the lever shown in the view. The end gate is lifted automatically, as shown. The wagons are furnished with metal covers, if desired, and the box is of steel. Where desired, an inclined fixed end is substituted for the tail board, which some would prefer where garbage and some other materials are being hauled. The wagons are made in various sizes by Wm. Becker, 340 Ohio St., Allegheny, Pa.

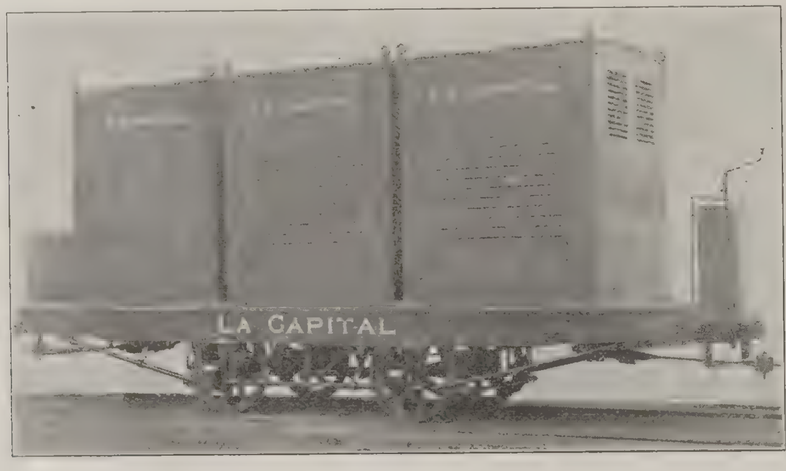


A Dumping Wagon for Garbage or Other Material, with Automatic Tail-Board.

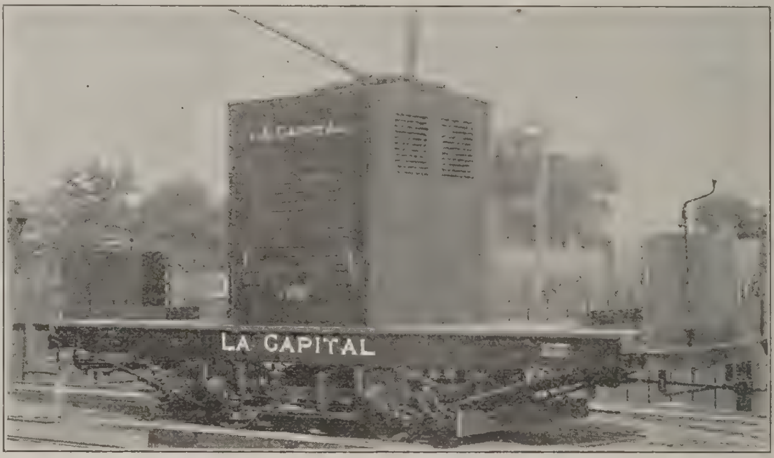
William Beckert, Manufacturer, Allegheny, Pa.

DISTRIBUTING MEAT BY ELECTRIC CARS IN BUENOS AYRES.

In Buenos Ayres, Argentina, the government owns and operates the abattoirs, and no slaughtering of cattle is permitted elsewhere; the purpose being to permit government inspection of all animals used for food, and to prevent the use or export of unhealthful meats. The abattoirs are located 14 miles from the city, and provide meat both for local use and for export in cold storage.



View of Trailer.



View of Motor Car.

DISTRIBUTING MEAT BY ELECTRIC CARS IN BUENOS AYRES.

The dressed meat is distributed to markets and butcher shops by special cars operated on a railway connecting the city and the abattoirs. In 1885 the J. G. Brill Co., of Philadelphia, built special meat cars for Buenos Ayres, Santiago, Montevideo and other South American cities. These cars were hauled by horses and were of necessity small and carried light loads. The carcasses were carried to the cars; hung up inside; hauled to the city, and at any point where meat was wanted the quarters of meat were taken down and carried into the market. This plan was laborious and slow, and involved considerable exposure of the meat to heat and dust.

The introduction of electric traction greatly improved the previous facilities for handling meat; and the illustration here given shows the latest cars built for this purpose by the J. G. Brill Co

By this arrangement the meat is taken from the refrigerators and placed in specially made boxes. These are placed by a crane upon a flatcar, which is hauled by a motor-car directly to the markets without exposure. Upon their arrival at their destination a powerful crane, at the curb line, lifts each box from the trailer and deposits it upon a strong three-wheeled truck, which takes it directly into the ice-box; the trailer then goes on to other points of distribution.

Two styles of car are used; a motor-car and a trailer, the latter may also be attached to a passenger or ordinary motor-car. These trailer-cars weigh 6,820 lbs.; and when loaded with three full boxes they weigh 23,250 lbs. The city has ordered 75 cars of this class. Of motor-cars there will be twenty mounted on 21 E trucks and weighing, with trucks, 8,600 lbs. In this type the center box is stationary and the top supports the trolley board and pole.

The meat boxes are 5 ft. 11 ins. square outside and 7 ft. 3 ins. high. They have double sides, are lined with zinc, and are provided with slat ventilators in the two sides and in the door. The door lifts upward; and to economize space in front, the part below the door lifts out. Inside the boxes have pipe racks in the center and along the sides and stationary racks in the roof; all of these are provided with sliding hooks for meat. As shown each outside corner of the box is fitted with a heavy iron strap terminating in a strong eye, by means of which the boxes are handled. The boxes carry 6,000 lbs. of meat, and weigh when filled 7,750 lbs.

The advantage of such a systematic handling and distribution of dressed meats for the supply of a city will be obvious. Those who will later have the charge of administering city governments in our new tropical possessions may do well to take a leaf from South American practice.

A NEW HIGH DUTY RECORD FOR PUMPING ENGINES.

We have received a copy of a report made by Prof. W. F. M. Goss, M. Am. Soc. C. E., of Purdue University, of a test of a 20,000,000-gallon triple expansion pumping engine, built by the Snow Steam Pump Works, Buffalo, N. Y., for the Indianapolis Water Co., under the superintendence of Mr. L. K. Davis, consulting engineer, 220 Broadway, New York city. The results give the remarkable figures of 150.1 million foot pounds of work per million British thermal units, and 11.26 lbs. of dry steam per I. HP. per hour. This duty figure, we believe, is the highest ever recorded on the heat unit basis, although the steam consumption per I. HP. per hour is not quite so low as that obtained by the Leavitt triple expansion engine at Chestnut Hill station, Boston, viz., 11.2 lbs. (Peabody's Thermodynamics, 4th ed., p. 355). That the figures are open to some question is apparent from the comments on them made by Prof. Goss himself, which we quote below, and it is to be hoped that another test of the engine may ere long be made, in which the water consumption may be measured by the feed water used in the boiler as well as by the water discharged from the hot well, the latter method being the only one used in Prof. Goss's test.

The test was made on July 8 after a preliminary run to give practice to the observers had been made the day before. The engine was in charge of Mr. E. C. Sornberger, representing the Snow Steam Pump Works, and the Indianapolis Water Co. was represented by Mr. John Rail. Some of Prof. Goss's comments on the test given in his report to Mr. F. A. W. Davis, vice-president of the Water Co., are as follows:

> Viewed as a piece of experimental work, the test was a most satisfactory one. The methods followed were carefully chosen, the apparatus employed was known to have been in excellent order, the desired conditions of running were well maintained, observers were employed in such number as to allow the work of each one to be easily performed in the time assigned, all observers were skilled engineers, and they were especially drilled by a trial run. It would appear, therefore, that the results as presented, possess a degree of accuracy which is fully equal to that usually attained in the course of such work.
>
> The duty disclosed by the data exceeds by a liberal margin that obtained in any test, the results of which have thus far been published. It justifies the conclusion that no engine exists which can equal the performance of the engine tested. The famous Milwaukee engine, known to engineers the world over, gave a duty of 127.1 million which is to be compared with the 150.1 million delivered by the Indianapolis engine.
>
> The plan of the tests was not sufficiently extensive to permit a complete analysis of all the conditions affecting the work of the engine, but it would appear that the high performance is due to good work by every part of the machine. Not only is the cylinder economy exceptionally fine but the frictional losses are extremely low.
>
> Leakage.—Very careful tests were made by the undersigned, and later by Mr. Rail, to determine the amount of water leaking past valves and plungers. It was found that leakages from all sources combined amounted to but a few thousandths of one per cent. of the water pumped, justifying the conclusion that for all purposes, either practical or theoretical, the pump is tight. The significance of this statement will be better appreciated when it is considered that the pump contains 540 suction-valves and 540 delivery valves, or a total of more than a thousand valves. A defect in a single one of these would have been disclosed by the tests which were made.
>
> Capacity.—During the eight-hour test, the lowest rate of speed for any five-minute interval was 17.6 revolutions per minute, the highest was 23.4 revolutions per minute, and the average speed for the whole eight hours was 21.46 revolutions per minute. This speed gives the pump a capacity of 20.6 million gallons per 24 hours.
>
> Friction.—The difference between the work done by the steam on the pistons and that delivered by the plungers is the work absorbed by the engine in the form of friction. The data show that but 4.6% of the indicated power was lost in this way. This is unprecedentedly small. It is altogether probable that a more elaborate test, in which special attention is given to the indicator work, may change this figure, since the relation is such that a change of 1% in the indicated power would produce a change of 20% in the value of engine friction. For the present, however, the figure given represents the best information that is to be had, and there is nothing in the data to discredit it.
>
> Steam Consumption per Horse-Power per Hour.—The performance of steam engines is often expressed in terms of the weight of dry steam required per horse-power per hour. A determination upon this basis for the engine tested gives a consumption of 11.26 lbs. This, so far as the undersigned knows, is less than is required by any engine the results of which have ever been reported. It is evident, therefore, that the engine excels both in the domain of hydraulic engineering and in that of steam engineering as well. [11.2 lbs. has been reported for the Chestnut Hill engine.—Ed. Eng. News.]
>
> Conclusion.—The preceding paragraphs prove the engine tested to be a very unusual one, and that a definite determination of its performance will demand unusual skill and care. The test herein described was undertaken upon

the supposition that the engine could be tested by methods usually employed in such work, and that its performance would fall within the range of ordinary results. It has been advanced by careful, painstaking and conservative methods, and it is believed that the facts disclosed may be accepted with as much confidence as those ordinarily resulting from such work. It appears, however, that these facts tell a story so unusual as to give rise to a question concerning their accuracy. It goes without saying that processes which would stand unquestioned when they lead to commonplace results are carefully scrutinized when they point to an exceptional result.

The undersigned is not disposed to question unduly or to discredit in the least degree the material facts which are herein presented, but, for reasons stated, he would earnestly recommend that they be looked upon as tentative until they can be verified by a test conducted on a broader plan. What is needed is an array of data so elaborate that the action of every part of the machine may be completely analyzed, so that the facts as stated can be reinforced by evidences of such a character that it cannot be questioned. I hope, therefore, that your company may see its way clear to undertake at an early date an investigation which will comport with the high efficiency which will be disclosed by it.

The results obtained in the test are condensed as follows from Prof. Goss's report:

Cylinder diams., ins.; h. p., 29; int., 52; l. p.	80.
Pump plunger diameter, ins.	33.
Stroke of all pistons and plungers, ins.	60.
Duration of test, hours	8.
Revs. per min.	21.46
Steam pressure at engine, gage, lbs.	155.6
Barometric pressure. lbs.	14.3
Temperature of water pumped, deg. F.	56.5
Temp. of discharge from condenser, deg. F.	79.5
Temperature of discharge from hot well, assumed as temperature of feed, deg. F.	111.7
Observed weight of water that passed weighing barrels, lbs.	68,648.
Weight of water discharged from hot well, assuming that 3% was vaporized, before reaching weighing barrels	70,771.
Weight of water that leaked through condenser during test. To be subtracted, lbs.	60.
Moist steam used by engine, lbs.	70,711.
Moisture in steam, %	1.2
Dry steam used by engine, lbs.	69,862.
Water pressure against which pumps delivered, lbs.	80.
Total pressure against which pumps were operated, suction lift included, lbs.	88.7
Total HP. delivered by pumps	740.
Water shown by leakage test to have leaked by plungers and valves during test, lbs.	31.4
Horse-Power, by Indicator:	
h. p. cyl., head-end	143.5
h. p. cyl., crank-end	132.1
int. p. cyl., head-end	125.5
int. p. cyl., crank-end	121.2
l. p. cyl., head-end	129.9
l. p. cyl., crank-end	125.3
Total	775.5
Dry steam per I. HP. per hour, lbs.	11.26
Total heat in 1 lb. steam, at a gage pressure of 155.6 lbs. and containing 1.2 % of water, B. T. U.	1,184.1
Heat in 1 lb. water at temperature of hot well, 111.7° F., B. T. U.	79.7
Heat taken from each lb. of steam, B. T. U.	1,104.4
Heat consumed by engine, B. T. U.	78,093,000.
Results:	
Duty per 1,000 lbs. of dry steam used, as defined by contract, ft. lbs.	167,800,000.
Duty per million B. T. U., ft. lbs.	150,100,000.
Capacity per 24 hours, gallons	20,600,000.

Notes Concerning Methods Used in Test.

Duration of Test.—As the test did not involve measurements at the boiler, 8 hours were considerd a sufficiently long period to give results possessing a high degree of accuracy.

Temperature of discharge from condenser is the average of readings, taken at 10-minute intervals, from a thermometer placed in the pipe between condenser and air pump.

Temperature of discharge from hot well is the average of readings, taken at 10-minute intervals, from a thermometer placed in the hot well. The increase in temperature of the hot well over that of the condenser is due to the discharge of hotter water from the jackets into the hot well.

Water from the hot well is, under normal conditions, led to a feed pump attached to the plunger of the low pressure engine, which forces it back to the boiler. For purposes of the test the feed pump was disconnected and its supply pipe blanked so that no water could pass it. It was assumed, however, in calculations incident to the test, that the temperature of the water delivered from the hot well was the temperature of the feed.

It has previously been noted that all water leaving the hot well is assumed to represent steam used by the engine. It came from three general sources, namely: From within the cylinders, from the jacket of the cylinders and the coils of the intermediate receivers, and from the drainage pockets between the cylinders. No effort was made to separate the steam from these several sources. There were no drains or pipes leading steam or water away from the engine which were not connected with the hot well.

The hot well is, however, provided with an overflow and a suction pipe leading to the boiler feed pump, but, as already noted, these were blanked in anticipation of the test. A small vent pipe leading from the top of the hot well was not blanked, but it was observed during the test that nothing escaped from its outer end.

Again, there was a small cold water pipe, the exhaust of a cellar pump and the exhaust of an air pump connected with the hot well; but, for purposes of the test, joints were broken except in the case of that of the air pump, which machine was not used during the test.

It is thought that these precautions were sufficient to ensure the delivery of all steam, chargeable to the engine, to the weighing barrels placed beneath the hot well.

Finally, the scales upon which the weighings were made were calibrated with 50-lb. standard weights and found to balance perfectly. There seems, in fact, to have been no possible chance for error in the observed weight of steam used by the engine, unless there was vaporization of water as it passed from the hot well to the weighing barrels, or a leak through the condenser. The extent of errors arising from these sources is next considered.

Weight of Water Discharged from Hot Well, Assuming that 3% was Vaporized Before Reaching the Weighing Barrels.—Any loss of water between the hot well and weighing barrels would apparently improve the performance of the engine. That there was some loss by vaporization cannot be doubted, since a slight amount of steam was always to be observed about the barrels. As, however, the temperature of the water delivered was but 111° F., it was thought at the time of the test that the effect of such losses would be entirely negligible. A review of the data, however, indicates the probability of a measureable loss from this cause, and it has been decided to fix its value at 3%. It could not have been greater than this, and if less it will be safe to reserve the establishing of this fact for a later test. This conclusion has the effect of raising the observed weight of steam used by the engine (68,648 lbs.) to 70,771 lbs.

Weight of Water Leaking Through Condenser.—Any leakage of cooling water into the steam of the condenser would apparently impair the performance of the engine.

The water space of the condenser constitutes in effect a portion of the main suction pipe of the engine. Under the conditions of the test there is a difference of pressure tending to produce leakage of about 10 lbs. As a preliminary to the main test, a man-hole in the lower part on the steam side of the condenser was opened; a valve in the main suction outside of the condenser was closed; and a primer delivering water from the force main to the suction was opened by such an amount as would maintain a water pressure on the condenser of 10 lbs., thus producing for the purposes of a leakage determination the same difference of pressure which exists where the engine is under normal working conditions. The amount of leakage thus determined amounted to but 7.5 lbs. per hour, an amount which, while insignificant, has nevertheless been carried forward in the calculations as a correction, its value for the 8-hour test being 60 lbs. The results prove the condenser to be exceptionally tight.

Percentage of moisture in steam was determined by a calorimeter applied to the main steam pipe close to the throttle of the engine.

Leakage by Plunger and Valves.—The sum of the various leakage amount to but 31.4 cu. ft. for the whole test, or about 0.003% of the total volume pumped. It is evident that so small a leakage is entirely negligible, and it is so recorded under the head of results.

Results.—Duty as defined by contract is the number of foot pounds of work done "per 100 lbs. of coal, assuming an evaporation of 10 lbs. of water per pound of coal." This statement is indefinite, but for the purpose of this report is is assumed to be equivalent to the foot pounds of work done by the pumps per 1,000 lbs. of dry steam under the conditions of pressure prevailing during the test. That is, the duty as defined by the contract is assumed to be the area of plunger in square inches multiplied by total pressure against which engine was used multiplied by length of stroke in feet multiplied by total number of single strokes multiplied by 1,000, divided by pounds of dry steam used.

Duty on basis of a million B. T. U., as defined by the American Society of Mechanical Engineers in their Transactions (Vol. XII., p. 534), is area of plunger in square inches multiplied by total pressure against which pumps were used multiplied by length of stroke in feet multiplied by total number of single strokes multiplied by 1,000,000, divided by heat consumed by the engine.

◆

A MINE EXPLOSION at Brownsville, Pa., on Sept. 23, entombed 70 men and killed 8. The accident is said to have resulted from a gas pocket which was opened by the loosening of a large block of coal and took fire from the open lamps. This was followed by a fire damp explosion. No general cave-in occurred and it is expected that the casualties will be limited to the number given.

◆

A DUST EXPLOSION, followed by a fire, totally destroyed the Union Elevator, at Toledo, O., on Sept. 20. The explosion had not sufficient force to tear asunder the bins and shafts, constructed of heavy planking well bolted together, but it blew off the whole roof and blew out every window. According to the Toledo "Blade," of Sept. 21, the chief of the fire department had only a few days before called the attention of the superintendent of the elevator to the fact that the building was full of dust and was therefore in danger of a dust explosion, and was told that fans were then being put in to remove the dusty air, but the work was not finished when the explosion took place.

◆

A SERIOUS DERAILMENT from a most unusual cause occurred at Wellingborough Station, on the Midland Ry. of England, Sept. 2, and resulted in the death of six persons and the injury of many others. The train was a through express, which runs past the station at 60 miles per hour. Just as it was due a light baggage truck on the platform rolled off onto the track, and the station attendants were unable to remove it before the train struck it. The moral of this accident, to American engineers, is that station platforms should never be made with a grade, save a very light inclination to shed water. The lesson to English engineers (but one which they will doubtless be blind to) is the value of the locomotive headlight and pilot as safety devices. Had the English locomotive been equipped with a headlight, the engineer would probably have seen the obstruction on the track in time to at least partially check his speed. A pilot on the locomotive would in nine cases out of ten have thrown the obstruction clear of the track.

◆

THE CHANGE FROM STEAM TO ELECTRICITY on the Manhattan Elevated R. R. is likely to be made at an early date, according to public statements by President George Gould. It is also reported that two Chicago railways—the Illinois Central and the Chicago & Eastern Illinois—will adopt electricity for their suburban traffic. The same report has so often been circulated before that undue importance will hardly be attached to it now. It is probably true, however, that both these companies are continuing the careful investigations which they have long had in progress respecting the merits of electric traction. On the Brooklyn Elevated R. R., the matter of substituting electricity for steam is to be submitted to the Board of Directors at their next meeting.

◆

THE READING RAILWAY SUBWAY, in Philadelphia, has been lately officially inspected by the Director of the Department of Public Works and other officials. This work was authorized in 1894, and construction was commenced, on Sept. 10 of that year, in the preliminary change in sewer location made necessary by the subway; which was completed in 1895, at a cost of $427,888. Work was commenced on the subway proper in August, 1895. The total work contemplated includes an elevated structure 959 ft. long; 4,180 ft. of open subway; a tunnel of 2,711 ft., and an open subway of 2,150 ft.; the total length of the work covering nearly two miles. At the present time most of the street bridges are open to traffic; the western half of the new freight houses, in the depressed yard at Broad St., and the track to operate them, are finished; work on the tunnel is rapidly progressing from the west end; in the open subway west of the tunnel the north retaining wall is finished and much of the excavation is done. The most difficult work called for was the underpinning of a number of great factory buildings alongside the subway; these included part of the Baldwin Locomotive Works, Wm. Sellars & Co., the Twentieth St. Grain Elevator, and other large establishments.

◆

THE AMOUNT OF UNDERGROUND ELECTRIC CONduit in Washington, D. C., is, according to Mr. Walter C. Allen, Chief Electrical Engineer, D. C., 459,393 ft. of conduit, with 2,745,050 ft. of ducts used in carrying light, power and telegraph wires, distributed as follows:

	Conduit, ft.	Ducts, ft.
U. S. Electric Lighting Co.	229,194	825,755
Potomac Elec. Power Co.	56,120	598,144
Postal Telegraph Co.	14,663	18,944
Chesapeake & Potomac Telephone Co.	79,781	698,216
Metropolitan Railroad Co.	31,417	204,140
Capital Traction Co.	48,218	399,851
	459,393	2,745,050

◆

A NEW INCANDESCENT FILAMENT for electric lights has been announced by Dr. Auer von Welsbach, the inventor of the incandescent gas light. He uses a filament of osmium, a rare metal, coated with a refractory oxide, like thoria. Osmium is found as an alloy of certain ores of platinum and iridium; it is a bluish-gray metal; 191.1 in atomic weight, and has the enormous specific gravity of 22.477, making it the heaviest substance known. It is practically infusible and resists temperatures in which platinum and iridium volatilize. It is well known that the intensity of light emitted by incandescent substances increases rapidly with their absolute temperature; hence, when osmium is heated in a vacuum by an electric current, strong enough to volatilize platinum, it emits a white light of agreeable color, but of great intensity. By coating the naked filament of osmium with the highly refractory oxide, it stands a greater temperature still. Economy in the production of electric light is the end sought by the use of this new metal; but osmium now costs $1.10 for 20 grains, hence the new light is likely to be only a scientific curiosity.

◆

STREET RAILWAY STATISTICS of an interesting nature are given in the last issue of the American Street Railway Directory. From these it appears that there is a total of 1,074 street railways in the United States, made up of 909 electric, 21 cable, 31 steam and 113 horse lines. These have a total capital stock of $975,625,827, and are bonded for $527,970,220. The total track mileage amounts to 16,466.78, of which 14,673.71 is electric, 485.68 cable, 618.54 steam, and 688.85 horse. In their operation are required 48,209 cars, 32,696 of which are motor cars, 7,824 trailers, 2,920 cable, 1,887 steam, and 2,882 horse. In addition, there are 610 steam locomotives and 3,504 horses. The four leading street railway states are as follows:

	No. roads.				Cars.		Track miles.	
	Total.	Electric.	Stock.	Bonds.	Total.	Electric.	Electric.	Total.
Pennsylvania	170	165	$234,960,000	$107,360,820	5,488	5,078	1,806	1,824
New York	120	88	198,857,600	105,901,100	10,291	5,537	1,600	2,102
Massachusetts	86	84	31,350,200	15,703,600	5,323	5,024	1,450	1,461

ACETYLENE GAS FOR STREET LIGHTING is to be tried in Wabash, Ind. This is said to be the first attempt to use acetylene for this purpose.

◆

THE DISCOVERY OF CHEMICAL ELEMENTS hitherto unknown has made great progress during the present year. No less than six have been reported, to which names have been given, as follows: Krypton, neon, metargon, coronium, polonium and etherion. The evidence that these new elements have been discovered is rather meager, as yet, and the existence of some of them may be open to doubt. The three elements first named were discovered by Prof. William Ramsay, of London, who, in 1895, in conjunction with Lord Rayleigh, had discovered argon. The three substances were all found with argon, after it had been isolated from liquid air. Taking the density of oxygen as 8, that of krypton is estimated at 40, that of neon at 10 or 11, and that of metargon, the same as argon, 20 or 22. The spectra of all these elements differ. Polonium is the name of an element not yet isolated, but which M. and Mme. Curie report to the French Academy of Sciences they have discovered in the form of a sulphide in pitchblende. The new element is said to resemble bismuth, chemically, and its radiating power is placed at 400 times that of uranium. M. Becquerel reported two years ago that salts of uranium threw off an invisible radiance much like that of the Rontgen rays, and a variety of pitchblende has been found by M. and Mme. Curie to possess that property to a much greater degree. Coronium is an element shown only; thus far, by the spectroscope, and only in the solar atmosphere. It has been found 300,000 miles from the sun's surface, and is believed to be much lighter than hydrogen. Etherion is the name given by Mr. Charles F. Brush, the well-known electrician, to an element which he thinks he has discovered in the atmosphere. He reported it at the recent meeting of the American Association for the Advancement of Science, in Boston. It is far lighter than hydrogen, and its heat conductivity is a hundred times as great as that of hydrogen. He estimates that its molecules vibrate with a velocity of a hundred miles a second, and thinks that it is not confined to the earth's atmosphere, but extends indefinitely out into space.

◆

BISMUTH IN BRASS, even in minute percentages, is a cause of fire-cracks, according to a paper by Mr. Erwin S. Sperry, of Bridgeport, Conn., which will be presented at the meeting of the American Institute of Mining Engineers, at Buffalo, next month. As the result of a series of experiments on brasses containing various percentages of bismuth, Mr. Sperry reached the following conclusions:

> 1. Bismuth renders brass cold-short, and is similar in this respect to antimony, although the effect is not as marked.
> 2. Bismuth is a cause of fire-cracks in brass.
> 3. High brass intended for cold-rolling should not contain over 0.01% of bismuth.
> 4. Bismuth produces hot-shortness in brass.
> 5. Bismuth is a cause of latent fire-cracks in brass.
>
> In the use of the term latent in connection with fire-cracks it is the author's belief that while annealing is the cause of their existence, they do not exist as cracks in the metal after annealing, but as lines of inferior cohesion in an apparently homogeneous mass; rolling, however, develops them, and to all appearances they then partake of every characteristic of true fire-cracks. It seems advisable, therefore, to apply such a distinguishing term, especially as latent fire-cracks are liable to be mistaken for rolling-cracks.

◆

DRYING THE MOISTURE OUT OF IRON ORE at the mines is a new project which is reported to be under consideration by the Carnegie Steel Co. and the Oliver Mining Co., of Pittsburg. An article in the "Pittsburg Times" states that experiments have been made by Dr. N. P. Hulst, manager of the Oliver Mining Co., on drying the ores of the Mesaba range, which contain from 7.5 to nearly 14% moisture. It has been found that on an average 10% of water could be dried out. It is estimated that the saving in freight on the moisture in 3,000,000 tons of ore would amount to $700,000 per year. It is said that the ore will not reabsorb the moisture after it has been driven off. No plans have yet been prepared for carrying out the experiment on a large scale, and the difficulties of doing the work on a commercial scale, without too great cost for fuel and labor, are no doubt formidable.

◆

TIN PLATE STATISTICS, compiled by the Bureau of Statistics, give some interesting figures relating to the production in the United States. Previous to 1891 tin plate was not produced to any considerable extent in the United States. On Oct. 1, 1890, a duty of 2.2 cts. per pound was imposed on tin plate, and the manufacture was commenced here. In the year ending June 30, 1892, 13,646,719 lbs. were produced; in the next year this rose to 99,816,202 lbs.; in 1894 it was 139,223,457 lbs.; in 1897 it was 446,982,063 lbs., and the estimate for 1898 is 640,000,000 lbs. The imports of tin into the United States in this period have fallen from 1,036,489,074 lbs. in 1891, which was much above the average, owing to anticipation of duty, to 171,662,345 in 1898. The former owners of one of the largest tin plate establishments in the world have sold their works at Swansea, Wales, and propose to establish a factory near Pittsburg, Pa. The value of the tin plate imported into the United States in 1889 was $21,222,653; while the value of the import of 1898 was only $3,309,148. The average price per pound has fallen from 2.9 cts. in 1889, and 3.5 cts. in 1891, to 2.2 cts. per lb. in 1898. The U. S. law permits a rebate of 99% on the duty paid on imported tin plate where the article manufactured from it is to be exported. This applies to coal oil cans for foreign trade, canned meats for export, etc.; and deducting the foreign tin plate re-exported in this way, the Bureau finds that only about 33,764,775 lbs. of foreign tin plate went into domestic consumption in the United States in 1898.

◆

THE EXPORT OF U. S. MANUFACTURED GOODS increases rapidly, and the Bureau of Statistics says that the exports of this class in July last amounted to $25,983,115 and formed 36.47% of the total exports. No previous July has shown such a record, and in no month have manufactures shown so large a percentage of the total exports. As compared with July, 1888, the exports have doubled and the percentage nearly so. The steady gain in percentage of total exports, for manufactured goods, is shown as follows: July, 1890, 24.82%; same month, 1894, 28.16%; 1895, 31.38%; 1896, 32.80%; 1897, 33.78%, and in July, 1898, 36.47%. This gain extends to nearly all the important industrial interests in the country, and must be read in connection with the general enormous increase in total exports. The exports of agricultural implements, in July, 1898, were about 50% above the previous July; the gain for the same month in cars and carriages was over 33%; there was also a marked gain in cotton goods and copper products. The exports of iron and steel, for July, 1898, were $7,012,977, as compared with $4,918,107 in July, 1897.

◆

A BOTANICAL EXPLORATION OF PORTO RICO will be undertaken by Dr. N. Z. Britton, Chief Director of the New York Botanical Garden, and Mr. Cornelius Vanderbilt will bear the cost of the expedition, which is to study and bring back specimens of the flora of the island. Dr. Britton will probably start in November next, at the close of the rainy season. There is very little known of the flora of this island, and the results will much enrich the general knowledge of the natural resources of Porto Rico.

◆

ROAD-BUILDING IN PORTO RICO, says Gen. Roy Stone, is easy and inexpensive; but the whole future of the island depends on the development of internal means of communication. Gen. Stone in six days converted into a road fit for army wagons a goat-path hugging the steep hills lying between Adjuntas and Utuado, ten miles apart. In this section there is an abundance of rotten granite which yields readily to the pick and shovel and forms an excellent road material. There is no frost to interfere with road construction, and Gen. Stone estimates that roads could be built almost anywhere in the island for from $750 to $1,000 per mile with native labor, which is satisfied with 20 cts. per day in American money. A marginal railway, about 300 miles long, will probably soon skirt the island, as 150 miles of this is now in operation between certain coast towns. The military engineering staff in Porto Rico is now investigating harbors, possible railway routes and centers, and are locating roads, and building some of the latter. Two mountain ranges extend through the entire length of the island and interior railways may be difficult and expensive to build; but owing to the density of the population electric roads could be profitably built to connect the interior and the coast towns.

◆

THE VOLUNTEER SIGNAL CORPS, under charge of Gen. Greely, has done good work in Cuba and Porto Rico, according to that officer's report. It destroyed submarine cables under fire from the enemy, and repaired cables useful to our forces; and it arranged and maintained a system of cable and land lines that enabled messages to be sent in 20 minutes from army lines near Santiago to Washington. In Porto Rico it was always in the advance, and kept each important command in telegraphic or telephonic communication with corps headquarters and the base of operations; the same was true in the army operations before Manila, and this corps connected by cables the principal forts in our great harbors and initiated and installed an entirely new electrical fire control system at these forts.

◆

NEW ATLANTIC STEAMSHIP ROUTES, to avoid the dangers of the Grand Banks off Newfoundland, are proposed by Capt. W. H. Smith, the Canadian Wreck Commissioner. The present routes are subject to fog in this region from May to August, inclusive, just when travel is heaviest. Capt. Smith suggests that steamers leaving this coast in the summer months shall sail due East on the parallel of 40° North, until they reach longitude 47° West, and thence sail on a great circle track to the point of destination. This route is safe from fog, but longer than the present routes nearer to the pole. Short passages save coal, and good time records advertise the company; consequently, nothing but a general agreement among steamship companies to use the new route, or the passage of laws punishing captains who meet with an accident by reason of being outside of prescribed routes, can turn the line of travel further south.

◆

A MEMORIAL TO GEN. RUFUS PUTNAM, one of the principal engineers of the Revolutionary Army, has been placed upon the old Putnam house at Rutland, Mass., by the Massachusetts Society of the Sons of the Revolution. Gen. Putnam, who must not be confused with Gen. Israel Putnam, was the engineer who planned the works which compelled the British to evacuate Boston and the fortifications at West Point. He also organized and assisted in carrying out the scheme of the Ohio Company, which, in 1788, commenced the settlement of the Northwest Territory. U. S. Senator George F. Hoar, in his dedication address, remarked that Washington classed Putnam as "the best engineer in the army, whether French or American." A bronze tablet, setting forth the services of Gen. Putnam, was placed upon the old house where he lived from 1781 to 1788, and in which he planned and matured the scheme that prevented slave holding in the great West and opened up that country to settlement. Gen. Putnam was born in Sutton, Mass., in 1738, and was a millwright by trade; he served in the French and Indian War in 1757-60, and later obtained a good knowledge of mathematics and surveying, and, in 1773, he was Deputy Surveyor of the Province of Florida. At the beginning of the Revolution he was a lieutenant-colonel of a regiment, and later commanded a regiment in Gen. Wayne's brigade. At the close of the Revolution he was made a brevet Brigadier General. He formed the Ohio Company and founded the town of Marietta. He died at Marietta in 1824.

BOOK REVIEWS.

MANUAL OF TOPOGRAPHIC METHODS.—Published by the U. S. Geological Survey. Sheep and paper; pp. 300; 18 plates. Sheep, $2.15; paper, 65 cts.

This excellent manual upon the government methods of making topographical surveys is again listed among the publications for sale by the Superintendent of Documents, at Washington, D. C. Remittance should be made by postal money-order payable, in this case, to the Director of the U. S. Geological Survey.

LIGHTING BY ACETYLENE. — Generators, Burners and Electric Furnaces. By William E. Gibbs, M. E. New York: D. Van Nostrand Co. 12mo.; cloth; pp. 141; 66 illustrations. $1.50.

The literature of acetylene has grown to vast proportions in the form of patent specifications, articles in the newspapers, etc., but the book before us is, as far as we know, the first book in the English language upon the subject. The author's reason for writing it appears in the following extract from the introduction:

> A recent serious explosion of liquid acetylene prompts the writing of what follows, since it would seem that ignorance or neglect of the admonitions of earlier experimenters was to blame for an accident which cannot but prejudice many against the use of a valuable and safe illuminant.

The book is an ably written, brief and plain treatise on acetylene, its history and its dangers, and on electric furnaces for the generation of carbide of calcium acetylene gas generators and lamps. In regard to the explosiveness of acetylene the author bolds that at atmospheric pressure it is no more dangerous than any other illuminating gas. While it is under certain conditions an unstable body, tending to resolve itself into its component elements, carbon and hydrogen, yet this dissociation can be effected at atmospheric pressure only by the detonation in the body of the gas of a small quantity of fulminate of mercury or other violent explosive "and by no other means." The author here seems to neglect the rule of logic that a negative cannot be proven, but he comes as near to attempting a proof as is possible in his next sentence:

> Heat, flame, the electric spark, or the electric arc itself will not, according to the most careful experiments, produce an explosion under these conditions.

Of course a mixture of air with acetylene is highly explosive, as is a mixture of air with any other hydrocarbon gas. The pure gas itself if condensed to a high pressure is also explosive, and the author says that it becomes more unstable with each increment of pressure,

> and in consequence more easily exploded, until the point of liquification is reached, when it becomes as dangerous as the high explosives. The disastrous results which have invariably followed the attempts to liquify acetylene on a commercial scale should be sufficient warning against this procedure. The onlv place where there is any excuse for compressing acetylene is in the chemical laboratory, where its properties are being studied by those dealing in unstable compounds, and where explosions are expected and provided for as a matter of course.

Another danger consequent upon the use of acetylene is the formation of the explosive salt, acetylide of copper. The use of copper and copper alloys should therefore be avoided in acetylene generators or holders.

The book contains the rules of the New York Board of Fire Underwriters for the installation of acetylene gas generators and for the storage of calcium carbide, and a list of United States patents on calcium carbide and acetylene apparatus, including carbide and electric furnaces. It describes a great variety of generators for making the gas from carbide of calcium, and of lamps and burners. We commend the book to all who desire to inform themselves on actylene, its generation and use.

The Cause of Rails Creeping—The Original Portable Asphalt Paving Plant (illustrated)—Notes and Queries.

THE U. S. BATTLESHIP "ILLINOIS," launched this week at Newport News, has the following dimensions: Length on load water line, 368 ft.; extreme beam, 72 ft. 2½ ins.; normal displacement draft, 23½ ft.; maximum displacement, with all ammunition and stores on board, 10,000 tons; estimated speed, 16½ knots; normal coal supply, 800 tons; loose storage, 1,200 tons; full bunker capacity, 1,500 tons; complement, 40 officers, 449 men. The main battery will include four 13-in. guns in Hichborn balanced turrets on center line, and 14 6-in. rapid-fire guns. The secondary battery will include 16 6-pdr. and four 1-pdr. rapid-fire guns, two Colt and two field guns. The armor-belt is 16½ ins. thick at the top, 9½ ins. at bottom, tapering to 4 ins. at the stem; it extends from 4 ft. below the normal water line to 3½ ft. above this line. Diagonal 12-in. armor connects the belt armor and the barbettes, and abaft the after turret the protective deck is 4 ins. thick on slopes and 2¾ ins. thick on the flat; this deck forward is 3 ins. and 2¾ ins. thick. The armor on the 13-in. gun turrets is 17 ins. thick on the front and 15 ins. on the rear and sides; on the barbettes the thickness is 15 and 10 ins. Above the armor-belt the sides of the ship, and diagonals connecting these sides, will be 5½ ins. thick. Coffer-dams, generally 3 ft. thick and extending the length of the ship, contain about 12,500 cu. ft. of corn-pith cellulose, as a protection against the entrance of water. Independent of the cellulose pockets, there are nearly 300 water-tight compartments, for containing the motive power, coal, stores, ammunition, etc. Any of these may be flooded or pumped out. There will be about 80 auxiliary engines in the vessel; and there will be two sets of triple-expansion, twin-screw engines, with a total of 10,000 I. HP. at 120 revolutions per minute. There are eight single-ended cylindrical boilers, each 15½ ft. diameter by 9 ft. 11½ ins. long; with a total grate surface of 685 sq. ft. and 21,200 sq. ft. of heating surface; the working pressure is 180 lbs. per sq. in. The characteristic of this ship is her high freeboard—20 ft. forward and 13¼ ft. at the stern. The axis of the 13-in. forward gun will be 26½ ft., and the after 13-in., 19 ft. above the water surface. The 6-in. guns will be from 15 to 22½ ft. above the water. The first keel plate of the "Illinois" was laid Feb. 10, 1897, and from 53 to 54% of the work is now done. The contract price was $2,595,000, and she is to be completed by Oct. 5, 1899.

◆

BIDS FOR THE FOUR HARBOR-DEFENCE MONItors were opened on Oct. 1, under the limit price of $1,250,000 each. The bids were as follows: Lewis Nixon, $825,000, to be finished in 24 months; Newport News Co., $860,000, in 27 months; Bath Iron Works, $862,000, in 27 months; Union Iron Works, $874,000, in 27 months; Maryland Steel Co., $876,000, in 26 months; Wolff & Zwicker, $937,500, in 27 months; The W. B. Fletcher Co., $927,000, in 21 months; Columbian Iron Works, $1,015,000, in 27 months; and John Dialogue, $1,171,000, in 26 months. The four bidders first named are likely to get one monitor each.

◆

SHIPBUILDING IN THE UNITED STATES, for the year ending June 30, 1898, is reported upon by the Navigation Bureau. There were built and documented in that year 952 merchant vessels of 180,458 gross tonnage, compared with 891 vessels of 232,233 tons in the preceding year. The decrease is almost wholly in the Great Lakes; the construction on the Pacific Coast amounted to 49,789 tons, as compared with 7,495 tons in the preceding year. This Pacific increase was chiefly in ships built for the Alaskan-Pacific and Alaskan river trade. On the Atlantic and Gulf Coast the returns show 514 vessels of 63,090 gross tons for the last fiscal year; on Western rivers, 123 boats of 13,495 tons were built. In the last year the returns show 359 sailing vessels of 180,458 gross tons; 343 wooden steamers of 57,337 tons; 51 iron and steel steamers of 48,501 tons; 20 canal boats of 2,386 tons; and 169 wooden barges and 10 steel barges of 37,818 tons in all.

◆

THE ATLANTIC TRANSPORTATION CO. OF NEW York has chartered some 35 vessels from the Lake fleets, having a total carrying capacity of over 50,000 tons of cargo. In addition, this company will build 12 or 15 new barges, with a combined cargo capacity of 36,000 to 45,000 tons. The total fleet of the company will eventually comprise about 70 craft of all kinds, with room for over 100,000 tons of cargo. Mr. Walter S. Bosse, of New York, is the General Manager of the Atlantic Transportation Co. It is a New Jersey corporation, with $3,000,000 capital, and has its headquarters at No. 1 Broadway, New York city. The lake vessels chartered will come down the St. Lawrence; and existing contracts call for the movement of more than 4,000,000 tons of coal annually from Newport News to New York, Boston and New England.

◆

A SELF-PROPELLING PUMP DREDGER, designed by Mr. Lindon W. Bates, is being built in Belgium for the use of the Russian government on the Volga River, says the "N. Y. Commercial." This dredger is double-hulled, each hull being the largest that will pass through the canal system uniting the Baltic Sea with the Volga. They can be operated together, making a single cut 62 ft. wide, or singly with a 31-ft. cut. The draft in working trim will be 4½ ft. and the hulls are built of steel. Each half is 216 ft. long by 31½ ft. and 9 ft. deep. They will be propelled and operated by electricity, each half-hull having its own generating plant, with four motors of 125-HP. each. There will be a stern-wheel tender connected with the dredging plant for use in towing, surveying, setting anchors, etc. No test has been made of this dredger as yet, but Mr. Bates expects an output of 7,000 cu. meters per hour under the conditions prescribed by the Russian government.

◆

THE DISMAL SWAMP CANAL may be completed by Jan. 1, next, in the widening and deepening work now going on, says the Baltimore "Sun."

◆

THE PROTECTION OF SANDY HOOK against wave encroachment is to be undertaken by building sand-catching dikes and planting soil-binding grass to preserve the beach made. The Sea Lyme and Marram grasses are best for this purpose, according to the long investigations of Prof. F. Lamson-Scribner, the agrostologist of the Agricultural Department. The Sea Lyme grass flourishes best along the Maine coast, but will grow as far south as Cape Hatteras, where it is replaced by the creeping bitter panic grass. The Marram grass does well from New Jersey to Florida. The Rolling Spinifex, of Australia and New Zealand, is being introduced in this country with a like purpose by the U. S. Agricultural Department. Japanese lawn grass is another variety which is being tried.

◆

A 2,000-C. P. SUBMARINE ARC LAMP for use in connection with raising sunken vessels, examining existing work or constructing bridge piers, coffer-dams and the like, has been undergoing a test at the Brooklyn Navy Yard, with apparently considerable success. The lamp is the invention of Messrs. Irving E. Burdick and Francis G. Hall, Jr., who were employed by the government in connection with torpedo and mine work in several of the Maine harbors. The idea of perfecting such a lamp occurred at that time. Later the Navy Department granted them permission to experiment. The result is the lamp before mentioned, which consists of an outer cylindrical casing ending in a straight glass globe, protected by a wire guard frame. Inside is the operating mechanism and what is termed an enclosed arc, a small opalescent globe surrounding the carbon ends, thus excluding the air. The lamp burns from 100 to 150 hours with one set of carbons. The wires carrying the current pass through a water-tight bushing in the top of the casing. A check valve is also provided to permit the escape of any gas which may form inside.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred, Sept. 28, on the Pictou branch of the Intercolonial Ry., near Stellarton, Nova Scotia, in which five persons were killed, and several were injured. The accident is attributed to a misunderstanding of orders, which caused a special excursion train and a work train carrying 60 miners to meet in a butting collision on a sharp curve.

◆

HEAVY WINDS raged along the Southern Coast on Oct. 2, doing a large amount of damage. The wind velocity is reported to have been from 50 to 75 miles per hour, and the conditions much the same as in the tidal storm of 1893. The abnormally high tide inundated large tracts of low land along the Georgia and Carolina coast. The loss of life is not at present known, but appears likely to reach a hundred or more.

FATAL FOREST FIRES are reported from the northern part of Wisconsin. The town of Cumberland and a number of towns in that vicinity are surrounded by fires and in danger of destruction. Reports from Denver, Colo., state that Colorado timber reserves are fast being depleted by forest fires which have destroyed many ranches and farms.

◆

TIMBER STANDING in the western part of Washington is, according to Mr. Henry Gannett, of the U. S. Geological Survey, 103.504,376,000 ft. B. M., made up as follows: Fir, 66,208,861,000 ft.; spruce, 6,403,405,000 ft.; cedar, 16,192,276,000 ft.; hemlock, 14,699,834,000 ft. The report states that about 45% of the timber district has been cleared, 23% having been cut and 22% burned. Only merchantable timber is considered, and the estimates are based upon present wasteful methods of logging.

◆

EXPERIMENTAL TREE PLANTING IN THE PLAINS is reported upon, in a pamphlet of 94 pages, by Mr. Charles A. Keffer, Assistant Chief of the Division of Forestry, in the Department of Agriculture. This experiment was commenced by the government in 1896, in Minnesota, South Dakota, Nebraska, Kansas, Colorado and Utah, and new stations are being established in Texas, Oklahoma and Montana. About 13 varieties of pines and 26 other and broad-leafed species are being tested at these stations. It is yet too early to arrive at and definite conclusions, and the present report of Mr. Keffer deals rather with the principles underlying such plantations and the best methods to be pursued.

◆

THE SMALL WATER CONSUMPTION of European cities is a standing wonder to those in charge of water supplies in American cities. The following is an official statement of the average daily consumption per capita in a number of the leading English cities, including also the average for the several water companies which supply London:

	Gallons per head.		Gallons per head.
Grand Junc. (London)	.55½	Liverpool	.31½
Chelsea (London)	.47	Croydon	.31
Southwark and Vauxhall (London)	.45	Manchester (aver. 27)	.30
		Halifax	.29
Brighton	.43	Swansea	.28
Plymouth	.43	Blackburn	.25
Hull	.43	Bristol	.23½
London (average)	.41	Bolton	.23½
Lambeth (London)	.40	Birmingham (average)	.23
West Middlesex (London)	.39	Huddersfield	.23
		Burnley	.23
New River (London)	.35½	Oldham	.22
Bradford	.35	Cardiff	.22
Leeds	.35	Sheffield	.21¾
East London (London)	.34½	Nottingham (aver. 17½)	19
Preston	.34	Birkenhead	.18
Kent (London)	.33½	Leicester	.18

◆

A PRIZE FOR THE BEST ESSAY on the economic arrangement and construction of subways, for carrying the sewers, water, gas, etc., in great cities, is offered by the "Cosmopolitan Magazine," of Irvington-on-Hudson, N. Y. The amount of the prize is $250.

◆

THE BUSK-IVANHOE TUNNEL on the Colorado Midland Ry. has been abandoned. The railway as originally built crosses the range at Hagerman's pass, 11,528 ft. above sea level. The tunnel was built by a separate company (The Busk Tunnel Co.) in 1892-3. The railway company made a contract to pay 25 cts. per ton of freight and 25 cts. per passenger for the use of the tunnel, and guaranteed the principal and interest of the 7% bonds which the tunnel company issued. All went well for the tunnel company until the railway company became bankrupt and the road was sold under foreclosure. Under the plan of reorganization the bondholders of the tunnel company were offered 4% bonds in exchange for their 7% bonds; but they refused to accept them. The sale under foreclosure, of course, wiped out the old railway company and rendered void its traffic contracts. The managers of the new company asked the owners of the Busk tunnel to accept lower tolls on traffic through the tunnel; and when they refused, the connections were torn up and the old line over the summit of the mountain was put in condition for operation, and trains were turned over it. Passengers greatly prefer the old line on account of the scenic attractions and because it avoids the smoke and gas of the two-mile long tunnel. In winter rotary snow plows will be used to keep the line open. Meanwhile the owners of the Busk tunnel have a tunnel for sale or to let and no customers in sight.

◆

FOREIGN PATENTS IN JAPAN, since 1897, are issued with the same rights as are accorded to Japanese. The Japanese Patent Regulations are avowedly modelled on those of the United States; but the following are not patentable: Articles of food, drink, or fashion; medicines, or methods of compounding them; and articles which have been in public use before the application for the patent. The latter exception is rigidly enforced by the Japanese examiners; and if a foreign patent has been issued one day before the Japanese application, and though there can thus be no public use, the application is rejected. For the year ending March 1, 1898, 104 foreign applications for patents were made in Japan; of these 10 had been finally rejected, and only one was granted. Of trademarks, 2,133 had been applied for in this year and 1,594 were registered.

THE PRESENT STATUS OF THE PANAMA CANAL.

By General Henry L. Abbot, Corps of Engineers, U. S. A.

After the failure of the old Panama Canal Company in February, 1889, the property passed into the hands of a receiver, who, seeking to save from ruin the vast number of subscribers of moderate means, referred the technical problems to a "Comite d'Etudes" selected from among the best engineers of France. In May, 1890, this commission made an able report, indicating the numerous points which demanded further investigation before final plans could be judiciously adopted, but suggesting the general features of such a plan, based on a study of all existing data. To make these further investigations a new company was organized in October, 1894; and since that date it has quietly prosecuted its labors and has now collected all the information needed to command the confidence of engineers in its definitive project. It is to set forth this project, and to indicate its superiority to anything possible in Nicaragua, that the present article is written. It may be proper to add that the writer, as a member of a technical commission of engineers, made last spring a careful examination of the entire route of the Panama Canal, and is thus possessed of definite personal information, in some degree assisted by having formerly traversed Nicaragua. The following are the essential features of this project, endorsed, with some possible future modifications in details, by a Comite Technique, containing French, English, German, Russian and American engineers. Among them the chief engineers of the Manchester and of the Kiel ship canals.

The original plan contemplated placing the canal in the bed of the Chagres, and conducting the river to the sea through artificial channels. This project was long ago definitely abandoned, being replaced by the familiar system of locks and dams which has been so often successfully applied to other rivers. Careful measurements and studies of the regimen of this torrential stream have shown the system to be entirely applicable to it, and that none of the constructions demanded will exceed the limits of recognized engineering practice. To these advantages it should be added that two good harbors already exist at the Atlantic and Pacific terminals; that an American railway is in active operation parallel and in close proximity to the line of the canal throughout its entire extent; that about 40% of the whole length has been actually excavated, and that great progress has been made on the intermediate portions; and finally, that extensive proparations have already been made for accommodating the army of laborers which will be required on any Isthmian canal. These reasons certainly demand that the comparative merits of this route should be considered before adopting any other location for the canal now generally believed to be essential to meet the needs of our Atlantic and Pacific coasts.

In Nicaragua the general conditions are distinctly inferior. Two ports must be artificially prepared; one at least of great practical difficulty, since nature has already closed the old harbor. About 120 miles of railroad must be built, mostly traversing a wilderness. Almost nothing has been done in the way of construction or of preparation for the work. Of the whole length of 176 miles, 68 miles follow the bed of a crooked river, where the prevailing trade winds and the currents resulting from the whole outflow of Lake Nicaragua will unite to aggravate the difficulties of shipping in transit. The length of the route is about four times that of the Panama canal, adding proportionately to the time of passage; finally, at least one dam is demanded, quite without precedent in our canal construction, besides several miles of huge embankments in the San Francisco basin, where the foundations are extremely bad, and where a rupture at any future time would entail veritable disasters.

But passing from generalities, the details of the Panama project will first be considered.

The Canal Proper.—The total length is 75 kilometres (46.5 miles), of which five (3.1 miles) lie in the Bay of Panama, between Isle Naos and La Boca. Of the 70 kilometres (43.4 miles) of inland construction, 24 kilometres (14.88 miles) on the Atlantic side (between Colon and Bohio) and 7 kilometres (4.34 miles) on the Pacific side (between La Boca and Miraflores) will be at the sea level, and of this distance about 25 kilometres (15.5 miles) are now essentially excavated, thus there remains only 38 kilometres (23.5 miles) to be traversed by the aid of locks; and here also so much actual work has been done that no visitor can pass over the line without appreciating that the canal can no longer be regarded as an experiment.

Of these 38 kilometres between Bohio and Miraflores, the first 22 (13.64 miles) extending from Bohio to Obispo will traverse a vast lake 5,500 hectares (13,585 acres) in extent, created in the valley of the Chagres by a dam at Bohio. Its level above the sea will range between a minimum of 16 metres (52.48 ft.) and a maximum of 20 metres (65.60 ft.), the normal level being 17 metres (55.76 ft.). A reservoir of 150 million cubic metres (52,950 million cu. ft.) is thus provided to control in part the floods of the river. Access to the lake will be furnished by two double locks at Bohio.

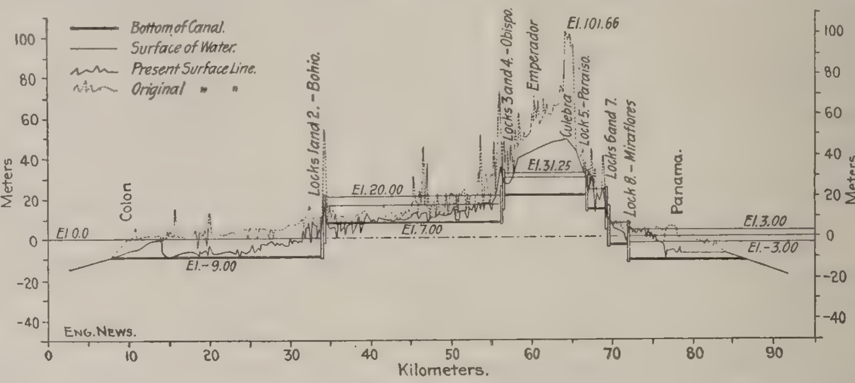

FIG. 1.—PROFILE OF THE PANAMA CANAL; BOTTOM OF SUMMIT LEVEL, AT ELEVATION 20.75 M., OR 68.06 FT. ABOVE DATUM.

LIFT OF LOCKS.

Atlantic Side.

Location.	Order, No.	Lift, ft. Maximum.	Lift, ft. Minimum.
Bohio	1	32.80	26.24
"	2	32.80	26.24
Obispo	3	25.02	16.00
"	4	25.02	16.00

Pacific Side.

Location.	Order, No.	Lift, ft. Maximum.	Lift, ft. Minimum.
Paraiso	5	29.52	21.32
Pedro-Miguel	6	29.52	26.24
"	7	29.52	26.24
Miraflores	8	30.34	7.38

There thus will remain to be considered only the 16 kilometres (10 miles) lying between Obispo, where the canal leaves the Chagres River and Miraflores, where sea-level is reached. This section includes the continental divide at the Culebra, approached on the side of the Atlantic by the valley of the Obispo, a tributary of the Chagres and on the Pacific by the valley of the Rio Grande. The great economic problem to solve has been to determine the most advantageous level for the bottom of the canal between these two points, with a view to afford the best balance between the cost and the time of constructing the locks and dams on the one hand and deep cutting on the other.

This problem, with its adjuncts of how to best supply the summit level during the dry season, how to regulate the floods of the Chagres during the rainy season, and how to provide hydraulic power for lighting and operating the canal at all seasons, has been most thoroughly studied on the spot by the new company since its organization in 1894. Space is lacking to detail the trial excavations, aggregating 3 million cubic metres, the surveys, the borings, the gagings of the water courses and the many other details which have been investigated in the most elaborate manner. Suffice it to say that, after comparative estimates of 16 variants, the Comite Technique has advised the adoption of a level of 20.75 metres (68 ft.) above mean tide, which, should experience in the active prosecution of the work render it expedient, will admit of modification, either by adding two more locks, raising the level of the cut to 29.5 metres (97 ft.), or of suppressing one or perhaps two locks, and thus reducing it to 10 metres (33 ft.).

This definitive plan, placing the bottom of the canal at a level of 20.75 metres, involves two double locks at Obispo, raising the water surface at the summit level to a maximum of 31.25 metres (102.5 ft.) and a minimum of 29.75 metres (97.58 ft.); one double lock at Paraiso dropping these levels to 23.25 metres (76.26 ft.) and 22.25 metres (72.98 ft.); two double locks at Pedro-Miguel, dropping them to 6.25 metres (20.5 ft.) and 5.25 metres (18.22 ft.); and a tidal lock at Miraflores, where the water level varies between 3 metres, or 10 ft., above, and 3 metres below mean tide. (On the Atlantic side the tidal oscillation is only a few inches, and no such provision is needful.) The length of these levels in every case exceeds 2 kilometres (1.24 miles), thus avoiding trouble from oscillations due to lockages. In reference to the deep cutting at Culebra—the bugbear of former days—it is only needful to say that the excavation has already been carried below the level of the soft upper strata, which gives so much trouble by sliding, and is now and will continue to be in an indurated clay schist, requiring blasting, and passing to veritable rock. Serious trouble need no longer be apprehended here. This problem has been studied most thoroughly by the new company—involving the removal of about 2 million cubic metres of material, the sinking of many pits and borings, and the construction at the worst point of a tunnel 210 metres long (689 ft.) at a level of 41 metres (134.5 ft.).

In locating the line of the canal, great care has been taken to avoid abrupt curves. A minimum radius of 2,500 metres (8,200 ft.) is adopted for the central cut, and of 3,000 metres (9,840 ft.) for the rest of the line, except near Bohio, where radii of 2,500 metres and 2,000 metres (6,560 ft.) occur in enlargements having a bottom width of 62 metres (203.4 ft.), and near Obispo, where one radius of 1,700 metres (5,576 ft.) occurs with a bottom width of 80 metres (262.4 ft.). Even with the large standard curves adopted, suitable enlargements will be provided to render the route perfect in this important detail, in respect to which it is more favored by nature than either Kiel or Manchester, as appears from the following figures.

	Canals Manchester.	Kiel.	Panama.	Nicaragua.
Total length, kilos	54	98.6	74.5	284
Minimum radius, meters	571	1,000	1,700	.....

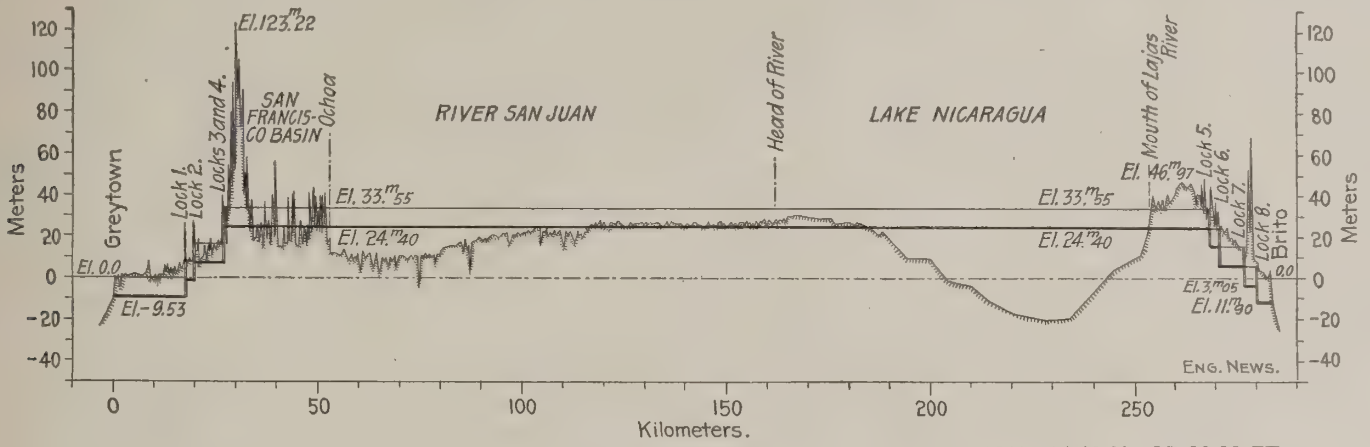
*Central. †Elsewhere. §Eastern divide. ‡Western divide.

The cross section to be given the canal varies in different localities, as shown in the following table: The depth is uniformly 9 metres (29.52 ft.); and the side slopes usually 3 base to 2 height in earth, and 2 base to 3 height in rocky cuts. In respect to berms and revetments, the latest practice, as recommended by the recent International Congress of Engineers at Brussels, will be followed.

	Earth Section, sq. m.	Earth Bottom width, meters.	Rocky cuts Section, sq. m.	Rocky cuts Bottom width, meters.
Colon to Bohio	406.5	30	380.2	34
Lake Bohio (minimum)	571.5	50	531.0	53
Summit level	379.5	36	379.5	36
Paraiso to Pedro Miguel	406.5	30	380.2	34
Pedro Miguel to Miraflores	406.5	30	380.2	34
Miraflores to La Boca.*	720.0	30	...	..
Bay of Panama (low tide)	693.0	50	...	..

*Low tide.

Enlargements 600 metres (1,968 ft.) long and 60 metres (196.8 ft.) wide at bottom, to enable vessels to pass each other, will be provided in the canal at intervals of about 8 kilometres (4.96 miles); but immediately above and below the locks these dimensions will be raised to 700 metres (2,296 ft.), and 62 metres (203.4 ft.).



PROFILE OF THE NICARAGUA CANAL; BOTTOM OF SUMMIT LEVEL AT ELEVATION, 24.40 M., OR 80.03 FT. ABOVE DATUM.

LIFT OF LOCKS.

Atlantic Side.

			Normal level of bottom of canal above mean tide, ft.	
Location.	No.	Normal lift, ft.	Lower.	Upper.
17.70 kilos.	1	26.00	0.0	26.00
19.83 "	2	28.00	26.00	54.00
26.95 "	3	28.00	54.00	82.00
27.15 "	4	28.00	82.00	110.00

Pacific Side.

			Normal level of bottom of canal above mean tide, ft.	
Location.	No.	Normal lift, ft.	Lower.	Upper.
268.60 kilos.	5	30.00	110.00	80.00
271.10 "	6	30.00	80.00	50.00
276.90 "	7	30.00	50.00	20.00
280.00 "	8	20.00	20.00	0.0

Note.—The height of tide being 1.25 ft. on the Atlantic side and 8.9 ft. on the Pacific side, the maximum lift of the locks at each end must be increased accordingly.

The Locks.—The locks, all founded on rock, are to be double, the larger chamber having a serviceable length of 225 metres (738 ft.), a width of 25 metres (82 ft.), and a depth of 9.5 metres (31.16 ft.) at the sides, and 10 metres (32.8 ft.) at the middle. The smaller chamber has the same serviceable length, with intermediate gates to reduce it to 130 metres (426.4 ft.) when desired; a width of 18 metres (59.04 ft.); and the same depth as the other. The larger will be constructed first, together with the foundations and head of the smaller, thus permitting the latter to be completed after opening the canal to traffic. The maximum lift has been fixed at 9 metres (29.5 ft.), except at Bohio, where provision for 10 metres (32.8 ft.) will be made, for use during extreme floods of the Chagres, which last only for a few hours.

The gates will be of the pivoted single leaf type. and water will be supplied by pipes buried in the lock floors and delivering on each side and throughout the whole length of the chamber. the flow being regulated by valves of the low level cylindrical pattern. Entrance to the chambers from either direction will be facilitated by crib piers, 60 metres long, with detached heads to protect the structure against shocks.

The Dams.—There will be six dams, five located on the line of the canal at Bohio, at Obispo, at Paraiso, at Pedro-Miguel and at Miraflores, and one at Alhajuela, 16 kilometres (10 miles) above, on the upper Chagres. Of these only the first and last need be considered, as the other four are minor affairs presenting no engineering difficulties (three of them are to be of masonry and one of earth).

The dam at Bohio will be of earth, abutting on conglomerate rock at the sides, and founded on a compact bed of clay, believed to be diluvial. The length of the crest will be 392 metres (1,286 ft.); the extreme height above the bed of the river, 23 metres (75.4 ft.), and above the foundation 28.5 metres (93.5 ft.). The width at the crest which rises 3 metres (10 ft.) above the highest level of the lake will be 15 metres (49.2 ft.); the upstream slope has a height of 1 on a base of 3, with four berms each 3 metres (10 ft.) wide, the whole riveted with stone laid dry; the downstream slope has a height of 2 on a base of 3, with one berm 3 metres wide, and is supported by a mass of loose rock rising to a sufficient height to protect the dam if, in spite of all precautions, it should chance to be overtopped by a sudden flood during construction. A puddled core, and a concrete wall at the upper toe, will cut off any possible leakage. The mass of the dam will be of excellent material found in the close vicinity. During construction the river will be diverted through the rock cut for the locks, with ample provisions by deversoirs for combatting larger floods. All the details have been carefuly studied and the project has received the unanimous approval of the Comite Technique

The dam at Alhajuela will be of concrete masonry founded on and abutting against compact rock. The length of crest will be 285.5 metres (936.4 ft.); and the height, 41 metres (134.5 ft.) above the bed of the river and 50 metres (164 ft.) above the deepest part of the rock foundations. The cross section conforms to the conditions of recent engineering practice.

To facilitate construction, a tunnel 300 metres (984 ft.) long and 75 square metres (807 sq. ft.) in cross section will be driven through the ridge to a bend of the river below, and a temporary dam will divert into it the minor flood discharges of the river. To meet the case of larger floods, the dam will be raised alternately on the two sides, thus allowing space for a portion to be overflowed without interrupting the work. These details have been carefully studied, and met the approval of the Comite Technique.

Engineers will recognize the immense advantages possessed by the Panama route, in the matter of dam construction, over the conditions found in Nicaragua, where the diversion of the San Juan river is admitted to be impracticable, and where the foundations present extraordinary difficulties and demand an unusual structure quite without precedent for canal purposes.

Regulation of the Chagres River.—This subject, comprising the control of the floods and the supply of the summit level, has received the elaborate investigation demanded by its importance. Space is lacking for details, but the general features are the following.

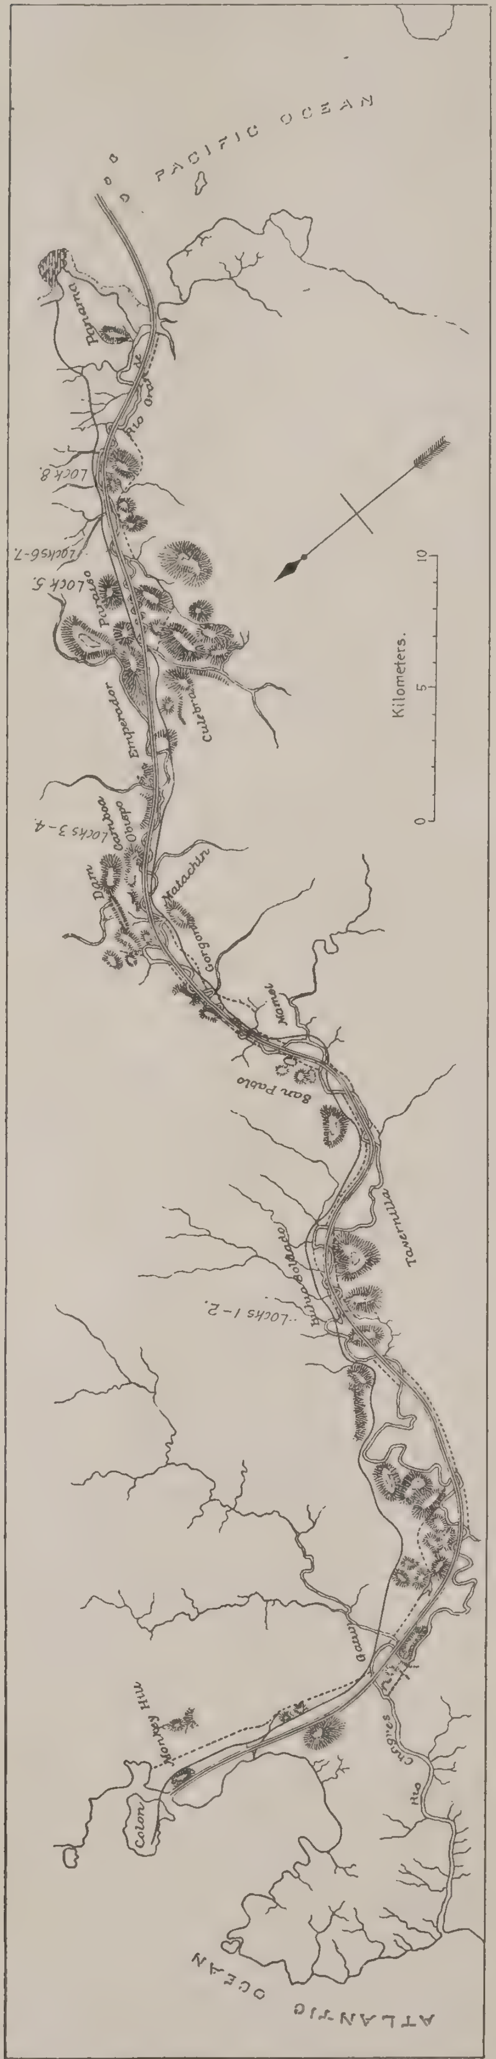
At Alhajuela the low water surface of the river is 28 metres (91.84 ft.) above sea level; at Gamboa, 14 metres (46 ft.); and at Bohio, 0 metres. The mean annual discharges at these three points respectively are 68 cubic metres (2,224 cu. ft.), 84 cubic metres (2,965 cu. ft.), and 121 cubic metres (4,261 cu. ft.) per second. During the three low water months (February, March and April) these mean volumes fall to 27 cubic metres (953 cu. ft.), 31 cubic metres (1,094 cu. ft.), and 39 cubic metres (1,376 cu. ft.), the minimum being 9 cubic metres (318 cu. ft.), 10 cubic metres (353 cu. ft.) and 14 cubic metres (459 cu. ft.). The maximum flood volumes, closely estimated on the basis of the floods of 1879, the largest within the memory of the inhabitants, is at Gamboa 1,630 cubic metres (57,539 cu. ft.) per second, and at Bohio 3,100 cubic metres (109,410 cu. ft.). The floods of the river, great and small, are all of the torrential type, resulting from the heavy and widespread tempests of the rainy season. Their duration is extremely short, rarely exceeding in the greatest floods 48 hours at Gamboa and 96 hours at Bohio. The maximum heights ever attained above the low water stage are about 11 metres (36.1 ft.) at Gamboa, and 12 metres (39.36 ft.) at Bohio. These figures, resulting from years of patient and careful observations, have furnished the basis for solving the two great questions of river regulation presented by the problem of the canal.

Upon an estimate, known to be safe, of allowing 1,000 cubic metres (35,300 cu. ft.) per second to freely pass Gamboa and 1,200 cubic metres (42,360 cu. ft.) to freely pass Bohio, reservoirs to contain 1 million cubic metres (35,300,000 cu. ft.) above Alhajuela, and 1.5 million cubic metres (52,950,000 cu. ft.) above Bohio are needful to restrain the greatest known floods; and these reservoirs are provided by the dams already described. In no other than the flood of 1879 would so large volumes be demanded.

The level of these lakes to be regulated by overflow weirs of the Stoney type, which have given perfect satisfaction on the Manchester canal, and which have the great merit of allowing the sills to be placed below the water surface without serious leakage.

The volume of 1,000 cubic metres (35,300 cu. ft.) per second permitted to pass Alhajuela will follow the bed of the Chagres to Lake Bohio. The volume of 1,200 cubic metres (42,360 cu. ft.) allowed to escape from the latter, will pass by two overflow weirs—one to the left of the canal discharging 500 cubic metrese (17,650 cu. ft.) per second through the bed of the Chagres and its derivations; and the other at the sources of Rio Gigante discharging 700 cubic metres (24,710 cu. ft.) by a route also separated from the canal.

To supply the summit level during the season of low water, the inflow of 20 cubic metres (706 cu. ft.) per second will be required. To provide 7,000 horse-power for lighting the canal and operating the gates, 15 cubic metres (530 cu. ft.) per second are demanded, falling 32 metres (105 ft.) at Alhajuela, and 16 metres (52.5 ft.) at Bohio, and acting on turbines driving dynamos to transmit the power in the form of electricity. The reservoir capacity, in excess of the low water flow of the Chagres, to supply these two needs, is 130 million cubic metres (4,589 million cu. ft.). The area of the lake above Alhajuela is 2,300 hectares (5,750 acres) at the level of 61 metres (200 ft.) above tide water and 3,000 hectares (7,500 acres) at the level of 65 metres (213 ft.), the crest being 69 metres (226 ft.), calling for a layer of water 9 metres (29.5 ft.) deep to contain 1 million cubic metres for flood storage and 130 million for low water supply. Upon this basis the capacity of the lake has been regulated.



MAP OF THE PANAMA CANAL.
(Reproduced from a map published in 1886.)

To transport the needful volume of water (20 cubic metres per second) from Alhajuela to the summit level, a feeder 16 kilometres (10 miles) long will leave the lake at a level of 58 metres (190.3 ft.) above tide, and follow the left bank to a lateral valley, discharging gently into the summit level about a kilometre (0.62 miles) from the locks at Obispo. The fall between the lake and point of delivery will be 17 metres (55.8 ft.), and the cross section is established to carry from 25 (882) to 40 cubic metres (1,412 cu. ft.) per second, with a view to meeting all possible contingencies of a largely increased traffic. At these heights water will flow into the canal even if the higher summit level should finally be found to be the more advantageous. The feeder traverses a difficult region and will be costly, but all details of construction have been successfully elaborated.

At Lake Bohio, as already stated, a capacity of 1.5 million cubic metres is needed for storage during great floods, and to assist the overflow weirs in regulating the level during the sudden influx of smaller floods. This volume calls for a layer of water 3 metres (10 ft.) deep; and another metre has been added, to contain a reserve for supplying evaporation in the lake during the dry season.

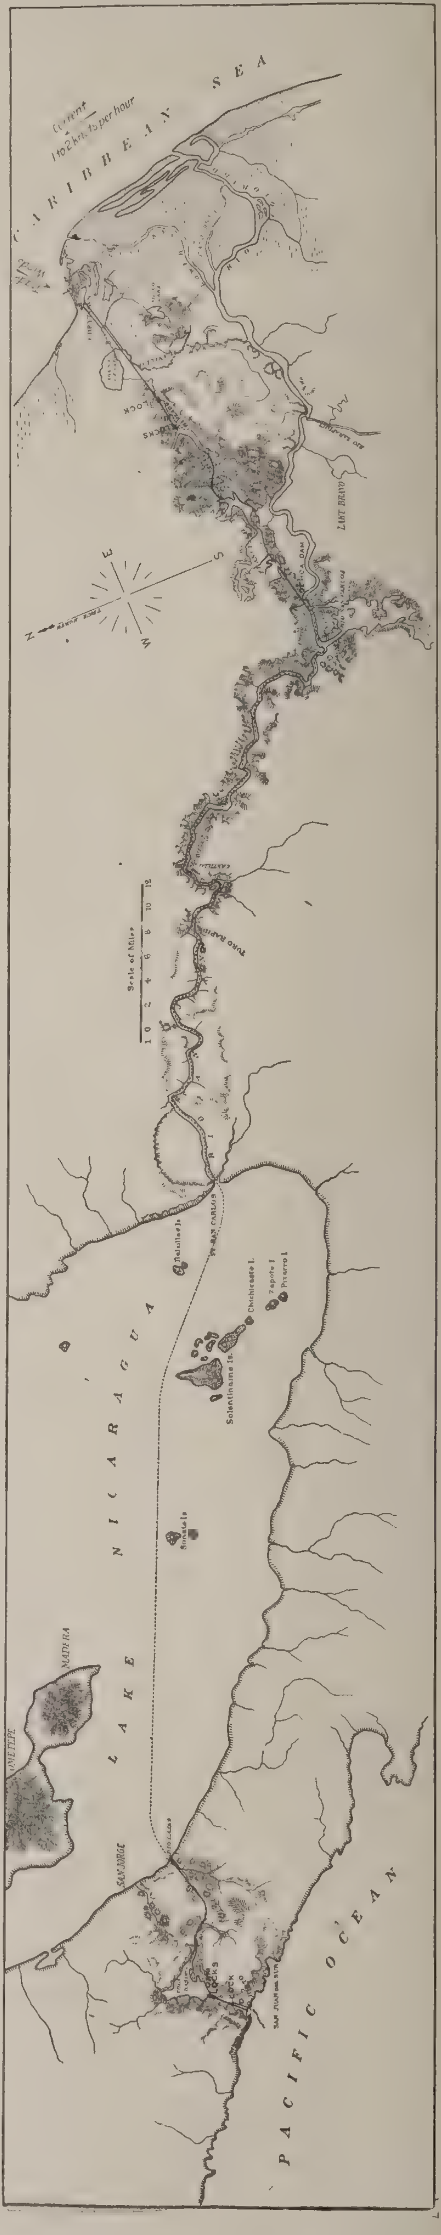
From the foregoing it will be seen that the hydraulic problems presented by this turbulent river—at one time regarded as so serious—admit of satisfactory solution. This is hardly the case in Nicaragua, where one of the great difficulties of project is the regulation of a summit level depending on that of an immense lake 2,700 square miles in extent, receiving directly the drainage of 8,700 square miles of territory, together with that of 2,250 square miles more through the tributaries of the San Juan river above the dam at Ochoa; conditions which render the ordinary method of storage reservoirs wholly inapplicable. Nevertheless a delicate regulation of this level, and at an artificial height, is essential to avoid on the one hand drowning a cultivated district on the west shore, and on the other hand exposing rocks in the navigable bed of the San Juan. These difficulties are aggravated by the necessity of placing the overflow weirs near Ochoa, at a distance of more than 100 kilometres (62 miles) from the lake.

In this connection it may also be noted that in the matter of rainfall the Panama canal is the more fortunate. All the difficult excavations and works of construction, except those near Bohio, lie in the interior where the annual downfall, as determined by 32 years of observation, is 93 ins., or only about 50% more than on our Gulf coast; while in Nicaragua, the most difficult constructions, including the Ochoa dam and the San Francisco embankments, lie in a district where the downfall, as determined from the data collected by the Nicaragua canal company (about 7 years observations), is 256 ins., or nearly three times as much.

Estimates.—This subject has received the most careful study, both in determining quantities and unit prices. Much valuable data as to the latter, based on actual experience on the Isthmus, has been available. The cost of each different project, and there have been 16 different variants, has been estimated in detail, and a selection between them has thus been reached intelligently. The sum needed for the work of construction proper is, in round numbers, one hundred million dollars. The element of time is more difficult to determine, but the volume remaining to be excavated at the Culebra being a little less than 12 million cubic metres (15,600,000 cu. yds.), it is believed that ten years is a conservative estimate.

The Nicaragua Canal.—To the general relative merits of the two canals already considered may be added that the Panama route lies in the interior of Columbia, while that by Nicaragua lies near the Costa Rican boundary; where hostilities are liable at any time to cause difficulties, as they already have done during the canal examination by the Walker commission last spring. Also that in respect to danger from possible earthquakes, which might easily cause trouble at the great locks, Panama is by far the more safe, because no active volcano is found within a distance of at least 200 miles from it, while three lie in the close vicinity of the route of the Nicaragua canal, and one within only 40 miles of its western locks. Last April an earthquake destroyed substantial masonry buildings at Leon, only 100 miles distant from these lock sites.

But while it is thus easy to compare the two



MAP OF THE NICARAGUA CANAL.
(Reproduced from a map accompanying the Report of the Ludlow Commission of 1895.)

canals in their general features, and to see that the route by Panama is much superior to that by Nicaragua, when details are considered, we are confronted by the fact that really no definitive project can be claimed for the latter. The company's project, as revised by the Government Commission, of which General Ludlow was president, is shown on the accompanying drawing; which may be compared with that given to illustrate the Panama project, but it should be noted that the latter has double the horizontal scale, thus failing to impress the eye, by fifty per cent., with its relative merit in respect to length. The data upon which this project was based were so unsatisfactory to the Ludlow Commission that they reported for obtaining the necessary data for the formation of a final project, eighteen months' time, covering two dry seasons, and an expenditure of $350,000, will be required." A new commission has been appointed, and new surveys inaugurated; and it appears from the views of the individual members, as given before the select committee of the Senate in June, 1898, that the changes undergoing study are radical in their nature, and that, although some at least of the engineering difficulties which impressed the former Government Commission are recognized as grave, no means of avoiding them have yet been discovered. Under these conditions it is apparent that confidence cannot be accorded to such a project; and that really there is only one canal, that of Panama, whose construction could be judiciously undertaken at the present time. It to to be hoped before the Govermnent embarks on so important a work that the relative merits of the two routes will be examined and judged by a commission of expert engineers, for it is certain that only one canal is now needed, and that that one should be the best possible.

(We are indebted to Gen. Abbot for the profiles accompanying the above article. The two profiles have the same vertical scale; but the horizontal scale of the Panama profile is double the horizontal scale of the Nicaragua profile. The map of the Nicaragua Canal is reproduced from the map accompanying the report of the Ludlow Commission of 1895. The map of the Panama route is reproduced from a paper by Mr. Chas. D. Jameson, M. Am. Soc. C. E., in the "Journal of the Association of Engineering Societies" for August, 1886.—Ed. Eng. News.)

◆

THE NATIONAL ACOUSTIC CO. has been organized, in Buffalo, N. Y., to carry out the ideas of Mr. E. Henri Kelly regarding the best form for churches and public halls with regard to their acoustic qualities. Mr. Kelly believes that these buildings should be so constructed that the interior should be shaped like the inside of an eggshell, and a church of that form has just been completed in Buffalo. Mr. Kelly's idea, however, was long ago adopted in the old Mormon temple at Salt Lake City; and it is a fact that this building has wonderful sound carrying qualities.

NOTES FROM THE ENGINEERING SCHOOLS.

Purdue University.—The engineering laboratory has, during the summer, been supplemented by the addition of a room 50 × 100 ft., known as the "Railroad Laboratory." In this room the equipment of machines for testing strength of materials, and the brake-shoe testing machine of the Master Car Builders' Association are already in place. There is also a full-sized model of the front end of a Richmond compound locomotive, and an exhibit of typical steel car trucks. The equipment of this room will be completed during the Fall by the installation of the air-brake testing rack of the Master Car Builders' Association. The number of students matriculating for the new year is larger than for several years past. The freshman class will number about 200, nearly two-thirds of whom are in the engineering courses. There are but few changes in the corps of instructors in the engineering department. Mr. Leopold O. Danse, for several years senior instructor in mechanical engineering, Lehigh University, has been appointed an instructor in machine design, and Mr. Robert S. Miller, assistant in the engineering laboratory, has been made instructor in the mechanics of machinery.

Public Appreciation of the Value of Engineering Education.—We frequently have complaints to the effect that the engineering profession is not as highly appreciated by the general public as it deserves to be, but there are indications that the public sentiment in this regard is gradually changing. We take pleasure in reprinting, as an evidence of this change, the following extracts from an editorial on "Progress in Education," in the "New York Tribune" of Sept. 27:

> The increase of students in colleges and universities during the last 25 years has been very marked. In 1872 only 590 persons in 1,000,000 were enrolled as college students, while in 1897 the number had risen to 1,216 in 1,000,000, being more than double the number. Moreover, during the same period the standard of admission to colleges and universities has been raised to such an extent as to require an average of an additional year's work in preparation for the freshman class.
>
> But it is in the remarkable multiplication of scientific and technical schools that education in this country best shows its value in fitting pupils for the duties of modern life. These schools have already gained a world-wide reputation. Pupils are sent to them from South America, Europe, and even from Asia, and their graduates are employed for difficult feats of engineering, mining and railroad building in every civilized country of the world. In the numerous developments of electrical science Americans now hold a position of unchallenged supremacy, and their future work in this fruitful field is likely to be still more important. Mechanical and electrical science is to-day revolutionizing the world, and is calling into its service a great army of able and brilliant men. The learned professions, important and honorable as they are and always will be, no longer dominate life. The real leaders of the world to-day, we may almost say the real builders of civilization, are the engineer, the electrician, the inventor, the man who, ignoring the barren logomachies of the philosopher, devotes his life to the discovery of some hitherto unknown law of Nature in order to make it serve the needs of the human race.

The only amendment we would make to "Tribune's" statement is to add the words "of law, medicine and theology" after the words "learned professions," for the words as they stand tend to give countenance to the idea that engineering is not a "learned" profession. No other profession has a stronger right to the title "learned." The engineering schools require of their entering students a higher standard of preliminary education, and their four years' courses are more severe, requiring longer hours of study, more intense application, and a stronger equipment of health of body and of brain to complete them, than do the professional schools of any other of the learned professions.

University of Wisconsin.—The Department of Electrical Engineering, which is under the charge of Prof. Dugald C. Jackson, has issued a circular giving the names of students who have taken degrees in electrical engineering during the last six years, with the positions now held by them. It states that over 20% of the members of the first five classes that graduated from the course have already become managers, chief engineers or superintendents in important industrial enterprises, and approximately 15% are teachers of engineering and science.

Rensselaer Polytechnic Institute.—H. H. Rousseau, of the class of 1891, Principal Assistant Engineer of the Pittsburg Bridge Co., stood first among the candidates in the recent examination held in Washington for civil engineer in the United States Navy. About 50 men started and 18 finished the examination. All these 18 were graduates of engineering schools. Last year at a similar examination, the papers of which were afterwards published in Engineering News, two other graduates of the Institute, Messrs. Chambers and Parks, stood at the head of the list. Another graduate, Mr. Arnold Sutermeister, of the class of 1892, recently passed first among the candidates for the position of Superintendent of Grade Crossings under the Railroad Commission of this state, and was appointed to that position.

Syracuse University.—The departments of civil and electrical engineering, physics and biology have moved into the new hall of physics, which is named after Mrs. Esther Baker Steele. Mrs. Steele will furnish the physical laboratories with a complete equipment of modern apparatus. The laboratories of the engineering departments have also been furnished with the best apparatus procurable.

Columbia University.—The list of appointments made since July 1 includes the following: Earl B. Lovell, C. E., adjunct professor of civil engineering. Richard S. McCaffrey, M. E., assistant in metallurgy. William A. Anthony, Ph. B., lecturer in electrical engineering.

Cornell University.—A portrait of John Fritz, the famous metallurgist and engineer, founder of the Bethlehem Iron Works, has been added to the portrait gallery of Sibley College.

George H. Shepard, Assistant Engineer, U. S. Navy, has been added to the staff of Sibley College and will have charge of the work pertaining to elementary steam engines.

Dexter S. Kimball, Stanford, '96, has been appointed instructor in machine design.

The new hydraulic laboratory of the College of Civil Engineering in Fall Creek has been formally transferred to the custody of that college. The laboratory will be in charge of a new professor, G. S. Williams, Michigan, '89, whose chair has just been created. Professor Williams has spent the nine years since graduation in the city waterworks construction, on the U. S. Lighthouse Board, and as civil engineer to the Detroit Board of Water Commissioners.

Fifteen graduates of Cornell are serving in the Volunteer Engineer Corps of the army. Forty Cornell men tried the examinations and all passed and were put on the eligible list, but 25 did not receive appointments because the lists were full when the war closed.

THE METROPOLITAN AND BELT RAILWAYS OF BERLIN.

(With two-page plate.)

In the May number of the "Revue Generale des Chemins de Fer" is a lengthy illustrated description of the Metropolitan Railway of Berlin, from which we abstract the following:

As long ago as 1872 the Deutsche Eisenbahnbau-Gesellschaft asked for a concession for building a railway through the city of Berlin; but as the cost was then estimated at 150,000,000 marks, the scheme was abandoned. The project was taken up again in 1873-74 by the Berliner Stadt-Eisenbahn Gesellschaft, and a contract was made with the city on March 20, 1874. The capital was fixed at 48,000,000 marks; and of this amount the state was to pay 21,000,000 marks, the construction company 12,000,000, and the three railways interested the remainder. A beginning was made; but a new agreement was entered into in 1878, raising the required capital to 65,100,000 marks, and modifying the original project by providing four tracks throughout. After much debate it was finally decided that no goods should be transported on this line, and that the four tracks should be devoted solely to the service of passengers; that the line should not be independent of the railways entering the city, but intimately united at all points with them; for the convenience of passengers arriving in the city. It was also decided that the tracks must be elevated in every part, so as not to interfere with surface traffic.

While work was actually commenced on the viaduct in the autumn of 1875, the slowness of appropriations and the modifications of plans found necessary delayed progress to such an extent that at the end of 1877 only about 3,000 lin. ft. of the viaduct were completed. In 1878 the Government actually took hold of the construction, and in this one year finished 9,184 ft. of the line and had half as much more under construction. Work now progressed rapidly and the line was opened, for city travel at least, on Feb. 7, 1882; and on May 15, 1882, it was ready for the terminal traffic of the great railway lines. The line was generally built by contract under State supervision, the State itself only building some special parts of the work. The operation of the railway was placed under the direction of the State Railways, Berlin System, by a decree of Aug. 18, 1881.

The actual cost of the construction of this system was 68,129,000 marks, or $17,032,250. This sum includes a portion of the cost of the terminal station at Charlottenburg, and the reconstruction of the other terminal station at Silesia. The whole cost was divided as follows, figured in marks, worth 25 cts. each:

	Marks.
Land acquired	33,305,184
Viaduct construction	18,602,212
Earth work	198,000
Superstructure, including falseworks	2,191,573
Signal system	281,740
Stations	7,870,869
Rolling stock	2,424,449
Engineering supervision	2,131,812
Miscellaneous expenses	737,898
Interest on capital during construction	384,062
Total	68,128,699

Since the completion of the work in 1882, little of any importance has been done; the additions only include new posts for the block system used and two new stations, opened in 1885 and 1896, for city service.

A general description of the Metropolitan Railway can be given as follows: The total length of the system, including the terminal stations of Charlottenburg and Silesia, is 39,835 lin. ft., or nearly 8 miles. Of this length, 16,038 ft. is curvature with radii of from 918 to 1,640 ft.; the grades are light, and the difference in level between the two ends is only 2.3 ft. In the central part of Berlin the viaduct is generally masonry, with the streets crossed by girder bridges, with a minimum clearance of 14.43 ft. under the lower chord. In only a few cases was it necessary to change the grade of the streets crossed. At the extreme ends the tracks rest upon simple earthen embankments, for lengths of 2,214 and 5,520 ft., respectively; but the remainder of the system is divided into 26,122 ft. of masonry viaduct, including masonry bridges, and 5,979 ft. of metallic viaduct and bridgework. The free space beneath the masonry viaducts is utilized for shops and storehouses near the streets crossed and wherever the viaduct borders on parallel streets.

The system has four tracks throughout; with the two northern tracks reserved for city service and the secondary stations, and the other two tracks are set aside for the service of the trunk line railways and the great stations. These two sets of tracks are separated by a central space generally 4 m., or 13.12 ft. wide. The rails were originally placed upon steel ties of the Haarmann type; but owing to rapid deterioration these ties were only retained upon the bridges and some other places where it was difficult to replace them, and heavy wooden ties were substituted, with eleven ties to every 27.5 ft., or one rail length. The first rails used weighed about 54 lbs. per yard; but those now laid weigh about 70 lbs. per yard, and to add to the security of the line an interior guard-rail is laid on all curves. The eleven stations vary in distance apart from 2,263 ft. to 5,543 ft.

There are five main stations open at all times to both city service and that of the trunk railways; while the intermediate stations are used only for city traffic. The general plan of the main stations is as follows: The station itself is formed by a widening of the viaduct, as indicated in the plan, with the two central tracks preserving their normal alinement and the two outer tracks widening out sufficiently to permit the establishment of the two platforms between them and the straight inner track. These platforms have a width of from 32.8 to 49.2 ft., and a length varying from 656 to 820 ft.; they are provided with six spacious stairways, three to each platform. The stairs for city service are divided into two parts by a central railing, one side being used for ascent and the other for descent; the entrance upon the platform is through a gateway where one employee receives the tickets of descending passengers, and another punches the tickets of ascending passengers. The public were formerly freely admitted to the platforms of the main stations; but admission is now only possible on the payment of 2½ cts., or the lowest fare. Beneath these platforms is a large room enclosing the stairways and accessible from two sides, extending the full width of the viaduct; and in this room are the ticket offices, distinct for the two services, placed near the stairways. There are also rooms for the reception and distribution of baggage, waiting rooms for the separate classes of passengers, a restaurant or buffet, water-closets and a police station. There are also offices for the operators of the line and storehouses, for tools, oil, etc.

On the level of the rails the entire space, including the platforms and lines of rails, is covered over by one corrugated, galvanized iron roof, generally semi-circular in form, and closed at the sides by light walls about 23 ft. high. This upper station varies in length from 475 to 538 ft., and in width from 115 to 131 ft.; it is lighted by a monitor running the length of the top and by side windows. At each end of the platforms of main stations are installed hydraulic elevators for handling baggage; indicator arms announce the destination of the coming train, for both tracks, and between the central tracks a fence completely isolates the two services, with a passage through it for the use of employees only.

The lower part of the station is warmed by steam heat to a nearly uniform temperature of + 20 C. when the outside temperature is — 20 C. The lighting is assured in the daytime by windows and a glass pavement between the central tracks, and at night by arc lamps. Advertising was at first prohibited in these stations; but a recent decree permits the placing of advertisements in the waiting rooms and vestibules and also on the curved ends of the platforms, an annual revenue of about $25,000 being now secured from these privileges. The writer of the article trusts that the administration will not be led into temptation by this revenue and permit such abuse of the available space as to make these advertisements a nuisance to the public—"as in England."

At the smaller stations the structure only covers the tracks for city service; or the two northern tracks. The outer track is widened out as before for the reception of one platform having a width of 23 or 30 ft. and a length varying from 426 to 558 ft. The lower story is usually raised about two steps above the street, and includes a large hall, waiting rooms, two water-closets, and offices for the employees. There are usually two stairways, and on the level of the rails is a glazed kiosk at the head of the stairs for shelter from the wind, and another kiosk for the stationmaster, telegraph, signals, etc. The platform and two tracks are roofed over for a length varying from 164 to 492 ft. and for a width of 39 to 52 ft. This shed is lighted by a monitor in the roof and by windows in the lateral walls.

The Belt Line Railway, which with the Central Metropolitan Railway makes up the city system, has replaced the so-called Junction Railway, built in 1851 to unite the stations of the trunk railways existing at that time. The definite plans for the belt line were adopted and the first work was commenced upon it in 1867. It was constructed entirely by the State, the first section being opened in 1871 and the circle finished in 1877. It was generally upon embankment, with some parts in cutting and a small part on the level of the surrounding country; it was built for double track, and the original completed cost was $6,948,500. The connection of this belt line, in 1887, with the central rapid transit system, gave it a greater importance than before, and the line now has four tracks, the stations have been remodeled and increased in size, and a number of new stations have been built; all grade crossings have also been removed. These improvements represent an expenditure of about $5,348,000.

This Belt Railway forms a continuous line, 23.37 miles long, completely surrounding the city. But since the opening of the Metropolitan line it has been divided into two sections, the North and the South Belt, each of which, with the great diametrical artery, forming a complete circuit about the two semi-circular parts of the city, north and south. Upon these two circuits are located 22 stations. The details of construction on the central viaduct and upon the belt line are not entered into, but the illustrations given sufficiently indicate the character of the Metropolitan viaduct, the more important of the two in this connection.

STRESSES IN RAILWAY RAILS UNDER MOVING TRAINS.*

Our present railway rails are in reality girders supported at many points, more or less elastic, upon which the weight of the locomotive or train is concentrated at a few points, i. e., the points of contact between the wheels and rails. There is a great diversity of opinion respecting the proper weight and shape of rails. In assuming that the rail acts as a girder, a perfectly proper assumption, and in making calculations on that basis the uncertain factor is that the point of support is indefinite, owing to the compressibility of ties and ballast. As the load rolls onto any section, the rails deflect, Fig. 1, and the ties, ballast and roadbed are compressed until action and reaction are equalized, or until the resistance of the roadbed equals the load imposed, the greatest deflection, as would be expected, occurring directly under the points where the load is applied. There is an unmistakable compression of the fibers in the head of the rail under the rolling contact, Fig. 2, a tension on the lower or base side of the rail and a shearing stress across the rail section at or near the ties which at that instant are bearing the load. The span of the deflection of the rail under the wheel is as a rule longer than the tie spacing. At a point a little distance on either side of the wheel the stresses are reversed, the head of the rail becoming in tension and the base in compression. The general effect of the weight of a locomotive and tender upon the track and the distribution of this weight from the track to the ties, ballast and roadbed, as just described, is shown in Fig. 1, which represents the base and wheel loads of a 100-ton Boston & Albany locomotive standing on 95-lb. rails. In plotting this the vertical scale was enlarged to make the depressions more distinct. The engine truck wheels carry 20,350 lbs. per pair; the drivers 37,500 per pair; the front tender truck wheels 18,500 per pair, and each pair of wheels in the rear truck, 23,500 lbs.

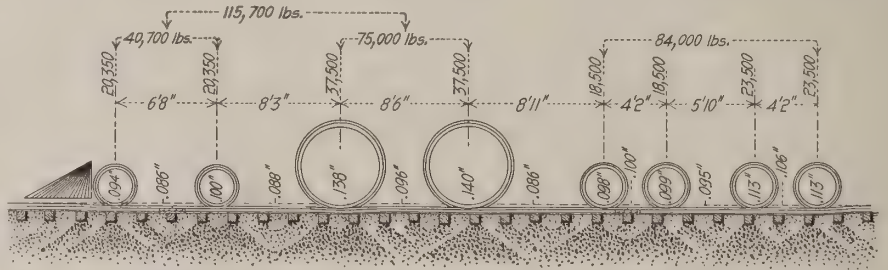


FIG. 1.—DIAGRAM SHOWING DISTRIBUTION OF THE WEIGHT OF 100-TON LOCOMOTIVE AND TENDER, BOSTON & ALBANY R. R.

The depressions of the rail were found to be 0.094-in. under the front truck wheel of the engine; 0.086-in. between the wheels and under the rear truck wheel 0.100-in. In the wheel space between the truck and the drivers the depression was 0.088-in. Under the front driver it was 0.138-in.; be-

*Abstract of a paper read by P. H. Dudley, C. E., before the New York Academy of Science and printed in the Academy Annals for 1898.

tween, it decreased to 0.096, while under the rear driver it increased to 0.140-in. These and the depressions found under the tender are shown in the figure. The amount of tension and compression in the different portions of the rail were measured by the Dudley "Stremmatograph," a device which is clamped to the rail at any desired point and records on a moving metallic strip the compression or elongation of the metal in a given length of the rail base. The section included is 5 ins. and the changes induced in this by the load rolling over the rail or standing above moves a system of multiplying levers which shifts a scriber which in turn traces a curved or wavy line upon the record plate. The departure of this line from a datum line, ruled when the track is not loaded, affords a direct measure of the tension or compression induced.

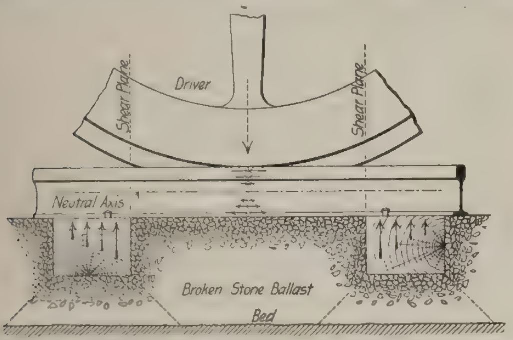

Fig. 2.—Sketch Representing the Rail as a Beam with Load Concentrated Between Ties.

In the case under consideration the following results were obtained, the values being reduced to apparent stresses per sq. in.:

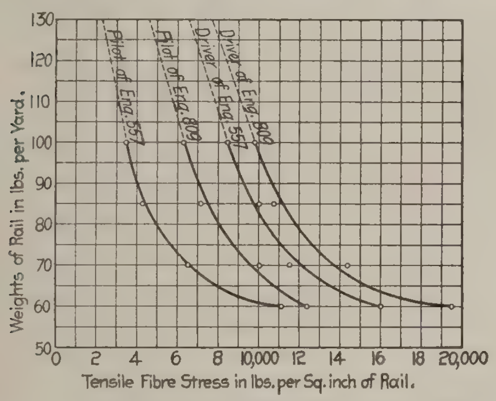

Fig. 3.—Curves Showing Maximum Fiber Stress in Base of Rail; Plotted from Values in Table I.

	Tension, lbs.	Compression, lbs.
Front engine truck wheel	6,780	.....
Center of wheel space	.....	1,530
Rear engine truck wheel	5,340	.....
Center space bet. rear trk whl & driver	.....	3,050
Front driver	9,160	.....
Center of space between drivers	.....	3.050
Rear driver	9,920	.....
Center space, drivr & front tendr whls	.....	2,290
Front truck front tender wheel	3,820	.....
Center of space between wheels	.....	760
Front truck rear tender wheels	3,820	.....
Center space between tender trucks	.....	1,530
Front wheel rear tender truck	6,100	.....
Center of space between wheels	.....	0000
Rear wheel of rear tender truck	6,870	.....

Further experiments along these lines were conducted since 1895 by Mr. Dudley and Mr. James E. Howard, Engineer of Tests at the Watertown Arsenal, Watertown, Mass., and the results of some of these tests are given in Mr. Dudley's paper. In Table I., which has been prepared from these data, it will be noticed that records were taken with two locomotives, a freight and a passenger, running on different weight rails (described in Table II.), using stone ballast in both cases. The curves in Fig. 3 are plotted from the figures given in Table I. for the tensile stress per sq. in. in the base of the rail due to the trucks and the drivers. While there are too few points to make these curves more than approximate, their general agreement in direction affords a sufficient check to permit their use to present to the eye the results obtained by the use of the Stremmatograph.

TABLE II.—General Dimensions of Rails.

W'ght, pr yd., lbs.	Height, ins.	Width, Base, ins.	Width, Head, ins.	Thickness, web, in.	Moment of Inertia, I.	Moment of Resistance, R = I/n'	Distance neutral axis to outside fiber. Head, n.	Distance neutral axis to outside fiber. Base, n'.
60	4¼	4¼	2⅜	½	14.222	6.693	2.125	2.125
70	4½	4½	2 7/16	½	18.055	8.282	2.32	2.18
85	5	5	2 9/16	17/32	26.374	10.853	2.57	2.43
95	5 1/32	5½	3	⅝	32.280	13.563	2.65	2.38
100	5½	5½	2 13/16	⅝	38.957	14.812	2.87	2.63

With the two locomotives used in the tests it will be seen that in rails below 70 lbs. per yd. the stress increases very rapidly. Tracing the curves in the other direction they are seen to become much steeper and straighter, showing, from about 90 lbs. on up to 125 or 130 lbs. per yd., almost a straight line with a slope of approximately 1 to 40, or a decrease of 40 lbs. per sq. in. in tensile stress for each pound increase in weight of rail per yd.

The fact that the Stemmatograph records directly with a considerable degree of accuracy the extension and compression of rails under moving loads, and hence, though indirectly, the stresses induced by the moving loads suggests its use for solving the mooted question of locomotive balancing and just what shape and disposition of counterbalance produced the least shock to track and bridges. It would settle once and for all the dispute as to the pounding produced by the present method of counterbalancing, and answer the question: , Does a uniform wave of deflection travel along the track with the train or are there recurrent points of greater deflection and therefore greater strain when the counterbalance is up or down?

A number of instruments could be mounted, on any section of track, in connection with photographic apparatus in such manner as to record the extension of the rail base and the position of the counterbalance at the instant the driver was over the instrument. By doing this with several engines at different speeds data could be obtained and comparisons made by means of curves which would show what really occurs when an engine runs over a track under working conditions of weight and speed.

* * *

PHOTOMETRY OF THE ENCLOSED ALTERNATING ARC LAMP.*

Arc light photometry, in so far as it involves the mere determination of luminous intensity yields unsatisfactory results for three reasons: The first is the marked difference in quality between the light of the arc and that of any of the ordinary standards. The photometrist realizes the general unsatisfactory character of the existing standards for the study of sources of a quality similar to that of gas light. Nevertheless, he is vastly better off, in this respect, than he is in the matter of a standard of suitable quality and intensity for arc light measurement. The eye estimates accurately an equality of brightness in two surfaces only when those surfaces are of the same tint. Moreover, with a color difference, the judgment of an equality differs with different observers. It should be said, however, that the difficulty arising from difference of color is less troublesome in the case of the enclosed arc than in the case of its progenitor, the open arc. The inner, opalescent globe absorbs the rays of short wave-length in greatest proportion, a fact which brings the color of the arc nearer that of the standard. When an outer globe of milky glass is used—the standard being a glow lamp maintained at, or above, its normal voltage—there is no annoyance from color difference.

The second obstacle to careful measurement is to be found in the variability of the quantity to be measured. These variations are largely due to the wandering condition of the arc—a peculiarity that is especially noticeable in the open alternating arc, and in both types of the enclosed arc. Indeed, it is to this feature of the enclosed arc that the flat-ended carbons are due. The change in luminous intensity corresponding to a shifting in the position of the arc from one side of the carbons to the other side is enormous.

To arrive at a fairly close value it was necessary to take the average of a number of readings. This required the construction of a special recording device which permitted rapid readings to be automatically recorded. This consisted of a long cylinder arranged just under the scale of the photometer and a marking point attached to the carriage which, when depressed, recorded the carriage position upon the cylinder. The details of this device were illustrated and described. Further apparatus, consisting of a Krüss-Bunsen photometer, a swinging crane with a 45° mirror, an incandescent glow lamp, a Hefner standard lamp, and various voltmeters, ammeters and wattmeters were employed.

A number of enclosed alternating current arc lamps placed at the disposal of the authors by their manufacturers were investigated very fully, and the paper described in detail the various tests and the results obtained.

The experiments show with considerable certainty that the economy of the alternating arc is less than that of the direct current lamp; that the use of opalescent globes materially reduces the candle power and that the great and rapid variation or fluctuations of intensity are due to the hunting of the arc rather than to any shifting of the carbons.

In opening the discussion Mr. L. B. Marks said that to his mind the first part of the paper was of the most value. There was a difference in the color of light to contend with, which made the setting of the photometer carriage difficult. An example of this was the Hefner lamp which has a reddish flame and the arc lamp which was decidedly violet. The sensation of color had a great deal to do with lights and there was no photometer which would take full account of this. The use of opalescent globes, he thought, had a tendency to change the quality of a light and to interfere with a correct comparison of the candle powers of a standard, such as the Hefner lamp, and an enclosed arc. He asked if the authors had not reversed "hunting" and its cause, and explained that he considered the flat ends of the carbon due to the burning with limited amount of oxygen and the hunting a result of the flat ends. The recording device was a good idea and likely to be of service to allusing photometers.

Mr. W. H. Freedman said that the flat ends were bound to result where the carbons were enclosed, and as the arc would always seek the path requiring the least expenditure of energy, hunting would naturally follow. His experience had been that in considering the alternating arc there was a power factor other than that due to the inductance of the mechanism. Its existence would be shown by determining the actual watts with a wattmeter and the apparent watts from voltmeter and ammeter readings.

He regretted that the results given in the paper were not in candle powers, as engineers were familiar with such units and could more readily make comparisons. The character of globe used made a very decided difference in the distribution of light and was quite capable of causing the difference in the form of curves which were shown in the paper.

Capt. John Millis, of the U. S. Lighthouse Board, asked Mr. Marks to explain more fully what he meant when he said that there was a difference between candle power and luminosity.

Replying, Mr. Marks stated that the term candle power implied a comparison. In the case of two candles the quality of light was the same; between a candle or a standard of some sort and an incandescent lamp a difference of quality might exist and there would be a still greater difference between the standard and an arc light. The latter might be 400 times as intense under a photometric test, but would it, if put in a room or out in the open, allow the observer to read or observe 400 times as clearly or as well. In other words, does not the illuminating power depend upon the use to which the light is to be put. There is something missing in the term candle power, for it should take into account the quality.

Capt. Millis considered it quite possible to obtain fairly close approximations notwithstanding slightly varying standards and different colors. In light-house work the vital question was how far could a certain light be seen, while in ordinary commercial work it was how much light. Two candles would give twice the light but they could not be seen further than one. The automatic recording device was good and would greatly facilitate photometric observations. Referring to the custom of painting the interior of photometer rooms all black, he had found that an arrangement of curtains was possible whereby the room could be white, or at least not black, thus making it pleasant to work in.

Open alternating arcs, as far as his experience went, had proved very satisfactory, especially with cored carbons. Prof. A. E. Kennelly said that engineers in making lamp tests should not forget that the ordinary buyer judges by appearance and prefers a pleasant and steady light without so much regard to its quantity. In considering the candle power of a lamp he favored the mean spherical candle power which could be described by calling it that light which could be caught up by a bag surrounding the lamp. The variation in candle power so frequently referred to he believed to be more largely a variation in direction than in the total candle power.

* * *

PAPYRISTITE is a new artificial stone, made from purified paper pulp and other ingredients by Fr. Gehre, a civil engineer of Zurich. It is an improvement on papyrolitte, invented by the same man. It is especially intended for jointless roofs or floors, and is a non-conductor of heat, cold or sound. It is hard as a stone, but has a soft, linoleum-like feeling under foot, and is noiseless. It weighs less than stone or cement, and 220 lbs. of the preparation in powdered form, spread 0.4-in. thick, will cover 90 sq. ft. The cost is said to be exceedingly low, and it can be laid without special machinery; it is dry in 24 hours and can then be highly polished. The Papyristite Co., Post Fach 10,469, Zurich, Switzerland, will supply samples at $4.50 per 220 lbs., free on boad cars at Zurich, to those wishing to make experiments.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; 6 *months,* $2 50; 2 *months,* $1.00. *To all other countries in the Postal Union: Regular Edition, One Year,* $7.60 (31 *shillings*); *Thin Paper Edition, One Year,* $6.31 (26 *shillings*). *SINGLE COPIES of any number in current year,* 15 *cents.*

In ordering changes of mailing addresses, state BOTH old and new addresses; notice of change should reach us by Tuesday to be effective for the issue of the current week. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number 328 *means that subscription is paid to the* 32d *week (that is the issue of Aug.* 11) *of the year* 1898; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line. Want noticees special rates, see page* 18. *Rates for standing advertisements sent on request. Changes in standing advertisements must be received by Monday afternoon; new advertise ments, Tuesday afternoon; transient advertisements by Wednesday noon.*

We are glad to record that each of the great political parties in the state of New York has formally promised the voters that if it is placed in power it will visit with exemplary punishment those who have been responsible for the wholesale frauds on the New York State Canal improvements. The planks on this subject in the two party platforms are as follows:

Republican.

> We pledge the candidate this day nominated to a resolute and thorough continuance of the investigation, so fearlessly begun by Gov. Black, into all alleged mismanagement of the canals. If there are errors in the system and the law, we will correct them. If there has been fraud, we will detect and punish the wrongdoers.

Democratic.

> We pledge the people an honest and economical administration of the canals of the state; no squandering of the public moneys; no more millions to be stolen, wasted, or needlessly expended, as reported by a Republican investigating commission to have occurred with the nine-million canal improvement fund; all public contracts to be fairly and honestly awarded to the lowest bona fide bidder; no special privilege to pet surety companies favored by political influence. We favor a reduction of canal expenditures, and are opposed to the intrusting of the work of carrying on further canal improvements to Republican officials responsible for the prodigality, favoritism, and corruption which has characterized the present administration of the canals. Reform in canal management is the supreme issue of the hour. We promise the taxpayers that, if intrusted with power by the votes of the people, there shall follow a vigorous procedure on all canal officials implicated in the theft, waste, or misuse of the public moneys, and the recovery of so much of the diverted funds as it may be possible, by diligent effort, to procure through legal proceedings.

We need make no comment on the above pledges. Either of them could easily be criticised from the point of view of the other side; but either of them certainly commits the party responsible for it to a vigorous prosecution of those who are responsible for the loss to the state treasury of over a million dollars. The high character of the candidate named by each party for the office of Governor gives good ground for the belief that the party pledges above quoted will be faithfully kept; and this outlook must give satisfaction to every friend of good government.

◆

In our opinion this matter of uncovering the canal frauds and visiting the penalty of the law upon those responsible for them is the most important issue by far before the voters of New York. The men who were false to their trust and who secured the state's money by unlawful means did so with their eyes open and with the full knowledge that they were committing a misdemeanor, for which the penalty is imprisonment. They deliberately took the chances, believing that the political influence behind them was strong enough to keep them out of trouble. If they are right, and if they escape scot-free, a precedent will be established in the conduct of New York's public works that will not be forgotten. The state may as well say good-by to honest work and honest administration hereafter, unless it can prove its ability to inflict exemplary punishment on those who have proved so false to their trust.

We sincerely hope and believe, therefore, that whichever party's candidates may take the state government next January, those responsible for the canal frauds will receive the punishment their deeds deserve. It should not be overlooked that the injury they have done is not measured alone by the direct loss to the state treasury in dollars and cents. Every such case of dishonesty in public office and disregard of the obligations of trust, strikes at the very root of popular government. If public officers may make merchandise of their positions with impunity, the state certainly cannot safely undertake the construction of great public works. Nay, more: it cannot even fulfil the ordinary governmental obligations to punish crime, protect persons and property and maintain public order. If those who are engaged on public works may use their official position for their own or even for their party's gain, why may not those who detect and punish crime and those who administer justice do the same? This means, it is true, the blackmail of the innocent, the shielding of the guilty for a bribe and the sale of justice to the highest bidder; but it is only the logical result of such frauds as those on the New York State canal works, if allowed to go unpunished.

◆

In the conduct of the late war, no one feature was more faulty than the transport of troops and supplies on ships commanded by civilian sailors nominally under the control of the Quartermaster's Department of the Army. From the hasty shipment of troops at Tampa to the carriage of sick soldiers home from Cuba and Porto Rico, the accounts of the work done by these transports furnish evidence of the lack of experience of the army officers in responsible charge and of the insubordination of the civilian captains of the vessels. At Santiago, for example, these captains, instead of anchoring where they could be found, put to sea whenever they pleased, with their holds full of food, ammunition, and supplies imperatively wanted on the fighting lines. The officers of the quartermaster's department, who were nominally over the captains of these transports, were, in nine cases out of ten, too ignorant of the handling of ships and their cargoes to exercise anything more than a nominal authority, and the result was a disorganization and lack of system that called forth expressions of astonishment from the foreign military attaches.

It seems to us that in considering how to remedy this evil we will do well to look to the practice of England, whose experience in conducting military operations in foreign lands exceeds that of any other nation. When British soldiers are transported by the sea they are simply passengers on Her Majesty's ships; and every army officer on board below the grade of captain is under the immediate command of the captain of the ship, and the senior naval officer present. In other words, this transport service is entirely in the hands of the naval establishment. The men who are thus placed in responsible charge are not only experts in the handling of ships and the transport of goods and passengers by sea, but are subject to rigid naval discipline and are under the direct orders of the naval commander in chief. There is no division of authority under this system, and the troops and their supplies are moved and landed with certainty and despatch.

The need for a reform in the transport service has been brought to the attention of the War Department by Captain F. M. Dickins, U. S. N., of the Bureau of Navigation; and it was proposed to convene a joint board of army and navy officers to discuss this subject and submit a plan for the more perfect carriage of troops and supplies at sea. The army, however, has declined to accept this invitation, and unless Congress intervenes and orders some change in the system the transport of troops for the occupation of Cuba is very likely to result in the repetition of past scandal. The army proposes to improve the ships used for transport service, as we have already recorded; but it had no officers experienced in handling vessels, loading and discharging them, and caring for the men and materials on board ship and must continue to rely on civilians for this service. It is too much to expect, however, that the civilian sea captain in charge of a vessel will be really subordinate to a landsman, ignorant of nautical matters, and the division of responsibilities can work only mischief in the future, as it has in the past. The refusal of the army to even discuss this subject with the naval authorities is most regrettable. Apparently the army authorities feel that the movement of the troops is their business alone, with which the navy has no business to interfere. As we said before, however, the movement of men and materials in ships is not the business of the army, and it is to be hoped that Congress will place the responsiblity for this important evil where it belongs.

THE PRESENT STATUS OF THE PANAMA CANAL ENTERPRISE.

Elsewhere in this issue we present a carefully prepared paper by Gen. Henry L. Abbot, U. S. A., on the present status of the Panama Canal enterprise. As the American member of an international commission of engineers appointed to report upon the plans for the completion of the Panama Canal, Gen. Abbot has personally examined the works at the Isthmus and has studied in every detail the plans now adopted for finishing this great work. As most of our readers are aware, Gen. Abbot is one of the most eminent members of the Corps of Engineers, and was in charge of important works from his assignment to duty with the Corps at the close of the war until his recent retirement for age. General Abbot's distinguished position and wide reputation as an engineer make whatever he has to say on the Panama canal matter worthy of serious consideration.

It must be confessed that up to the present time American engineers have been inclined to receive with a good deal of incredulity the reports concerning the resumption of work at Panama. It has seemed impossible from both the engineering and financial point of view that the terrible wreck in which the De Lesseps' scheme was involved could ever be repaired. It is apparent that those in charge of the new Panama Canal company realized that it could only be done by beginning wholly anew and by laying a foundation of careful engineering preparation, the lack of which was one chief cause of downfall of the De Lesseps company.

As some of our readers may recall, after the Panama bubble burst in 1890, and work on the canal came to a standstill, the company's affairs were placed by the courts in the hands of a "liquidator," or receiver, as we should say, who remained in charge until 1894, when the concession and all the assets of the old company were transferred to the new company.[*] According to information from official sources, this new company was organized by leading bankers and financiers of France who had no connection whatever with the old company, and by them a working capital of $13,000,000 was subscribed. In taking over the old company no cash was paid for its assets; but the holders of stock in the old company are entitled to receive a certain portion of the residuary profits of the new company from the working of the canal, should there be such

---

[*] A partial list of the officers of "la Nouvelle Compagnie du Canal du Panama" is as follows: President, M. Bannardel (said to be also President of the Western Ry. Co. of France, though his name does not appear in the International Directory of Railway Officials for 1898); Directors, M. Brolemann, of the Credit Lyonnais; O. Melidon, a Director of the Comptoir Nacional D'escompte of Paris; MM. Chanove, De St. Quentin and others; Director-General, M. Maurice Hutin; Company's Agent in New York, X. Boyard, 29 Broadway; Attorneys in New York, Sullivan & Cromwell, 45 Wall St.

profits, after the charges on the securities to be issued by the new company have been provided for.

From all we can learn, this new company has devoted itself almost entirely to the task of investigating the engineering problems at Panama and determining in the most thorough manner the best solution of these problems. De Lesseps' proposition for a sea-level canal was abandoned, it will be remembered, even before the collapse of the old company; but the details of a new location, the height of its levels, the lift of its locks, and more important than all, the questions of the control of the Chagres River and of the sliding of the great earth mass at Culebra, had all to be investigated and settled by the engineers of the new company.

The detailed plans thus prepared were submitted first to a board of French consulting engineers, which included representatives of the Receiver of the old company. After this board had further elaborated the project and approved it in detail, an international engineering commission was appointed, which again went over the entire project, visiting and inspecting the works on the Isthmus, and examining the engineering problems involved.

General Abbot's paper in this issue of Engineering News is the first publication to be made anywhere respecting the work of this Commission and the conclusions which they reached. According to this paper, a satisfactory plan has been developed for the control of the Chagres, and the water supply of the summit level. Additional work at the Culebra cut has shown that the sliding of its sides can be successfully controlled. The work actually done by the old company is estimated to have been equivalent to an expenditure of about $125,000,000; and the cost of the work remaining to be done to complete the canal ready for traffic is set at $100,000,000. The time required to complete the canal is apparently fixed by the excavation remaining to be done on the great Culebra cut, and is set at ten years. The interest charges on the company's securities during this period are apparently not included in the above $100,000,000, and will increase the actual cost of the canal by one-fourth or more.

General Abbot's paper makes little or no allusion to the financial status, prospects or plans of the new company, which is the question of greatest practical interest just now; and the company's representatives in this country are not authorized to make any statement as to its future policy, except to say that no governmental aid will be asked from any source.

From all the information that we can glean, however, we believe that a few months hence, when the complete report of the International Engineering Commission is made public, an effort will be made to raise funds for the completion of the work; and it seems quite probable that the project will be placed in so favorable a light before European financiers that the required amount may be obtained.

This report of the Engineering Commission, we are informed, will probably be ready for publication before the close of the year, and will be accompanied by reports prepared by eminent French statisticians (among them M. Leroy-Beaulieu) upon the probable traffic and earning power of the canal. This is a matter which has been heretofore lightly passed over, both by De Lesseps and the Nicaragua Canal promoters, and the results of a careful statistical investigation will be awaited with interest.

The most important matter upon which General Abbot touches in his paper—at least to Americans—is the relative merits of the Panama and Nicaragua enterprises; and we are obliged to say that this seems to us the weakest part as well, for points in which the Nicaragua route has advantages over its more southern rival are left untouched. We shall not attempt, however, a discussion of the relative merits of these two enterprises at this time, for the very good reason that the public is not yet in possession of the data which would enable a fair and intelligent comparison to be made. When the full report of the International Commission of which General Abbot was a member, is made public, and when the detailed reports of the surveys made under the Walker Commission in Nicaragua are presented, an independent examination of the relative merits of the two enterprises from an engineering point of view will for the first time become possible.

General Abbot's paper does make clear, however, the very important fact that the Panama canal enterprise is not dead, but very much alive; and that it must be taken into consideration in making our decision as to what our national policy is to be with respect to the Nicaragua enterprise.

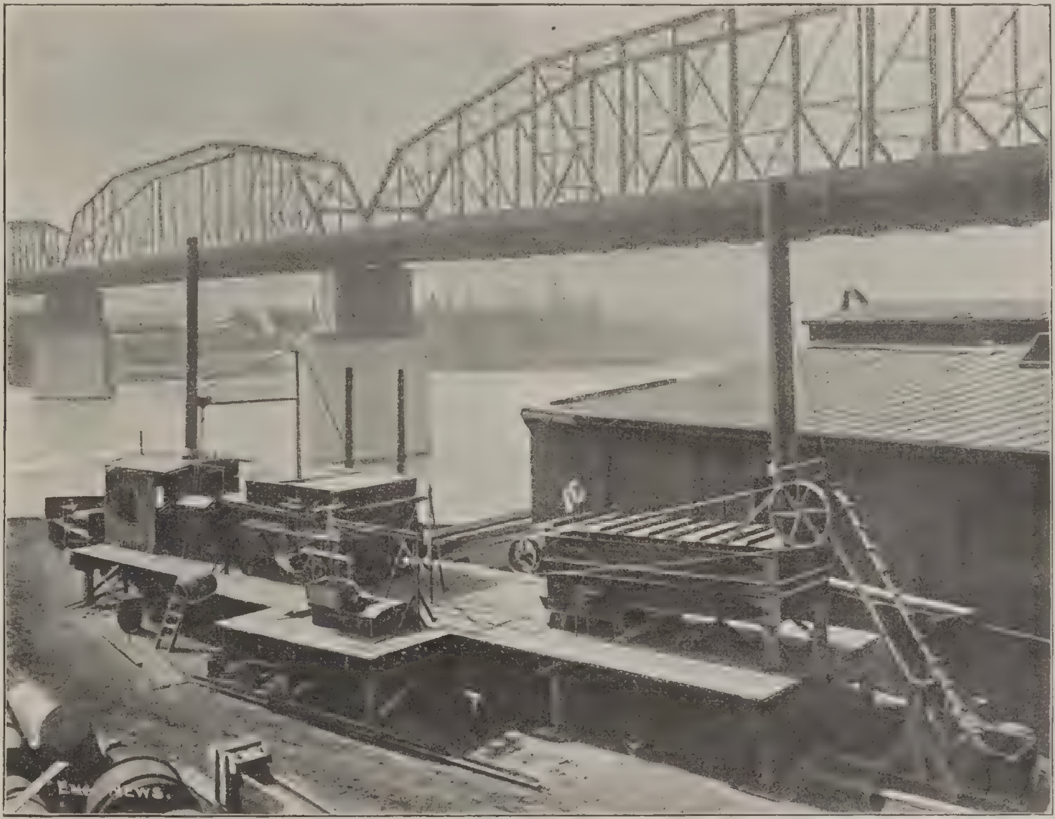
◆

LETTERS TO THE EDITOR.

The Cause of Rails Creeping.

Sir: In the committee report of the annual meeting of the Roadmasters' Association of America (Eng. News, Sept. 15, 1898) I notice again the current explanation for the creeping of rails, viz., the wave-motion of the track under load. According to my experience the creeping of rails is partially due to this wave-motion, but not exclusively. Of even more importance are the shocks between the wheels and the rail-heads (at joints and when the flanges come in contact with the rails). The effects of these shocks on the track have always a horizontal component in the direction of the traffic; and are, of course, heavier on the outer rail than on the inner rail of a curve, on the down-grade than on the up-grade. Although generally the methods for restricting the creeping of rails will be the same for both causes, it may be desirable to reckon in special cases with the shocks as the principal factor. J. J. Israëls.

312 McPhee Building, Denver, Colo., Sept. 23, 1898.



THE FIRST PORTABLE ASPHALT PLANT IN OPERATION AT CINCINNATI, O.

◆

The Original Portable Asphalt Paving Plant.

Sir: In connection with the very interesting description of the portable asphalt paving plant manufactured by Messrs. Hetherington & Berner, of Indianapolis, in Engineering News of Sept. 15, your readers may be interested in a brief description and the accompanying photograph of the pioneer portable asphalt paving plant.

This plant was designed by the writer, and built by the Warren-Scharf Asphalt Paving Co., in the year 1889. It was intended for use in the towns and smaller cities where the amount of work likely to be required would not be sufficient to justify the erection of a permanent local plant. It was designed to turn out sufficient mixture to lay from 500 to 700 sq. yds. of pavement per day, but it has done much better in practice, and its actual capacity is about 1,000 sq. yds. per day.

Without going into a lengthy description of the machine, I may say that it is built on two flat cars, one of which carries the two revolving drums for drying and heating sand, the sand being fed to them from the ground, at the rear of the plant, by elevators. The front half of the car is used as a platform for storing the heated sand. The mixing apparatus is at the side of the car, near the stored sand, and is supported on a platform which, when the plant is to be moved, slides back onto that part of the car used for storing hot sand when the plant is in operation.

The second car carries the steam boiler and a 20-HP. engine protected by a cab. The engine drives a main shaft supported under one side of the cars and having a universal joint between the two cars to provide for any lack of accurate alinement of the cars. The same car carries the large kettles for melting the asphalt. The sides of the cars are hinged, and when let down form a platform around them. The plant was designed to use either oil or coal for fuel, but oil fuel has been found best and most economical.

The photograph, which was taken at Cincinnati, shows the plant set up, ready for operation, gives a good idea of its general plan and some of the details. (N. B.—This is a photograph of the paving plant, notwithstanding that the most prominent feature in it is the Chesapeake & Ohio Ry. bridge over the Ohio River.)

The design and construction of such a plant necessarily requires some ingenuity and mechanical skill in adapting well-known mechanism to the ends in view, but does not necessarily involve much invention. Such features of the plant as were novel were patented at the time. (Patent No. 451,989, issued to the writer May 12, 1891.) It will be seen that while the later plants, like the Hetherington & Berner, are larger, and involve some improvements and some new features, they follow pretty closely in general design this pioneer plant. The plant is still in use, and while limited in capacity, compares, in economy of operation, quite favorably with its more pretentious successors. S. Whinery.

New York, Sept. 22, 1898.

Notes and Queries.

On the double-page engraving in our issue of Sept. 15 the numbers and titles of Figs. 5 and 6 were accidentally transposed. The cut marked Fig. 5 is properly Fig. 6, the Northern Pacific R. R. truck; and that marked Fig. 6 is properly Fig. 5, the Schoen pressed steel truck.

R. S. W., Milwaukee, Wis., asks which corrodes the most rapidly, wrought iron or steel?

According to the best information at hand, the difference in liability to corrosion between the two is not great, and the corrosion of a given specimen will vary with its chemical composition and probably also with its physical structure. This refers, of course, to soft structural steel. Harder grades of steel and tool steels, we believe, corrode more slowly. If any of our readers can answer the query more definitely we shall be pleased to hear from them.

C. W. S., New Rochelle, N. Y., writes:

Will you give through the columns of your paper your views as to the proper way in which the Department of Public Works should be administered in cities having a population up to 100,000? It is a subject in which engineers are interested, and the appointment of others than engineers as the head of such department is often a detriment to the profession as well as expensive for the taxpayer.

Our correspondent asks an easy question. The Department of Public Works in any city, large or small, should be administered on business principles, that is with the sole aim of carrying on all operations under its charge in the public interest. A competent engineer, if he has executive ability in addition to his technical knowledge should make an ideal head of a Public Works Department; but equally good results may be attained with a business man in that place, provided he also possesses executive ability, that he knows enough to seek expert advice on technical matters, and above all, that he is unswervingly honest and faithful to his trust. This is what ought to be. We are obliged to confess that those who select candidates for such offices are generally more particular to inquire concerning a candidate's "popularity with the boys," the extent of his probable contribution to the campaign fund, and the likelihood that he will use his official position to help his party.

ELECTROLYSIS OF WATER PIPES AT DAYTON, O.

One of the most thorough investigations of damage by electrolysis in a city's water mains that has been made in a long time was undertaken last summer at Dayton, O. Several cases of serious damage by electrolysis had come to light, and the trustees of the city water-works decided to have the extent of the damage determined as carefully as possible. They, therefore, called in as experts, Messrs. Harold P. Brown, of New York city; E. E. Brownell, of Dayton, and J. H. Shaffer, of Pittsburg. The reports of these engineers, together with a report by Mr. Chas. E. Rowe, Secretary of the Dayton Water-Works Board, have just been printed, and form a valuable contribution to the engineering literature on this subject.

It is now generally admitted that electrolytic action exists in all localities where a "ground return" is used for heavy electric currents. Any denial by railway companies that their currents are causing injury is always based upon the claim that the tracks are well bonded and that an ample metallic return circuit is provided for the current.

The burden of proof that damage is done is therefore thrown upon the complaining party, and an investigation, such as that undertaken at Dayton, must be made.

The fact that an electric current is flowing along a line of water or gas mains can be easily established by taking voltmeter readings at different points, attaching one terminal of the instrument to the hydrant, fire-plug or gas pipe being tested, and the other to the rails of the electric railway. Quoting from Mr. Brown's report:

> The current to operate the trolley cars leaves the dynamo and passes through the trolley wires in various parts of the city, then through the motor of each car and the wheels to the rails. To complete the circuit, it must return to the negative pole of the dynamos. To reach this pole, two paths are open to it; first, by the rails and feeder wires leading from the rails to the dynamos, and second, through the moist earth to the water or gas pipes below, along which it passes until within 1,000 to 3,000 ft. of the power house, when it leaves the pipes, again passing through the moist earth to the rails. A current of electricity passing through a conducting fluid, like water, decomposes it, and the oxygen and acids, if any, in the compound are delivered at the positive or outgoing pole, while the hydrogen and alkalies are delivered at the negative or receiving pole. This oxygen corrodes the metal of the positive plate, while the hydrogen produces no chemical effect on the negative plate.

It will be seen from the above that the tendency to corrosion by electrolysis on a line of underground pipes will exist wherever the current is leaving them. In remote parts of the city where the current passes onto the pipes or where it is passing along them without leakage there will be no electrolysis.* Wherever the current is leaving the pipe for the rails, however, the fact will be indicated by the pipe being at higher potential than the rail. In the Dayton investigations by Mr. Brown, voltmeter readings were made on all the streets of the city having electric railway tracks, and the difference between the trolley wire and the rail, between the trolley wire and the water main, and between the water main and the rail. At each hydrant along the line of the electric roads these readings were repeated for each of the four rails of the double tracks.

In making the readings, the time of the day was also noted, since the pressure depends upon the amount of the load carried at the power house. The results of the voltmeter readings were plotted upon a map of the city, showing the railways and water mains, and the extent of the mains where current was leaving the pipes and electrolysis was going on was thus plainly shown.

It was next necessary to determine the extent of the damage already done by exposing the pipes here and there at places where the instrument observations indicated the greatest action. Quoting again from Mr. Brown's report:

> A number of excavations were made in different parts of the city to determine how much damage had been done to the pipes and how much electrical pressure was required to seriously injure the cast iron. A pressure of three volts and less was found to cause a graphite-like coating not exceeding 1-32-in. in depth; the iron beneath seeming uninjured. At potentials of 3 to 4½ volts the thickness of the layer is increased in a ratio which depends upon the length of time the pipe has sustained this pressure. With a knife or file soft spots can be found in the pipe from 1-16-in. to ¼-in. in depth. With higher pressures the extent of the injury is even greater. * * * * * In ordinary soil the effect of electrolysis upon cast iron, if unprotected by sufficient amount of tar, is to produce an oxide of iron, which is a poor conductor of electricity, so that, with a given pressure, the deeper the layer of iron rust, the slower the rate of corrosion. To my surprise, the soil in which the pipes are buried, in Dayton, gives an entirely different reaction when the current passes from a pipe to the moist soil. The tar seems to be no protection whatever and the pipe is covered with a layer of black material, resembling graphite. This material proves to be an excellent conductor, so that instead of checking the action, it tends to increase the action by reducing the resistance of the path through which the current must flow. Furthermore, the stones or pebbles near the pipes, seem to be electro-plated with the metal of the pipe. This condition I have not seen in any other place, and as far as I know it has not been observed before.

It was next necessary to determine whether the soil itself had caused corrosion of the pipe in any degree, independent of the electric current. A pipe was uncovered which had been laid in 1874, at the same time as some of the pipes, which had been found seriously corroded. This pipe showed no evidence of electrical current and was so located that it could not carry current from one part of the city to another. It was in soil apparently the same as that surrounding the corroded pipes. It was still heavily coated with tar, and on scraping through this layer its surface was found as good as new. It was, therefore, evident that the soil contained nothing which would injure a cast-iron pipe, unless assisted by electrolytic action.

The question of the amount of injury which pipe has received is one difficult to determine in any quantitative way. The best method probably would be to take up several lengths of corroded pipe and compare the results of hydrostatic tests upon them with similar tests of pipe removed from unaffected districts, An easier method is to cut test pieces from the pipes and subject them to physical tests.

> In the investigation at Dayton, four test bars were cut from the very best portion of the pipes, and tensile and transverse tests were made which gave the following average results:

	Tensile strength, lbs. per sq. in.	Transverse strength, lbs. per sq. in.	Deflection, ins.
Affected pipe	11,425	1,085	0.20
Unaffected	16,000	1,800	0.25

> That is, the affected pipe had only 69.4% of the tensile strength and 54.3% of the transverse strength of the unaffected pipe.
>
> The pipe from which these bars were cut was also tested hydrostatically and leaked in several places at a pressure of 150 lbs. per sq. in.
>
> An analysis of pieces of these pipes, the incrustation upon the corroded one and soils from around both pipes was made by Mr. Jas. O. Handy, Chief Chemist of the Pittsburg Testing Laboratory, with the following result:

	Unaffected. pipe.	Affected. pipe.	Incrustation.
Phosphorus	0.789	0.800	1.821
Sulphur	.073	.057	none.
Silicon	2.270	2.500	not det.
Iron	not det.	not. det.	33.43
Combined carbon	.13	.24	7.12
Graphitic carbon	3.48	2.88	

	Alkalinity, %	Salt, %
Soil from unaffected locality	0.016	0.015
Soil from affected locality..............	.032	.810

Table I. has been prepared from data given in the report of Mr. J. H. Shaffer, which forms one section of the complete report from which we have been quoting. In it are shown the effects of electrolytic action as they were found at 15 places where the mains were uncovered. It will be noticed that the distance between pipe and rail varied from 3½ to 7 ft., and, further, that the pipe in all cases where actual corrosion was found, had a positive potential, which ranged from a fraction of a volt to as much as 9 volts, and in every instance the destination of the pipes varied with this difference of potential, being greatest for the higher and least for the lower values.

This is what could be expected, and the facts are well stated by Mr. Brown, who says "the amount of electrolytic action is directly proportional to the amount of current transmitted (which depends upon the potential) and the length of time the current flows; it is inversely proportional to the area in contact with the soil." This being the case, we would expect, what actually does happen, a greater or more rapid destruction of the smaller pipes.

The following remarks are also taken from Mr. Brown's report. While not absolutely new, they will bear repetition since they are applicable to nearly all cities and towns where electric railways are operated:

> The rate of electrolysis depends directly upon the electrical condition of electrical pressure between the positive and the negative plates (the pipes and rails). This rate is increased by the presence of any acid or alkali in the fluid (or soil in contact with pipes and rails). A slight leakage from the gas pipes, or a small amount of acid from the surface, or the presence of an alkali in the soil will increase the action, and the current itself, by carrying the metal oxide into the (ground) water, reduces the resistance of the solution, and tends constantly to cause a further increase of action. This increase of rate is augmented by the rusting of the bonds between the rails and by their mechanical loosening by hammer-blows from car wheels. The maximum laboratory electro-deposition of iron is obtained from a saturated solution of sal-ammoniac. In such a solution 100 amperes of current will remove over 3 lbs. in 24 hours, or with the proper solution, the same amount of current will remove over 20 lbs. of lead in the same time. The lead calking or service pipes will therefore sustain more damage than iron pipe. A difference of ½ volt between a lead pipe and a rail will injure the pipe. The fact that the bell of the iron pipe is nearer to the rail than the lead tends, however, to reduce the rate of injury of the lead below it. Since wrought-iron pipes are much more rapidly destroyed than cast iron, all natural gas service pipes in the vicinity of electric railway power houses should be ventilated at the curb, in order to prevent leakage into the houses and explosions. Inasmuch as gas can be ignited by sparks between separated portions of gas pipes, as at terminals where meters are to be inserted, the use of wire conductors between gas service pipes and gas pipes in houses is advisable. The difference of pressure between water and gas pipes in private houses has often been sufficient to cause fire, and it is therefore advisible to bind together electrically water and gas service pipes inside of the house line.
>
> It has been claimed by some that cast-weld joints would entirely obviate the effects of electrolysis. A comparison with the measurements made last February in the business portion of Dayton, O., however, does not bear out this claim, since the only variation is directly proportional to the variation of the loads then and now. To definitely determine this, measurements were made be-

TABLE I.—Effects of Electrolysis on Water Pipes at Dayton, Ohio.

No. of reading.	Time.	Size of mains, ins.	Date of laying.	Distance from rail ft.	Character of soil.	Potential with reference to rail (volts)	Remarks.
1	July 11, 1898 4:45 p. m.	6-in.	1874.	3½	Moist gravel.	+9	Tar coating destroyed; iron reduced from ½-in. thickness to ⅜-in.; iron decarbonized.
2	July 11, 1898 5:00 p. m.	6-in.	1874.	4	"	+5½	About the same as No. 1; lead pipe nearby completely destroyed.
3	July 11, 1898 5:30 p. m.	6-in.	1874.	4	"	+9	Pipe badly damaged.
4	July 12, 1898 2:20 p. m.	4-in.	1888.	4	"	0	Remote from influence of current; coating unaffected, showing no soil corrosion.
5	July 13, 1898 5:00 p. m.	6-in.	1893.	4½	"	+4½	Pitted and badly eaten; will soon give out.
6	July 15, 1898	6-in.	.....	6	"	+3½	Coating destroyed, good evidences of electrolytic action.
7	" "	4-in.	.....	7	"	+4½	Practically the same as No. 6.
8	" "	6-in.	.....	5	"	+4¼	Pipe eaten from ⅛ to 3-16-in.
9	" "	4-in.	.....	4	"	+2¼	Coating destroyed and pipe affected about 1-16-in.
10	" "	6-in.	.....	7	Dry gravel.	+1¾	Coating destroyed and slight evidence of electrolytic action.
11	" "	4-in.	.....	4	Good "	+2	Practically the same as No. 10.
12	" "	12-in.	.....	3½	Moist "	1†	Very slightly eaten.
13	" "	10-in.	.....	4	Good "	—5	Perfectly preserved; coating not the least affected.
14	July 16, 1898	12-in.*	.....	..	....	..	Perfect; made for electrical purposes.
15	" "	6-in.	.....	4	Good.	+2	Coating disturbed; pipe slightly affected.

*12-in. gas and 6-in. water. †Neutral at light loads.

---

*It has been claimed by some engineers that electrolytic corrosion to a certain extent will take place at the lead joints of a pipe along which a current is flowing. The amount of such corrosion, however, is a disputed point. We may also note here that soon after the destructive effect of electrolysis was first observed it was suggested that the trouble could be remedied by reversing the polarity of the railway system—that is, by making the current on the overhead wires positive. This was tried in a number of instances, but it was soon found that the cure was worse than the disease, for, instead of preventing the electrolytic action, it simply removed the destructive region from the vicinity of the power house to distant and scattered sections of the city.

tween two hydrants on different corners along the line two blocks apart. Similar readings were then taken on each of the four rails opposite these hydrants, using in each case an insulated wire stretched along a dry, paved street. The measurements showed that the pipes between these points were carrying 19-20 of the current returning, while 1-20 was divided between two of the rails; and the other two were carrying no current.

The report concludes with a resume of the results obtained, and a calculation of the damage done based upon the data obtained during the tests. In making the calculations no account was taken of mains that were found neutral or negative to the car rails, but only of those that were positive. The total length of affected pipe, ranging in size from 4 to 16 ins. in diameter, amounted to 46,065 ft., the indicated voltage as taken showing this amount of pipe to be carrying from 0.3 to 9 volts positive to the rails. This was made up as follows:

	ft.
Total length of mains on streets running parallel to the railway	40,825
Length of 143 intersecting streets, estimated as affected 20 on each side	2,860
112 fire hydrant branches, affected 20 ft.	2,240
7 fire cistern branches, affected 20 ft.	140
Total	46,065

The idea of calculating 20 ft. either side from the car tracks for side streets and fire hydrant branches, is based on the fact that in making excavations little effect of electrolysis on the surface of the pipe is observed, beyond this distance. As already stated the measurements were taken to pipes contiguous to the track, yet it is not improbable that the current in seeking the most favorable path would follow other pipe lines away from the tracks, and the water pipes could become positive to either the artificial or natural gas pipes. It was known that service pipes have been destroyed, about 1,300 ft., beyond the limits of the danger district. The conditions at the time of the tests were ordinary, and as all were favorable to obtaining average values the figures here given are considered very fair.

Mr. Chas. E. Rowe, Secretary of the Water-Works, says, in concluding his report:

> In making the report the matter of damage is confined entirely to the city's property, which comprises the main lines and fire hydrant branches. No account is taken of the enormous risk, in case of fire, while removing the damaged pipes and replacing them with new ones, which will require closing off some of the main arteries for probably weeks. Neither is any pecuniary consideration given of the loss and inconvenience to the business interests of the city in closing off hydraulic elevators, fire protection and power lines. There are 110 of this class of consumers, whose services range from 2 to 6 ins. in diameter, whose pipes are undergoing the same process of destruction. There are also in the confines of this positive district 1,419 domestic and other consumers with lead service connections, ranging from ½-in. to 1½ ins. in diameter.
>
> The action of the current on lead and wrought-iron pipes appears to be much more destructive than on cast iron, and as it is known that the aptness of pipes to destruction by the electric current is for cast iron, 1, for wrought iron, 3, and lead, 7, which fully accounts for the large number of services, both water and gas, that have had to be repaired, and the difference in the thickness of the metal between large and small pipes, naturally destroys the small pipes in much less time than the mains. Wherever the main lines are damaged to the extent that they would have to be replaced, service pipes would be in a much worse condition and replaced several times.
>
> As the property owner is responsible for the repairs to the service from the main, the cost of replacing the services and repaving the streets would be very great (and almost ruinous to the streets), which entire cost would have to be borne by the property owners on the abutting streets, and no estimate is here made of the cost. Of the nearly 9 miles of pipe lines affected there is only 1,600 ft. of the pipe on unpaved streets. There is 10,845 ft., or more than two miles of the pipe line, that is laid directly between the two car tracks, or under what is called the dummy track. The ties of the railroads nearly join each other between the tracks, and it will be very difficult to get at this pipe, and the annoyance of the cars passing and repassing adds still more to the expense, and will be very dangerous to the workmen.
>
> In calculating the cost of replacing the pipes in the whole affected territory, it is estimated at $77,208.80. There is 17,513 ft. of pipe that shows a voltage of from 2 to 9 volts positive, and from pieces of pipe removed where electrically charged to this extent, it is found that they have deteriorated 50% in four years. Where they were required, when laid, to withstand a hydrostatic pressure of over 300 lbs. per sq. in., a pipe, when tested, after being subjected to 4.5 volts for four years, leaked at 150 lbs. pressure. It has been clearly demonstrated by the test made that the physical condition of the pipe corresponds to the voltage of current traveling thereon. At 4.5 volts it has been shown that a 6-in. pipe can certainly become useless in five years. At a lesser current the pipes are being corroded, but the life of the pipe is simply prolonged to correspond with the amount of current.
>
> The fact having been established that all pipes positive to the car tracks are damaged, and the agent causing the damage not having been removed, and the fact that the water pipes are used to convey the return current of electricity to the power stations of the electric railways, a purpose for which they were never intended, it remains for the Board of Water-Works Trustees, or others having authority, to see that the city is reimbursed for the damage sustained, and to enjoin the railway companies from using the water pipes as a return conductor. There is 28,412 ft. of pipe that shows .3 to 1.75 volts positive. This division is made to show that at least a portion of the pipe that is positive from 2 to 9 volts is now in a very dangerous condition, and from the tensile and hydrostatic tests made would indicate that at the ratio of depreciation the pipes are now undergoing that they would soon burst under the fire pressure (100 lbs.). It should be stated that the coating on the water pipes hermetically seals the iron from any ordinary conditions that would be apt to corrode them, but after the electric current has affected the pipe so that the coating begins to scale, the destruction will be much more rapid.

In conclusion, Mr. Rowe suggests the following pertinent questions:

> Should the pipes be at once replaced, or should the city wait until some calamity occurs? With the direct pumping system would not the unexpected bursting of some large main be apt to damage the pumping machinery? If new pipes and services are put in where others have been destroyed, and the current is not eliminated therefrom, or the pipes made neutral to the rails, are the conditions changed, and will not the pipes so replaced be again subject to destruction?

MODERN CUPOLA PRACTICE AND THE PHYSICS OF CAST IRON.*

By Bertrand S. Summers, Chicago, Ill.

The question is sometimes asked, What is the most important element governing the quality of cast-iron for any particular purpose? Some twenty years or more ago, silicon was regarded by foundrymen as one of their worst enemies; but since the work of Turner and of Keep, silicon has been greatly growing in favor, until it is regarded in some quarters as the panacea for all evils encountered in the iron-foundry. This has led to the founding of a school, the followers of which seem to regard silicon as the one element of decisive importance in pig-iron. It is the writer's opinion that graphite is the controlling element in pig-iron, and that a greater success is obtained where this metalloid is governed, than in cases where the silicon only is watched.

The most prominent function of silicon is that of promoting the formation of graphitic carbon, while it also lowers the saturation-point of iron for carbon. The former is the property that concerns the foundry-man almost exclusively; and it is necessary for him to know about how much silicon cast-iron should carry, in order to have the desired properties. It seems fair to say that nothing absolute can be stated regarding this question. Frequently, we notice in text-books and journals, that if iron carries this or that percentage of silicon it will have certain properties. This sweeping general proposition the writer cannot accept, being of the opinion that other conditions will affect the content of graphitic carbon as much as, if not more than, the content of silicon. In general, if it is desired to make good machinery-castings of close structure, and at the same time so soft that no difficulty will be experienced in tooling them, the silicon should be between 1.50 and 2%, or may even run to 2.25%. It is always wise in these cases to consider the iron used in the mixture. It is well enough to say in a general way that if we have the same chemical composition in cast-iron we will have the same properties, but experience has shown that this is true in a general way only. For example, mixtures in which the chief component is charcoal iron, show a perceptible difference from those made entirely from coke-iron. The reason for this seems to lie in the different conditions of the carbon, which will be mentioned later.

For light hardware, in which great strength is not a very important item, it is well to run the silicon up even as high as 3%. This practice tends to make the iron more fluid, so that it will take delicate molds well, and avoid difficulty or loss due to shrinkage. It is also said to enable the foundry-man to carry more scrap in his mixture. This assertion, however, is open to serious doubt, as the amount of scrap which a mixture will carry is dependent upon the carbon-content of the mixture and the scrap.

As silicon approaches or exceeds 3%, the casting becomes more and more brittle, and it is desirable to keep well within the limit of 3% in most classes of foundry-work. For most foundry purposes, on the other hand, a silicon-content below 1.5% is to be avoided.

Sulphur.—The good effects of silicon are frequently counteracted by the presence of sulphur, and mysterious troubles encountered in the foundry are not infrequently traceable to this element; the practical foundry-man being, in this respect usually at the mercy of the pig-iron manufacturer. Most brands of soft iron, both charcoal and coke, are usually considerably below the danger-limit in sulphur. Foundry-men, however, are frequently misled by the statement that sulphur need not be considered, as it never occurs in pig-irons in sufficient quantities to affect the results of their work. If analyses are made of drillings from castings that give trouble to foundry-men not possessing means for determining sulphur, the trouble will, in many cases, be traceable to this element. In most instances, sulphur is introduced into the mixture through the ferro-silicon irons used to supply the silicon to the charge. The writer has found well-known brands of ferro-silicon containing 0.17 and 0.18% of sulphur, and in one case 0.34%. If a careful watch is not made of these irons, or if strict specifications are not drawn upon them, it is not infrequent that 0.10% of sulphur is found. Most furnace-men endeavoring to do so can keep the sulphur below the limit of 0.05%.

A maximum limit of sulphur for good foundry-practice should be fixed at 0.10%; but foundry-men should strive to keep it below 0.08%.

Phosphorus.—The element is present to a greater degree than is commonly supposed in most cast-irons. It may be said that for the greater part of foundry-work it is an excellent ingredient up to a certain limit. This limit, for most cases, is about 1%. Where great strength and resiliency are desired, the phosphorus should be very much below this point. However, in cases of this kind, it will seldom be noticeable in high graphitic iron, where it is kept below 0.5%. In snap-flask work phosphorus is a very desirable element to the foundry-men, tending to make the metal fluid and to keep it so. Its effect on strength is not immediately discernible, if the test-bar of cast-iron is subjected to a transverse stress. A severe blow upon the bar, however, will soon make apparent the difference in irons. It is weakness under sudden shock that phosphorus most distinctly promotes; and for this reason it should be kept low, wherever this property would be a detriment. Like sulphur, phosphorus occurs in large quantities in the ferro-silicon irons commonly used in foundry-mixtures. It may be stated that most of the common brands of these compounds on the market carry 1% or more of phosphorus. The writer has known cases in which 7% silicon-iron carried more than 1.60% of phosphorus. Of course, this is unknown to most foundry-men not having facilities for analyzing their iron; and in this way phosphorus is frequently introduced into mixtures which never should carry a high percentage of it.

Manganese.—Manganese is an important element in many ways. It will scarcely be noticed in a mixture, up to 0.8%, as far as the ordinary foundry-man is concerned. Frequently an excellent casting is found to contain over 1% of manganese. It is not long since it was suggested that manganese is a very beneficial element in cast-iron, and it has been asserted by some metallurgists that a considerable content of this element is desirable. The writer's experience with manganese in general practice has not been extensive, but it seems to him that this modern view is to be looked upon with favor. Although it is well known that manganese promotes combined carbon, silicon predominating in the iron would tend to counteract this effect. Manganese, however, has considerable effect on the magnetic properties of the iron, which have been discussed in another paper by the author ("Journal of the Society of Chemical Industry," December, 1897).

Carbon.—The consensus of opinion seems to be that a great deal is yet to be discovered relative to carbon. There is no question that graphite carbon is the softening agent in cast-iron; and, so far as silicon can control this, it is the governing agent. The writer hopes to show, however, that, in many cases, silicon is powerless to effect this change in the state of the carbon.

Combined Carbon.—It is usually admitted that combined carbon embraces more than one kind of carbon. This is, to some extent, substantiated by work upon the magnetic permeability of metals relatively high in carbon. However, the present state of the art will not permit much to be said with certainty in this direction. Reference may be made in this connection to recent work of Messrs. Donath and Haissig on silicon-irons, in which they cite the fact that a high-silicon iron, when analyzed for carbon by ordinary methods, gives about 1.36% less of carbon than when the drillings are oxidized completely by combustion with lead chromate, or volatilization in chlorine. Lower results were also obtained when the metal was oxidized with chromic and sulphuric acid. This differece, Messrs. Donath and Haissig suggest, is due to some silico-carbide. The writer has endeavored to duplicate these results, working on a ferro-silicon containing about 7.5% of silicon. The total carbon, obtained by solution in a double chloride and the residue burned in a combustion-furnace, was 2.24%. In every case in which the carbon was determined either by direct combustion with lead chromate, or the residue from the chlorine treatment burned in a combustion-furnace, the results agreed quite closely with those obtained by solution in a double chloride. It is possible, however, that the results obtained by these scientists may be true for ferro-silicon higher in silicon; or it may be that the metal used for their experiments was in some respects anomalous.

Relation of Silicon to Graphite.—Let us now endeavor to see what grounds there are for the assumption that silicon is the governing factor in cast-iron. If we have several pieces of cast-iron, made at different dates from practically the same mixture, the analyses of which show practically the same total carbon and a variation in silicon, we have an excellent opportunity to trace the effect of silicon. For example, in the following table, are irons which would seem to show this quite clearly:

Table 1.—Analyses of Charcoal-Iron Castings.

	I.	II.	III.	IV.
Silicon	2.20	2.66	2.92	2.41
Graphitic carbon	2.92	2.93	2.77	2.98
Total carbon	3.44	3.48	3.41	3.42

---

*Condensed from a paper to be presented at the Buffalo meeting of the American Institute of Mining Engineers, Oct. 18, 1898.

The other constituents of these irons are nearly the same, and all of them are controlled as far as possible in foundry-practice. They were made from almost identical mixtures, as is clearly indicated by the uniformity of total carbon. It is evident that this table does not support the unqualified assertion that an increase in silicon causes a proportional increase in graphite, and the practical rule, based on that theory, that silicon may be blindly added to the foundry-mixture, without considering other conditions, in order to increase graphite and soften the iron, is not substantiated. Comparing irons I. and III., we find that although the latter contains 0.72% more of silicon than the former, the graphite is 0.15% lower, while the total carbon is practically the same. Obviously this increase in silicon has not produced graphite, yet the total carbon indicates that there was no marked difference in burden.

Taking IV. as the second in the series, we see that silicon increases by about 0.20%, yet that the graphite is nearly constant, except as to III., which is both highest in silicon and lowest in graphite. The fair deduction seems to be, either that silicon has no marked effect upon graphite in ordinary foundry-practice, or that there are other conditions more potent. The latter view seems the more probable.

The above analyses are taken from a vast number made in the course of practice, which confirm this conclusion. Daily records for months show conclusively that the silicon varying between 2 and 3% has not nearly the effect on the graphite that it is usually supposed to produce. No relation apparently exists between the change of silicon and the content of graphite within these limits, and there is little if any doubt, if we can judge from this long series of tests, that there are other influences in cupola practice which are more potent than the variation in silicon.

Another proof of this proposition is seen in the analyses of pig-iron, before they are introduced into the cupola. Pig-iron shows the effects of the metalloids in the blast-furnace, instead of in the cupola; yet even in the blast-furnace, with its high temperature, the silicon is not always able to govern the graphite. For example, the following are strong indications in this direction:

Table II.—Analyses of Pig-Irons.

	I.	II.	III.	IV.
Silicon	7.94	7.48	3.36	3.30
Sulphur	0.041	0.029	0.051	..
Phosphorus	1.39	1.05	0.606	..
Graphitic carbon	2.02	1.95	3.31	3.26
Total carbon	2.24	2.19	3.33	3.37

Here it appears that the irons carrying more than 7% of silicon have less graphite in proportion to the total carbon than the one containing 3.36%. Number III., however, is a remarkable iron, and one that is seldom seen, although its high proportion of graphite to total carbon is quite characteristic of the brand, and has been found in most shipments received from this furnace. This anomaly must therefore be due to local conditions.

The castings in Table I. were all compounded from high-graphitic charcoal-iron. In coke-iron mixtures the failure of silicon to increase the percentage of graphite is even more marked. The following analyses are taken from casts made entirely from coke-irons:

Table III.—Analyses of Coke-Iron Castings.

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.
Silicon	2.85	3.76	2.62	2.47	3.18	3.11	2.79	2.95
Sulphur	0.073	0.083	0.074	..	..	..	..	..
Phosphorus	0.557	0.612	0.469	..	..	..	..	..
Manganese	0.39	0.260	0.42	..	..	..	..	..
Graphitic carbon	3.13	3.05	3.17	2.55	2.69	2.78	2.67	2.61
Combined "	0.18	0.24	0.08	0.74	0.51	0.62	0.54	0.60
Total carbon	3.31	3.29	3.25	3.29	3.20	3.20	3.21	3.21

The first four members of this table have about the same total carbon, and were made from the same irons, with but minor changes in the burdening. From these irons little if any relationship can be traced between the silicon and the graphitic carbon. Looking at the last four members, the total carbon contents are seen to be practically identical, while the graphitic carbon is very nearly the same in the irons containing the highest and the lowest content of silicon; and, again, no relation can be traced between silicon and graphitic carbon. As in the case of the first four, these mixtures were compounded from the same irons with but minor changes in the burdening.

That temperature controls the effect of silicon is shown when a close examination is made of different shipments of the same brand of pig-iron, the blast-furnace running on the same ore-mixture. A case came under my personal observation recently, in which the graphitic carbon ran from 3.40 to 3.50%, the silicon remaining in the neighborhood of 1.5%; but when the silicon rose to 1.8 or 2%, the graphitic carbon rose above 3.50%. In nearly every case of this kind a decrease in the total carbon was likewise noticed. This has also been frequently noticed with other brands of iron, and it is more apparent with charcoal-irons than with coke. The heat in the blast-furnace seems to be great enough to make the silicon a more important factor.

It is hardly legitimate to attribute these differences to the effect of the other elements, as a glance at the tables will show that they do not vary enough to enter into the consideration. It would seem, on careful consideration, that the effect of silicon is largely governed by the temperature at which it is allowed to act. It is doubtful if the necessary temperature is obtained in the cupola to permit the silicon to have a very strong effect upon the carbon, where its contents does not vary beyond certain limits. It also seems probable that, where the burden is light, the effect is not as marked as in the case of large burdens, where more heat is developed.

Influence of Oxidized Material, Especially Rusty Scrap, Upon Mixtures.—Little attention has been paid to the peculiar effect of introducing rusty material into the cupola. Only one experience of this kind is necessary to convince a foundry-man of the deleterious effect of corroded scrap. The surface-rust on pig-iron is usually not noticeable, but where corrosion has taken place to any considerable depth, a very bad effect is quickly discovered. This is particularly true where light scrap is used, and a large surface has been exposed to the corrosive effect of the atmosphere, in proportion to the small volume. A prominent effect in bad cases of this kind is to make the iron exceedingly dirty and spongy, and when this dirt is noticeable, the cleaner the material introduced into the cupola, the cleaner will be the casting obtained.

Effect of the Blast.—There is scarcely any one factor in cupola-practice deserving of more close and constant attention than the blast. There are reasons to believe it exerts considerable influence in furthering the mutual reactions of the different elements in the metal, but this has not been clearly demonstrated in the tests thus far made. Aside from its effect in this way, increase of blast seems to have a decided tendency to increase the total carbon in the cast-iron, and correspondingly to increase the percentage of graphite. It is not unlikely that when the results of further investigation are known, the amount of air passed through the cupola will be found to condition, to a certain extent, the effect of the metalloids in the iron.

Iron-Mixtures and Iron-Specifications.—An attempt has been made in the foregoing pages to demonstrate that the desire for silicon has been carried to an extreme. This desire has become a mania in some quarters. If the foregoing tables prove anything, they certainly prove that high-silicon irons are, in many cases, a useless luxury. A certain amount of silicon is undoubtedly necessary, but the plan of gaging the value of irons by their content of silicon is but one step in advance of the old fracture-method. The carbon is undoubtedly the governing factor in irons, and the most radical advocate of silicon can do nothing with foundry-mixtures without a certain carbon content. It seems, then, that total carbon is one of the most important elements to specify in purchasing foundry-irons. The writer has yet to meet with an iron too high in carbon to be of excellent use in the foundry. It has been the custom in our practice to specify 3.75% of total carbon in our No. 1 iron, especially when charcoal-irons are purchased, while a very lenient specification is allowed in silicon, it being, for charcoal-iron, not below 1.50%. The furnace man is allowed to have silicon about anywhere he wants it as long as he can furnish iron with the necessary carbon. A minimum graphite specification is also inserted in nearly every case. In the cupola, comparatively little combined carbon is changed to graphite, and this is especially true when the heats are small, and, consequently, the heat developed is not sufficient to produce any marked change in this direction. This fact can easily be demonstrated in practical work, where frequent analyses are made of daily casts, and the compositions of the irons composing the mixture are known.

In these specifications the minimum is specified, and any variation must be above this limit. This is thoroughly practical, and has been in operation long enough commercially to demonstrate its value. It is difficult to get iron merchants to make carbon-determinations, but they will agree to furnish iron under specifications requiring certain minimum limits of total carbon and graphite. Whether the latter is specified or not, there can be no doubt about the necessity of specifying total carbon. Very little attention is paid to silicon in the work, as most of the high-carbon irons will carry sufficient silicon for most classes of work. However, it is often useful to require a certain silicon-content in the iron, so as to get sufficient graphite, as the heat of the blast-furnace is sufficient to enable the silicon to control the graphite to a great extent. In the best snap-flask work, where a large proportion of charcoal iron is used in the mixture, 2% of silicon is found to make elegant castings, and in such mixtures no ferro-silicons are used; but a high-silicon coke-iron, carrying over 3% of silicon and about the same of graphitic carbon, is used. This gives good results, especially where a high grade of machinery-castings and fine snap-flask work are poured from the same mixture. This is further substantiated by analyzing some of the best castings of tools and machines that can be found on the market. Some of the best-known firms making this class of work will be found to be using this variety of iron. With coke-iron it is well to run the silicon a little higher, although for machinery-work it is best not to have it too high.

When trouble is experienced with open or spongy iron, and the trouble cannot be traced to some such cause as rusty scrap, a good procedure is to run the total carbon in the casting as high as possible. This will give a higher content of combined carbon, and at the same time the high content of total carbon, with the graphite, usually increased slightly in this way, will keep the iron soft. When this is done it is well to consider the content of silicon, and if this is much over 2% a decrease will be found beneficial.

The Use of Carbon.—As mentioned in the first portion of this paper, silicon is commonly believed to enable a mixture to carry more scrap. This belief is open to serious doubt. It is obvious that if a mixture is running low in carbon, and ferro-silicon is added in greater amounts to enable the mixture to carry more scrap, this procedure will not only fail to enrich the carbon content, but will actually impoverish it. The reason for this lies in the fact that high-silicon iron carries less graphitic and total carbon than a good scrap, and much less than a good cast-iron. Inasmuch as the iron is dependent upon carbon for its softness, it is open to grave doubt whether, by increasing the silicon, and thereby decreasing the carbon, by adding ferro-silicon, any more scrap can be carried, and the same quality of iron poured from the cupola. The amount of scrap that can be loaded into the cupola without changing the quality of the iron is dependent upon the carbon, and especially upon the graphite. Even if we admit that an increase of silicon can cause an increase of graphite, yet, if there is not sufficient carbon present to be changed into graphite, the graphitic carbon cannot be obtained in the required proportion. Further, when it is doubtful that silicon will cause any appreciable increment in the graphite, it is open to question if the ferro-silicon does not tend to lower the scrap-carrying ability of the mixture.

A high-carbon mixture averaging, for example, 3.10% graphite, and about 2% silicon, will carry considerably more scrap than a mixture containing over 3% silicon, and lower in graphitic carbon, or than a mixture impoverished in total carbon, no matter what the silicon-content. This assertion can be proved in practical work, and it would seem that the popular idea to the contrary is based on a fallacy.

SPECIFICATIONS FOR FOUNDRY CASTINGS.

The specifications for castings adopted by the J. I. Case Threshing Machine Company, of Racine, Wis., are given in the "Iron Age" of Sept. 29. We reprint them in a slightly condensed form below. They will be found to differ in some essential particulars from those given by Mr. Summers in the article printed elsewhere in this issue:

No. 1.—Special Hard Iron. (Close Grained.)

Designed for air and ammonia compressors, high pressure engine cylinders, valves, etc.

Silicon must be between 1.20 and 1.60%. (Below 1.20 the metal will be too hard to machine; above 1.60 it is liable to be porous unless much scrap be used.)

Sulphur not over 0.095%. Any casting showing 0.115 or more of sulphur will be the cause for rejection of the entire mix. (Above 0.115% produces high shrinkage, shortness and "brittle hard" iron.)

Phosphorus below 0.70%, unless specified for special thin castings. (High phosphorus gives brittle castings under impact.)

Manganese not above 0.70%, except in special chilled work.

Transverse breaking strain, with load applied at the center and supports 12 ins. apart, on a square test bar 1 in. square and 13⅓ ins. long, must stand a stress of not less than 2,400 lbs. All bars to be micrometered and figured to an exact square inch.

Deflection not less than 0.08 in.

Shrinkage, measured on a 13⅓-in. bar cast in a yoke, giving chilled ends, must not exceed 0.161 in. after deducting one-tenth, so as to compute the shrinkage in 12 ins.

Chill, measured on the end of a test bar cast in a yoke, not more than 0.25-in., except in chilled work where certain depth is required.

Tensile strength of an extra test bar cast in sand, without the yoke, not less than 22,000 lbs.

The castings must be free from blow holes, slag, dirt, shot, cinder, kish and cold shuts.

A clean, close grained and strong iron is required for this class of work.

The mixture for this iron may be made from charcoal iron, low silicon foundry, home scrap and steel scrap not to exceed 25%, or wrought scrap not to exceed 10%.

Enough scrap should be used so as to keep the graphitic carbon down low enough to produce a close grained iron.

Extra strength and greater chill may be obtained by adding from 1 to 10 lbs. of 80% ferromanganese to every 1,000 lbs. of the charge, but should not be added unless specified.

No. 2.—Medium Iron.

For engine cylinders, gears, pinions, etc.

Silicon to be between 1.40 and 2%. (Silicon 1.50 gives the best wearing result for gears.)

Sulphur not over 0.085%. Any casting showing on analysis 0.095% or more will cause the rejection of the entire mix. (Sulphur preferred at 0.075 to 0.080%.)

Phosphorus below 0.70%, except in special work.

Manganese below 0.70 unless otherwise specified.

Transverse breaking strain, as described under No. 1, not less than 2,200 lbs.

Deflection not less than 0.09-in.

Shrinkage on test bar cast in yoke, not over 0.151-in.

Chill below 0.15-in.

Tensile strength of a test bar cast in sand, above 20,000 lbs.

The iron must be free from blow holes, shrink cavities, slag, kish, shot, cold shuts, blisters, etc.

This mixture may be made with No. 1, 2 or 3 foundry pig, home and foreign scrap. Total scrap should not be over 50%. For safety, in a 50% mix the foreign scrap should be figured at 0.100% of sulphur.

No. 3.—Soft Iron.

For pulleys, small castings and general agricultural implement work.

Silicon not less than 2.20 or more than 2.80%, with a preference for about 2.40. (Below 2.20% small castings will be very hard; above 2.80 large castings will be somewhat weak and have an open grain.

Sulphur in no case over 0.085%. (If above 0.095 the whole lot will be condemned.) High sulphur makes iron "brittle short" and causes excessive shrinkage.

For frictional wear in brake shoes, etc., the sulphur may run up to 0.150%.

Phosphorus below 0.70%, except in cases where great fluidity is required, as in thin stove plate, when it may run up to 1.25%. (Phosphorus makes iron brittle under impact.)

Manganese below 0.70%, except in chilled work. (Manganese toughens iron, produces chill and causes excessive shrinkage.) For a heavy chill the manganese may vary from 0.70 to 1.25%.

Transverse breaking strain not under 2,000 lbs.

Deflection not under 0.10-in.

Shrinkage in no case above 0.141-in., when figured to a 12-in. bar, this being equivalent to ⅛-in. to the foot on castings molded in sand.

Chill should be under 0.05-in.

Tensile strength on a sand cast bar not below 18,000 lbs.

The iron must be free from defects, such as blow holes, shot, blister, cold shuts, slag, shrink cavities, kish, contraction cracks, etc.

Misplaced cores, poor molding and insufficient cleaning will also be cause for rejection.

This mixture may be made from Nos. 1 and 2 foundry pig, home and foreign scrap.

Scrap should be used in sufficient quantity to prevent formation of kish and to obtain the desired strength. It should run from 30 to 50%, being governed by the sulphur. Equal parts or 15% home with 30% foreign scrap is a good proportion to use. Scrap or remelted iron gives strength to castings by reducing the graphitic carbon and closing the grain.

In mixing by analysis it is better to figure foreign scrap at 0.100% sulphur.

When the sulphur in the castings rises above 0.081% the per cent. of scrap should be reduced in the next mix in order to regulate the sulphur. With low sulphur (0.071% about) 50% of scrap may be used.

◆

THE VOLUME INCLOSED BY TWO INTERSECTING CYLINDERS.

Notwithstanding the excessively warm weather of the past summer, a number of our readers sent us solutions to the problem suggested by Mr. Alex. Miller in our issue of Aug. 4, in which the volume included between two cylinders of different diameter intersecting at right angles was desired. These solutions received are of two kinds, the geometrical and the mathematical, the former depending upon scale drawings, developments of the same and the use of the planimeter; the latter using the calculus and winding up in most cases with a long formula in the form of a series. In these each term decreases in value so that all except the first three or four terms may be neglected.

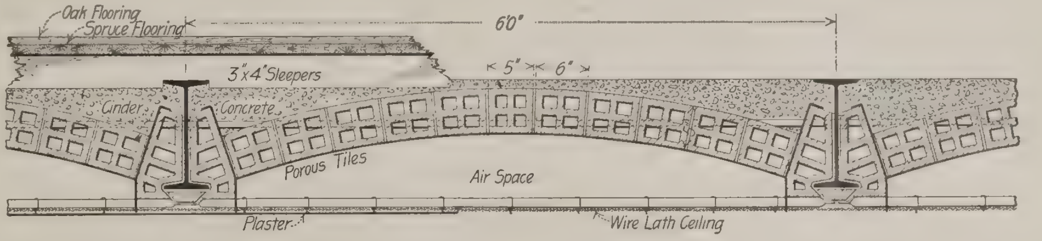
We cannot spare space to give the derivation of the various formulas and the necessary explanation, but we present in the accompanying table the formulas suggested, and the names of their authors. If values are given to (a) and (r) and the formulas tested, it will be found that 4, 5 and 6 agree quite closely. We also received a solution from Mr. Guy P. Burch, of Dubuque, Ia., and Mr. Chas. H. Clark, of Canastota, N. Y.; but as their final formulae contained other quantities than the radii of the two cylinders we do not give them here.

We desire to compliment our correspondents on the industry they have displayed at a season when industry is not popular. We are still inclined to advocate the "solution by water," which we originally suggested, as the coolest way, at least, of solving the problem for a given case.

◆

THE MERRICK FIREPROOF FLOOR.

We illustrate herewith a new form of fireproof floor construction designed by Mr. Ernest Merrick and controlled by the Merrick Fireproofing Co, of 1 Broadway, New York, N. Y. This floor consists of a true curved arch of porous terra-cotta blocks, filled above with cinder concrete, and having a wire-lath ceiling suspended beneath the arch. As will be seen from the illustration, a special skew-back block protects the floor beam, and has suspended from it a metallic hanger which hooks over its top and passes down the joint between the skew-back and the adjacent arch block, with a free end, to which is fastened the metal bars supporting the wire-lath ceiling. The arch is constructed on light portable centers of pressed steel construction, the skew-back blocks being set first and the wire hangers inserted before the arch blocks are set. This construction permits the ceiling bars and wire-lath ceiling to be erected by the plasterers after the centers have been removed and the floor proper has been completed in all other respects. Among the other claims made for the floor, in addition to the cheapness and convenience of the ceiling construction, are the greater strength of the circular arch construction and the especially complete protection of the floor-beam flanges. We are indebted to the Merrick Fireproofing Co. for the information from which this description has been prepared.



THE MERRICK CIRCULAR ARCH, TERRA COTTA FIREPROOF FLOOR WITH SUSPENDED WIRE-LATH CEILING.

The Merrick Fireproofing Co., New York, N. Y.

◆

FIRST ANNUAL CONVENTION OF THE CENTRAL STATES WATER-WORKS ASSOCIATION.

The first annual convention of this association was held at Springfield, O., Sept. 27 to 29. The membership now numbers about a hundred. The number of papers presented was small, partly due to the youth of the organization, which was only started in February of the present year. The membership is divided into two classes, active and associate, and the former are subdivided into resident and non-resident active, on the plan which has been so successfully followed by the New England Water-Works Association. The resident active members are limited geographically to Ohio, Indiana, Michigan, Illinois, Kentucky, West Virginia and Western Pennsylvania, and the place of meeting must be within this territory, a restriction similar to that which the New England Association removed at its last meeting. Thus far nearly the whole membership and all the officers have been from Ohio, due largely, it is presumed, to the fact that the original idea was to form an association of Ohio men alone.

The convention opened Wednesday afternoon with the usual addresses of welcome, the President, Mr. Jerry O'Shaughnessy, of Columbus, O., being in the chair. The report of the Secretary, Mr. John Fisher, of Hamilton, O., showed total receipts of $360, and a balance of $134 in the treasury.

Electrolysis and Quality of Water Supplies.

A paper dealing with these two subjects was presented by Mr. Joseph J. Pater, of Hamilton. He urged that the association should investigate the subject of electrolysis.

TABLE OF FORMULÆ FOR SOLVING THE PROBLEM OF VOLUME INCLOSED BY TWO INTERSECTING CYLINDERS.

Formulæ submitted by	Formulæ a = smaller radius. r = larger radius.
F. W. Salmon, Burlington, Ia.	Lay out to scale on paper; develop intersection of cylinders in a plane; determine area of this figure; multiply by average height obtained with planimeter, as with indicator card.
John Peterson, Montclair, N. J.	Divide upper cylinder into slices by planes intersecting axis of large cylinders, get area of each segment of large cylinder thus formed, and subtract from area of rectangle formed by chord tangent and side of upper cylinder; average the area between adjacent sections and multiply by distance apart. The sum of these products equals volume.
George N. Linday,* Chicago, Ill.	${}^2/_3\, d_0^3$; d_0 being a medium of the diameters if they are nearly alike.
Ward Baldwin,† Cincinnati, O.	$\frac{a^4}{r}\pi\left\{\frac{1}{8}+\frac{1}{64}\left[\frac{a}{r}\right]^2+\frac{5}{4\times256}\left[\frac{a}{r}\right]^4+\frac{35}{64\times256}\left[\frac{a}{r}\right]^6+\frac{147}{256\times256\times2}\left[\frac{a}{r}\right]^8+\text{etc.}\right\}$
L. K. Sherman, Lockport, Ill.	$\frac{4}{5}a^2\left(r-\sqrt{r^2-a^2}\right).$
J. H. Serviss, Closter, N. J.	$4a^2\left[\frac{r}{4}\pi-r+\frac{a^2+r^2}{6r}-\frac{2a^2r^2-a^4-r^4}{40r^3}-\frac{(a^2+r^2)(2a^2r^2-a^4-r^4)}{112r^5}-\frac{4(a^2+r^2)(2a^2r^2-a^4-r^4)-(2a^2r^2-a^4-r^4)^2}{1{,}152r^7}+\ldots\right]$
Charles W. Comstock, Golden, Colo.	$4\pi r a^2\left\{\frac{1}{32}\left[\frac{a}{r}\right]^2+\frac{1}{256}\left[\frac{a}{r}\right]^4+\frac{5}{4{,}096}\left[\frac{a}{r}\right]^6+\frac{35}{65{,}536}\left[\frac{a}{r}\right]^8\ldots\right\}.$
C. F. Peterson, Edge Moor, Del.	$r\,a^2\left\{\pi-\left[\frac{a}{r}\right]^2 0.3955-\left[\frac{a}{r}\right]^4 0.0500-\left[\frac{a}{r}\right]^6 0.0157-\left[\frac{a}{r}\right]^8 0.0069-\ldots\right\}$
S. W. Frescoln, Reading, Pa.	$a^2r\left\{\pi-\frac{1}{30}\left\{97-14\left[\frac{a}{r}\right]^2-3\left[\frac{a}{r}\right]^4\right\}\ldots\right\}.$
Fred'k M. Thomas, Skaneateles, N. Y.	$0.4a^3P\left[1+\frac{P^2}{8}+\frac{5P^4}{128}\right]$ In which $P=\frac{a}{r}$. This is an approximate formula for practical use.
A. N. Talbot,§ Champaign, Ill.	$\frac{\pi}{8}\times\frac{a^4}{r}\left\{1+\frac{1}{8}\left[\frac{a}{r}\right]^2+\frac{5}{128}\left[\frac{a}{r}\right]^4+\frac{35}{2{,}048}\left[\frac{a}{r}\right]^6+\ldots\right\}.$
George R. Dean, Rolla, Mo.	$\frac{\pi a^2 r}{8}\left\{\left[\frac{a}{r}\right]^2+\frac{1}{8}\left[\frac{a}{r}\right]^4+\frac{5}{128}\left[\frac{a}{r}\right]^6+\ldots\right\}.$

---

*1323 Monadnock Block. †University of Cincinnati. §University of Illinois.

The discussion indicated that the subject was new to many of the members, although some pointed out that it had been exhaustively treated before similar societies in past years. A special report on the subject, being a study of the conditions at Dayton, O., by Mr. Harold P. Brown, of New York city, and other experts, was presented in printed form, by Mr. Chas. E. Rowe, of Dayton, and is abstracted at length elsewhere in this issue. Mr. J. R. Cook, of Toledo, said his city was one of the first to have electric railways, but they had never had an instance of injury to the water mains. Great care had been taken so to connect the tracks and the water mains as to maintain a positive current in the latter. Mr. Rowe cited an instance of a cast-iron welded joint where a test showed the rails were not carrying more than 5% of the return current. The subject of electrolysis was referred to the Executive Committee, to report to the next regular meeting, with power to pay the expenses to the next convention of some one who had made a study of the subject and would give them an address.

The other division of Mr. Pater's paper, the quality of water supplies, was designed to awaken the interest of the members in the subject. On request, Mr. B. H. Flynn, an inspector employed by the Ohio State Board of Health, outlined some work he has been doing on stream pollution. He had found that on the Sandusky River, for instance, Crestline, Bucyrus, Upper Sandusky, Tiffin, Fremont and Sandusky, located in the order named, are taking water from the river and discharging it back again as sewage for the towns below to drink.

The Additional Water Supply for Columbus, O.

Mr. O'Shaughnessy described briefly what is being done in his city in this line. About 8,000 ft. of 42-in. perforated cast-iron pipe is to be laid, of which 3,000 ft. is now down, for an infiltration gallery. Near by and connected with this pipe are 18 driven wells, 6 ins. diameter, 75 to 80 ft. deep, and 32 ft. apart. The water in the wells rises to the surface of the ground. The formation here, in a typical section, consists of 12 ft. of clay, 24 ft. of gravel, 6 ft. of boulders, 12 ft. of sand, 8 ft. of blue clay and 8 ft. of yellow clay, below which is rock. The perforated pipe is in the gravel, from 15 to 18 ft. below the surface of the ground. Bids for a concrete dam 52 ft. high, across the Scioto River, were to be received Oct. 3, the site being 5½ miles above the wells. It is thought that the effect of the water stored by the dam will be to keep the water level along the wells more constant than it would be otherwise. If water is taken directly from the river the State Board of Health expects the city to filter it.

Mr. Pater stated that where galvanized iron well points are used the perforations should be made before galvanizing, to prevent them from filling with rust.

The Purity of Public Water Supplies.

This paper was read by Mr. J. J. Hoppes, M. Am| Soc. M. E., of Springfield, O. He referred to the fact that the comparatively few recent deaths from typhoid fever in the army had stirred up the newspapers to much comment and criticism, while they scarcely mention the fact that 40,000 deaths from this disease occur annually in the United States, and many times that number of cases. The last analysis of the water from the filter gallery at Springfield, O., showed only 45 bacteria per cu. cm. He urged the members to work for legislation against the pollution of streams.

Idiosyncracies of Some Water Consumers.

In a very brief paper on this subject Mr. C. W. Wiles, of Delaware, O., cited instances of alleged bad odors in water from certain services, which odors, he said, were really due to bad plumbing in the sinks at which the water was drawn.

Sanitary Sewers and Automatic Flush Tanks.

Mr. H. C. Stilwell, of Marion, O., stated that his company was obliged, by its franchise, to furnish water free of charge for certain public purposes, including 2,500,000 gallons per year for sewer flushing. In 1894 sewers were put in operation, with automatic flush tanks. After a struggle, meters were secured on the services for the tanks. The first year afterwards the city paid nearly $200 for excess flushing water. The next year it kept under the limit. Last year the city began extra cleaning on the sewers, without notifying the company, and for the year used 5,000,000 gallons, or double the amount allowed free of charge. He was convinced that the regulating apparatus of flush tanks is not reliable, and that such devices are a menace to good fire protection.

A member stated that his works supplied 225 flush tanks, it was supposed, through orifices. The consumption running up to a high point, it was found that ½-in. faucets had been put in and were running full stream. On regulating the tanks the consumption fell 500,000 gallons a day.

Repairs to a Submerged River Crossing at Hamilton, O.

This work was briefly described by Mr. John Fisher, of Hamilton, O. On March 23, 1898, a freshet damaged a 20-in. submerged pipe, 600 ft. long. About 100 ft. of the main was undermined and a break occurred. A coffer-dam and centrifugal pumps were used in making the repairs. It was found that there were eight leaky joints, besides the broken ones. The injured portion of the pipe has been protected by piling, cut off at the top line of the pipe. It is proposed to continue this protection across the whole length of the submerged pipe. Calking with cold lead would not stop the leaks, so bands were used in addition.

Mr. J. R. Cook, of Toledo, O., said he had a 16-in. main, 1,300 ft. long, beneath the Maumee River. A leak occurred in 28 ft. of water at a ball and socket joint. Sand blast action made a large hole. A hand-hole plate was used as a temporary repair and a sleeve and lead joint as a permanent repair.

Closing Business.

The following are the principal officers elected for the ensuing year: President, Mr. T. R. Cook, Toledo, O.; Secretary, John Fisher, Hamilton, O.; Treasurer, Chas. E. Rowe, Dayton, O.; Editor, J. J. Pater, Hamilton, O. For the next place of meeting Cincinnati was chosen, it receiving 22 votes, against 15 for Put-in-Bay, O.

Excursions.

Besides several interesting trolley rides, there were excursions to the State Masonic Home, the shops of Warder, Bushnell & Glessner, manufacturers of reapers, binders and mowers, and to the pumping station of the local water-works. A lunch was served at the pumping station by the water department.

An account of the exhibits of water-works appliances will be found under Industrial Notes.

◆

OHIO HAS 1,228 COAL MINES, according to the annual report of Chief Mine inspector R. M. Haseltine. Most of these are small, however, only 413 employing more than ten men. The total production in 1897 was 12,448,822 tons, a decrease of nearly half a million tons over 1896 and 1½ million tons over 1895.

Of the year's coal production 4,106,124 tons were mined by machinery, a gain of 737,775 tons as compared with 1896. 732 hands were engaged in operating the machines, as against 579 in 1896, and there were 5,001 men engaged in blasting down and loading out the coal after being undermined by the machines. Coal is produced by machinery in 53 mines, as compared with 44 during last year. At the close of the year there were 166 electric machines and 67 which used compressed air.

There were 277 casualties reported, of which 40 were fatal, 142 were serious, and 95 were of minor consequence. There were 311,220 tons of coal mined to each life lost, as compared with 314,942 tons during 1896. There were 87,667 tons produced to each serious injury received and 44,841 tons were secured to each casualty that occurred as compared with 64,563 tons during 1896. 35.4% of the accidents were due to falls of roof, 17.3% to falls of coal, 25.3% to contact with mine cars, and 5.8% to premature explosions of powder.

Light carburetted hydrogen gas (fire damp) was present in 34 mines as compared with 38 during 1896, 4 serious and 1 minor accident are reported as emanating from this source.

◆

COTTON PRODUCTION, in the United States, has shown a remarkable increase and a coincidental fall in price. U. S. Treasury statistics show that since 1872 the United States has quadrupled its cotton production, and the price is now about one-fourth of what it was then. In 1872 the cotton crop was 1,384,084,494 lbs., with an average price of 22.19 cts. per pound—with paper money at some discount. In 1898 the crop was 5,667,372,051 lbs., and the average price was 6.23 cts. per pound. Twenty-five years ago the United States produced 70% of the cotton of the world, and now produces 85% of all that is used. The cotton crop of other cotton-producing countries was an average of 1,618,000 bales per year between 1872-78 inclusive, and 1,924,000 bales for the average of the years 1890-97. The price of cotton cloth is also reduced at about the same rate. In 1872 "cotton printed cloth" was quoted at 7.38 cts. per yd.; in 1898 the same grade of goods bring 2.17 cts. per yd.

◆

THE EXPORT TRADE OF THE UNITED STATES, as shown in an article on the world's export trade in the Antwerp "Journal of Maritime Interests," has increased nearly 150% since 1872, and has passed from fourth to the second place in the list of nations. In the interval, 1872-1898, the exports of England increased $207,475,000, while those of the United States gained $620,109,000. France, since 1872, has changed places with the United States, and is now fourth instead of second; she has lost $69,673,000 in this time. Germany holds third place and Russia fifth, with Austria-Hungary and Belgium holding sixth and seventh places. The total amount and relative rank of different nations at the two periods is shown in the following table:

	—Amount of exports.—			Relative rank.	
Countries.	1872.	1896.	Increase.	'72.	'96
England ...	$1,235,200,000	$1,422,000,000	$207,475,000	1	1
United Sta's	430,583,000	1,050,692,000	620,109,000	4	2
Germany ..	559,700,000	994,156,000	384,456,000	3	3
France	726,066,000	656,393,000	*69,673,000	2	4
Russia	270,586,000	513,908,000	261,322,000	5	5
Aust-Hngry	250,900,000	369,016,000	118,116,000	6	6
Belgium ...	193,000,000	283,324,000	90,324,000	7	7

---

*Decrease.

A PROCESS FOR MAKING LEVEL GLASSES which is a decided improvement over old methods is described in "Iron Age" for Sept. 29. This process has been adopted by the Stanley Rule & Level Co., of New Britain, Conn. The level glass is centered properly and brought into contact with a 6-in. cast-iron wheel running at 2,500 revolutions per minute. The wheel has a sharp ridge on its circumference, and the friction between this and the glass melts the glass and small particles of iron are fused into the glass, leaving a sharply defined permanent mark without weakening the glass, as in the ordinary method of marking by scratching.

◆

TESTS OF THE STRENGTH OF FLAT HEADS for cylinders subject to internal pressure were recently made by Prof. C. Bach and reported in the "Zeitschrift des Vereines Deutscher Ingenieure." The heads tested were over 2 ft. diameter. For cast-iron heads the author deduces from his tests the following formula:

$$K_b \geqq 0.8 \left\{ \frac{r}{s} + \left(\frac{a - 0.5\,r\left(1 + \frac{r}{a}\right)}{s} \right)^2 \right\} p.$$

For riveted flanged heads with a good sized radius for the curve at the junction of flange and head he proposes the following:

$$K_b \geqq \left\{ \frac{1}{2}\,\frac{r}{s} + \varphi \left(\frac{a - 0.5\,r\left(1 + \frac{r}{a}\right)}{s} \right)^2 \right\} p.$$

In these formulas—

K_b = assumed working stress for bending.

a = diameter of head in inches.

φ = percentage of elongation of metal in ultimate tensile test.

r = radius of curve at junction of flange and head.

s = thickness of metal in inches.

p = internal pressure on head in pounds per sq. in.

Prof. Bach states that his tests indicate that the strength of flat heads varies not as the thickness, as D. K. Clark supposed, but as the square of the thickness.

◆

RAINFALL IN INDIA is variable. English engineers report as follows concerning the rainfall in the Midnapur and Howrah districts of Lower Bengal: The average annual rainfall in this section is about 70 ins.; but observations made at Ban Kura record a rainfall as follows for the four days ending at 8 a. m. on the dates set down:—

June 16	0.90 ins.	June 18	12.48 ins.
June 17	6.45 "	June 19	2.40 "
Total			22.73 "

◆

THE UTILIZATION OF OLD RAILS in railway track is a very important matter, in order to increase the service life of the rails and several methods have been tried to make old rails again available for use in the main track. Many rails are removed from the track on account of worn, battered or depressed ends, and the Holland Co., of Pittsburg, Pa., has a plant for cutting off the ends and re-drilling the rails. A sufficient length is cut off to remove any marking due to the old splice bars, so as to get a good bearing for the new bars. The rails are calipered and arranged in regard to height, being graded to 1-32-in. in height, so that they go together well in the track. This method was described in our issue of Aug. 18 (p. 102). Rails which have been in service for 15 years have been treated in this way and put back in the main track. The plant has a capacity of 200 tons per day, and the company has several contracts on hand. The Holland Co. also re-rolls old rails to smaller sizes. This practice was introduced a few years ago by the McKenna Rail Re-Rolling Co., of Joliet, Ill., which has treated large quantities of rails.

BOOK REVIEWS.

CAMBRIA STEEL.—A Handbook of Information Relating to Structural Steel, Containing Tables, Rules and Formulas for the Use of Engineers and Architects. Cambria Iron Co., Johnstown, Pa. Leather; 4½ × 7 ins.; pp. 350; illustrated; $2.

This is the fourth edition of the Cambria Iron Co.'s pocket-book, and it shows considerable improvement over preceding editions. In place of the tables of weights and dimensions of the earlier editions it includes plates of sections, complete tables of weights, dimensions and properties of the principal structural shapes manufactured by the company, together with numerous tables and formulas useful to the structural engineer. It is stated that the tables pertaining to structural shapes were especially prepared for this edition. Those giving the properties of I-beams, channels and angles, safe loads of channels and I-beams and spacing I-beams are given in detail for each section, so that the required information can be obtained without interpolation. The various mathematical tables, formulas and other information have been compiled from authentic sources and revised and corrected to bring the information up to date. Altogether the book is very creditable in contents and make-up, and every engineer having structural work in charge can profitably add it to his list of manufacturer's pocket-books. A good index is provided.

OUTLINES OF PRACTICAL HYGIENE.—By C. Gilman Currier, M. D., Assoc. Am. Soc. C. E., Fellow of the New York Academy of Medicine, etc. Third edition, revised and enlarged. New York: E. B. Treat & Co., 242 West 23d St. Cloth; 6 × 8 ins.; pp. 461; 86 illustrations; $2.

This book treats a great range of subjects, and on the whole in a very satisfactory manner, considering the necessary limitations of space. The principles laid down seem to be well in accord with the best ideas and practice. The greatest faults of the book seem to be the failure, in the latest revision, to bring some of the sections wholly up to date. Thus, under garbage disposal, no mention is made of utilization or reduction processes, which have been prominently before the public of late and deserve some words both of praise and caution. Under water, more might well have been said regarding mechanical filtration, while it would help many readers to know that slow sand filtration is now being used in this country with notable success at a number of places. Besides the subjects already indicated the book discusses soil, climate, clothing, bathing, diet, exercise, lighting, heating, ventilation, plumbing, infectious diseases, disinfection, and many other vital matters affecting the health of the individual and the community.

EXPERIMENTAL MECHANICS.—Tests and Experiments made by the Class of '99 of the Stevens Institute of Technology during the Supplementary Term, June and July, 1898. By D. S. Jacobus, M. E., Professor of Experimental Mechanics and Engineering Physics, Stevens Institute of Technology, Hoboken, N. J. Press of the Stevens Indicator. 8vo.; cloth; pp. 67, with blank pages for notes. $1.50.

This book was printed for the use of one class in the Stevens Institute, but we understand that a few copies are for sale. It consists of brief directions for making tests, formulae for calculating results, and tables to be filled out by the students when the tests are completed. The preface states that experience has shown it to be necessary to modify from year to year, tables and directions such as those given, and it has been decided, therefore, not to issue a number of books to be used by succeeding classes, but only enough for one class each year, so that any desired changes may be made. The tests, concerning which directions are given, all of which with many others are required to be made, comprise tests of two steam boilers, of a condensing engine with independent vacuum pump and with a jet condenser, of a compound engine, of a simple non-condensing engine, of a rotary engine, of a steam turbine, of a gas engine connected direct to a dynamo, of a hot-air engine, of a steam pump, of a centrifugal pump, of ejectors and injectors, of air-compressors, fans and blowers of different kinds, of dynamo meters, of a water wheel, flow of water, and of steam in pipes, of lubricating oils, of a steam radiator, of non-conducting coverings, etc.

A large number of blank pages are bound in the book for additional notes and sketches. We commend the idea of this little book to the professors of mechanical engineering in other technical schools. It is the result of many years of experience in testing work in Stevens Institute.

THE NEW ROADMASTER'S ASSISTANT.—A Manual of Reference for those having to do with American Railroads. By George Hebard Paine. New York: "The Railroad Gazette." Limp cloth; 4¾ × 7¼ ins.; pp. 253; illustrations, 259. Price, $1.50.

This book is the successor to the "Roadmaster's Assistant," written by William C. Huntington in 1871 and revised by the late Charles Latimer in 1877. The arrangement and treatment of the subjects follow mainly upon the lines of the former work, but while the new book is more comprehensive than the old one, it is much less thorough, the style being general and brief rather than detailed. This is necessary in view of the variety of subjects included in this small book, but it is in many cases unsatisfactory, as it allows of but very little information being given on any one subject. As an example, the man looking for information as to the once much discussed "miter joint" for rails, finds only a diagram plan which "shows what is called the mitered end, a plan that has been largely followed on the Lehigh Valley R. R." There is no reference to the merits or demerits of, or the results of experience with, this joint, and as a matter of fact the Lehigh Valley R. R. some years ago abandoned the use of this joint. In the same way frogs are disposed of in a little more than one page of type, and the brief description of the automatic switchstand states that if the switch is "set wrong it will be thrown by the train itself whether going over the main track or side track route." This might be understood to mean that a train approaching the toe of a misplaced switch will throw the switch right, which is, of course, incorrect. The book nevertheless contains a considerable amount of information and is a useful addition to modern literature on railway track. It is well printed in large type, but considerable space is wasted by wide margins with unnecessary marginal paragraph headings.

PRISMOIDAL FORMULÆ AND EARTHWORK.—By Thos. U. Taylor, C. E., University of Va.; M. C. E., Cornell University; Assoc. M. Am. Soc. C. E. John Wiley & Sons, New York. Cloth, 9 × 5½ ins.; pp. 102; diagrams. $1.50.

This is not a book of earthwork tables, but an historical and practical treatise on prismoidal formulæ and their application to earthwork under many varying conditions of surface. Mr. Taylor, in Chapter I., takes up the formulæ of Newton, Hirsch, Koppe and Kinklin, proves and extends them and shows their limitations. He proposes no new formula, but points out that the term "prismoidal formula" is misleading, inasmuch as in another chapter on two-term formulæ he shows that there are an infinite number of formulæ more characteristic of the prismoid than that formulated by Newton. But the rules of Newton and Kinklin apply to the prismatoid and cylindroid, and they will thus apply with exactness to all forms of earthwork that fall in the class of ruled surfaces. As the burden of the work of finding the volume of earthwork cuts or fills consists in obtaining the areas of cross-sections, Mr. Taylor devotes himself to developing methods by which these areas can be found correctly, and with the least labor. To this end he explains the construction of a diagram which applies to all three-level sections and renders the work easy. He illustrates this by a number of problems worked out, including five-level, or very irregular surface sections, borrow-pits, etc. The cost of earthwork is discussed, chiefly based upon data taken from Trautwine; and included in this section are drag and scraper work, steam-shovel work, overhaul, etc. In another chapter he treats of correction for curvature, giving also Rankine's and Henck's methods. He concludes with the chapter on two-term formulæ, before referred to. The treatment of this subject is necessarily mathematical; but it is simple in form and easily understood, and according to the bibliography appended, on both the prismoid and earthwork, Mr. Taylor gives us a very complete and satisfactory resume of all authorities.

AMERICAN CEMENTS. — By Uriah Cummings. Boston: Rogers & Manson. Cloth; 6 × 8½ ins.; pp. 299; illustrated; $3.

In his preface the author of this book, who by the way is a manufacturer of natural cement, states that the chief motive which has animated the work "has been a desire to an adequate consideration paid to the claims and merits of American rock cements." In this connection he says:

> It has always seemed to the writer that scant justice has been done to natural hydraulic cements and that the tendency to regard artificial products as, in some mysterious manner, much superior to all others has no sufficient justification in the facts of the case, and that when all the evidence is heard it will be found and conceded, that for enduring qualities, for excellence in places of trial, for permanence and for worth, no artificially made cement can be found to compare with that mixed in the molds of nature.

As the author, on p. 192, states that what he should consider an ideal cement would

> consist in a selection of the raw materials which were found to be best adopted for the purpose (especial care being taken at least as to the quality of the clay) and then to be thoroughly and finally commingled in correct proportions, then calcined to a mild clinker, sufficiently vitrified to produce a medium weight, and then ground exceedingly fine.

It is evident that he refers in his prefatory statement to artificial cements as they are generally made and not to such cements as they might or should be made. In a word, the gist of the author's argument throughout the book is that the modern methods of Portland cement manufacture which produce a high short-time testing product are entirely faulty. That he succeeds in proving this is perhaps doubtful, but he at least presents evidence strong enough to be worth pretty careful study, and any cement user trained in modern doctrines in this matter will do well to read Chapters III., IV., VI. and VII. of this book. Outside of these chapters the book is not to be extravagantly commended, to say the least, and in some parts reads much like a trade catalogue. With these parts improved or cut out entirely and the really important chapters written in a more temperate tone the author's argument would have carried much more conviction to his readers than it is likely to do with the book in its present shape.

AMERICAN STREET RAILWAY INVESTMENTS.—A Supplement to the Street Railway Journal. Published annually for the use of bankers, brokers, capitalists, investors and street railway companies. 1898. The Street Railway Pub. Co., Havermeyer Building, New York. Cloth; 12¾ × 9½ ins.; pp. 279; maps. $3.

This excellent publication adds several new features to its annual exhibit of the mileage, equipment and financial condition of the street railways throughout the United States and Canada. The preface makes a comparison of gross receipts in 1896 and 1897 that has a general interest. According to this statement, 26 properties earned over $1,000,000 each in 1897; 19 earned from $500,000 to $1,000,000; 46 properties earned from $100,000 to $500,000; 51 earned from $50,000 to $100,000, and 33 properties earned from $25,000 to $50,000. In the first group the average rate of increase over 1896 was 2.20%; in the second group there was a decrease of earnings amounting to 0.11%; in the third an increase of 1.87%; in the fourth an increase of 1.61%, and in the fifth group the average decrease was 0.67%. This table rates 175 properties in all, and the total receipts from these were $113,394,903, with 75.2% of this amount credited to the 26 companies in the first group. The proportionate receipts of the other groups respectively were 11.3, 9.4, 3.0 and 1.1%. The gross receipts of the 175 companies in 1897 were 1.9% higher than in 1896. The various street railway companies are then taken up in alphabetical order; and in every case, where accessible, the statement covers the population in 1880, 1890 and 1896; date of charter or consolidation; plant and equipment at latest possible date; capital stock, funded debt, liabilities and earnings and operating expenses; officers of the road, etc. A new and useful feature is the presentation in tabular form of operating expenses and receipts and a balance sheet for four or five years past. This table enables comparisons to be made without referring to previous issues of the annual. There is also an increased number of excellent maps showing the street railways of principal cities throughout the United States.

SOME COMMON ERRORS IN IRON BRIDGE DESIGN.—By W. C. Kernot, Professor of Engineering, Melbourne University. Ford & Son. Melbourne, Australia. Cloth; 6 × 9 ins.; pp. 49; illustrated.

The trite saying that an engineer learns more from his failures than from his successes receives considerable substantiation from this little volume, in which Prof. Kernot has collected and analyzed something over a score of the most common errors made in designing iron and steel bridges. These errors are considered by the author under the following headings: Disproportion of Foundation Area to Load Carried; Excessive and Disproportionate Size of Columns; Girders Supported in an Unfavorable Manner; Imperfect Expansion Apparatus; Insufficient Depth of Girders; Unfavorable Disposition of Material for Enduring Bending Moment; Insufficient Connection Between Chord and Web; Vertical Stiffeners Absent or Wrongly Placed; Incomplete Triangulation; Redundancy; Curvatures of Members; Eccentricity; Unscientific and Wasteful End Pillars; Unduly Numerous Systems of Triangulation; Inefficient Forms of Compression Members; Imperfect Joining of Tension Members; Local Weakness at Intersection of Web Members; Arrangements Involving Serious Secondary Stresses; Arrangements Involving Severe Temperature Stresses; Insufficient Lateral Bracing; Cross Girders Not Placed in Proper Relation to the Web System of Main Girders; Improperly Designed Cross Girders; Unscientific Forms of Footpath Brackets; Faulty Parapets.

In each of these cases the author defines the error in a general way, then follows by quoting and describing several actual examples in which it occurs, and, finally, points out the best method of remedying or avoiding it. Generally the examples selected are legitimate ones and the criticism is well taken, and if once in a while the author dwells upon errors of old practice now generally avoided or selects cases which are purely local it does not come at all amiss to remind engineers that they are examples to be avoided. It will repay bridge engineers to obtain and read this book to refresh their memories concerning some of the errors which have been made in the past, and which are to be avoided in the future.

A POCKET-BOOK FOR MECHANICAL ENGINEERS.—By David Allan Low, M. I. Mech. E., Professor of Engineering, East London Technical College (People's Palace), London. With over 1,000 illustrations. Longmans, Green & Co., London, New York and Bombay. Cloth; 4¼ × 6⅝ ins.; pp. 740. $2.50

This new addition to the long list of "pocket-books" for engineers is a very creditable production. It differs from all other recent books of its class in the great number of its illustrations, and in the unusual amount of space given to details of design of power transmission appliances, such as pillow blocks, hangers, keys, pulleys, etc. We notice, for example, two pages of illustrations of different styles of lock nuts, a page of spanners or wrenches, with proportions of sizes, a page of wire rope fastenings, 2½ pages of details of connection of iron or steel roof trusses, two pages of types of cross-heads, etc. Over a dozen forms of steam boilers are illustrated, more than 20 pages being devoted to them, including their descriptions and lists of sizes. The most notable differences between this pocket-book and the American books of Trautwein, Haswell and Kent, are the large proportion of space given to illustrations, the smaller size, the smaller number of pages and the larger type used. The book, therefore, contains probably less than one-third of the amount of text that is given in either of the other books named. The subjects treated and the amount of space given to each are approximately as follows: Mathematical tables, weights and measures, notes on geometry, algebraic and trigonometrical formulae, etc., 203 pages, of which about 25 are devoted to tables of comparison of Metric and British measures. Center of gravity and moments of inertia, 14 pages. Statics, kinetics, friction, efficiency of machines, etc., 28 pages. Sizes, weights and strength of materials, 98 pages. Stress diagrams for framed structures, 17 pages. Screws, bolts, nuts, keys, cotters, pipes and pipe joints, 25 pages. Shafting, coupling, bearings, 32 pages. Belt, rope, friction, and toothed gearings, and wire rope transmission, 36 pages. Cranks, eccentrics, connecting rods, cross-heads, pistons, stuffing boxes, valves, 31 pages. Heat, combustion, fuel, properties of steam, factors of evaporation, 37 pages. Steam boilers, riveted joints, boiler details, 62 pages. Steam engines, 43 pages. Locomotives, permanent way, 49 pages. Gas and oil engines, 19 pages. Compressed air, hydraulic transmission of power, hydraulics, 25 pages. Miscellaneous notes and data, 8 pages. Index, 18 pages.

The author states in his preface that the preparation of the work has occupied the whole of his spare time during the past five years, and he has had the services of several assistants in the calculation of tables and the preparation of the illustrations. The older tables have been checked by comparing them with those given by the best authorities, English, American and German. So far as we have been able to examine it, the work seems to have been exceedingly well done. Since the book contains so much less matter than the standard American works of its class, it can by no means be considered as a substitute for them, but since it contains much matter which they have omitted, chiefly in relation to details of design, such as are found in works on machine design, it may prove to be a useful companion to them.

RESERVOIR SITES IN WYOMING AND COLORADO.—Report from Capt. H. M. Chittenden of a Preliminary Examination Made by Him of Certain Reservoir Sites in the States of Wyoming and Colorado. House of Representatives, Document No. 141. Paper; 6 × 9 ins.; pp. 110; illustrated. Address Members of Congress or the author, care of Missouri River Commission, 1515 Locust St., St. Louis, Mo.

This investigation originated in an appropriation of $5,000 in the River and Harbor bill of June 3, 1896:

> For the examination of sites and report upon the practicability and desirability of constructing reservoirs and other hydraulic works necessary for the storage and utilization of water, to prevent floods and overflows, erosion of river banks and breaks of levees, and to re-enforce the flow of streams during drought and low-water seasons, at least one site each in the states of Wyoming and Colorado.

The report discusses briefly but quite comprehensively the various phases of water storage and stream flow regulation mentioned in the above quotation, reviewing some classic French studies of flood prevention made in the middle of this century and giving especial attention to the storage of water for irrigation. Among the appendices to the volume is a monograph by Mr. Jas. A. Seddon, Assistant Engineer, "On Reservoirs and Their Effects on the Floods of the Mississippi System." Sites for five reservoir systems, including seven reservoirs, were surveyed under Captain Chittenden's direction, and estimates of their cost were made and are included in the report. Three of these systems are in Wyoming, the Laramie, Sweetwater and Piney Creek systems, and two in Colorado, the South Platte and Loveland systems. The character of the dams recommended are straight and curved masonry, and combined rock-fill and earth structures. The primary function of these reservoirs would be the storage of water for irrigation and power. Possibly they would also alleviate flood conditions in the rivers. Captain Chittenden is convinced that the cost of a reservoir system for the Mississippi large enough to materially diminish the height of floods would be too great to warrant the expenditure, "unless it is called for by other and more direct causes." He is strongly of the opinion that reservoir construction is essential to the wisest development of the arid West, and that it should be carried out by the general government, which should control all the water rights involved and own and operate the reservoirs, holding "the stored waters absolutely free to public use under local regulations, subject only to the right to close the reservoir whenever flood protection or other emergency should require."

The report is illustrated by good half-tone reproductions of a number of handsome photographic views of reservoir sites, by several diagrams, and by seven large folding maps of the reservoir sites examined.

FORESTRY CONDITIONS AND INTERESTS OF WISCONSIN.—By Filibert Roth, Special Agent. With a discussion by B. E. Fernow, Chief of the Division of Forestry, U. S. Department of Agriculture, Washington, D. C. Paper; 9 × 6 ins.; pp. 76; map.

In an introduction, Mr. Fernow describes the object of and the methods followed in ascertaining forest conditions; while Mr. Roth enters into the detail of the investigation, by counties, and describes the principal timber growing in Wisconsin. A summary of Mr. Roth's report shows that Wisconsin, with a population of 2,000,000 and taxable property worth about $600,000,000, annually consumes over 600,000,000 ft. B. M. of lumber, besides enormous quantities of other wood materials. In the northern part of the state, with a land surface of more than 18,000,000 acres, only 7% is under cultivation, and the rest is a continuous body of forest and waste land. From this area in the last 60 years over 85,000,000,000 ft. B. M. of pine lumber alone has been cut, with an annual average of 3,000,000,000 ft. for the last ten years. The lumber industries of the state employ 55,000 men, receiving $15,000,000 in wages per year, and the value of the product is $35,000,000; to this $25,000,000 more must be added as coming from wood manufactories. The standing timber is estimated as follows: Of pine, 17,000 million feet; hemlock, 12,000 million feet; hardwoods, 16,000 million feet; the present annual growth amounts to about 900 million feet, of which only 250 million feet is marketable pine, and this growth is largely balanced by natural decay in over-ripe timber. At present nothing is being done to restock 8,000,000 acres of "cut-over" land, and Mr. Fernow recommends that the state of Wisconsin in its own interest, establish a permanent forestry commission, and control the manner of exploiting forests under state ownership.

NOUVEAU TRAITE DES BICYCLES ET BICYCLETTES.—Equilibre et Direction; Le Travail. Par C. Bourlet, Docteur Es-sciences Mathematiques, Etc. Encyclopedie Scientifique des Aide—Memoire. Second edition. Paris: Gauthier-Villars et Fils. Two volumes. Paper; 7½ × 4⅝ ins.; pp. 180, and pp. 186; illustrated.

The first edition of these two volumes on the design of and the work done by bicycles was published in 1895; but the rapid development and radical changes made in these machines render a new edition necessary. Mr. Bourlet calls those machines bicycles which have the motor wheel in front, and is thus at the same time a motor and a directing wheel; and terms those having the motor wheel behind, bicyclettes. In succeeding chapters of the volume on "Equilibrium and Direction," he treats of the trajectories of the two wheels, the analytical conditions of equilibrium upon the level and upon inclined ground, or the security of the machine; and finally discusses effects of a change in direction. In this volume he devotes a chapter to the construction of bicycle race-tracks. He handles this from a mathematical and a practical point of view, and discusses gradients and curves for semicircular, elliptical and parabolic tracks.

The second volume, that on "Le Travail," is devoted to a mathematical discussion of the resistances to be overcome by the cyclist, or the friction in transmitting gear, the rolling friction, resistance of the air, etc. A chapter is also given upon the measure of work performed on the level and on grades, by the pedal, etc., and the influence of weight. The final chapter is upon the product of work; a study of pedal and crank pressure and the choice of gear. In the latter connection he argues that the maximum work, under the best conditions, is obtained with 115 revolutions of the crank per minute. Mr. Boulet compares the work done by a pedestrian and by a cyclist and concludes with a number of tables giving air-resistances at various speeds; the resistance and work performed at varying speed on a level or an inclined road, on the race track and on a mountainous route. The two works combined are a careful mathematical and theoretical discussion of bicycle design and operation.

MECHANICAL HEATING AND VENTILATION.—An Exhaustive Analysis of All Systems. Second edition. By M. C. Huyett, Heating and Ventilating Engineer, 66 Piquette Ave., Detroit, Mich. 8vo.; morocco; pp. 155; $3.50.

The author of this work is a man with a grievance—several grievances, in fact—and therefore his book is forcible and interesting, although his style is not above criticism, and his statements sometimes lack in technical precision. His two chief grievances are that "text-books, so called," do not give the kind of information concerning heating and ventilation that he thinks they should give, and that manufacturers of fan blowers tell falsehoods in their catalogues concerning the capacity of their fans and the horse-power required to drive them. The book is addressed "To Architects," and he tells them

> The following pages present the essentials of heating and ventilation; the tables are original and are given to aid in the development of your part of plans on a scientific basis. It is information which has been withheld by manufacturers and engineers.

A sample of the author's method of treating technical questions is the following. On p. 13 he says:

> The subject has been treated from a theoretical standpoint by most writers; in no "text-book," so called, can anything be found helpful or even suggestive which will aid architects in proportioning flue areas required for heating and ventilation.

This certainly encourages us to hope that in this book at least something helpful and suggestive on the subject will be found, and here it is on p. 25, under the heading, "Proportioning Areas of Heat Risers and Ventilating Flues."

> Conditions are seldom alike, consequently no iron-clad rule can be stated for initial velocities. The judgment of a heating and ventilating engineer, based on practical experience, is the ony safe guide. Velocities must base on size and exposure of rooms, kind of occupancy, and location and distribution of displacement openings.

Then follows a "rule for computing pipe and riser areas for heating and ventilation based on changing air times per hour," given in a most complicated form, but which may be translated into a simple form as follows: Multiply the capacity of the room in cubic feet by the number of times the air is to be changed in an hour; divide the product by the velocity the air is to have in the flue in feet per second, and the result will be the area of the flue in square feet. Following this are several pages of tables of figures giving flue areas for different capacities of rooms and different velocities of air.

With all this how much has the architect learned that is helpful or suggestive in proportioning flue areas? Why, simply that he must first call in a heating and ventilating engineer of practical experience who will use his "judgment" in determining the number of times the air should be changed and the velocity to be given the air in the flue, and then with these data given he may by reference to Mr. Huyett's tables and rules compute the area required. There is not a word in the book so far as we can find by means of which a student of the subject of heating and ventilation may arrive at a "judgment" as to the velocity, or by which he may check the "judgment" of the "practical man."

Mr. Huyett's criticism of the fan manufacturers for publishing false information in their catalogues is no doubt deserved. He gives examples from the lists of four makers whom he calls A, B, C and D, showing that the actual capacity of their fans is only about half, and in some cases less than half of that claimed, and that the horse-power required to drive them at the stated number of revolutions is often understated by about half. A disk fan rated at 25,000 cu. ft. per minute was found by anemometer test to deliver less than 7,000 cu. ft. He has done a public service in thus protesting against this evil, and it is to be hoped that fan manufacturers will pay attention to it and mend their ways.

The book contains some good suggestions in regard to specifications for heating and ventilating apparatus, from which we quote the following:

> Any seller who fails to specify the actual quantity of 1-in. steam pipe, diameter of fan wheel, and its width at the periphery, r. p. m. and speed of engine, does so with the intent to get a contract that shall be definitely indefinite—except they hedge behind "we are responsible" and "we guarantee." Responsibility and guarantee never yet warmed and ventilated a building. That requires a definite quantity of steam pipe and volume of air contact therewith.

NORTHWARD OVER THE "GREAT ICE." A Narrative of Life and Work Along the Shores and Upon the Interior Ice-Cap of Northern Greenland in the Years 1886 and 1891-1897. With a Description of the Little Tribe of Smith Sound Eskimos, the Most Northerly Human Beings in the World, and an Account of the Discovery and Bringing Home of the "Saviksue," or Great Cape York Meteorite.—By Robert E. Peary, Civil Engineer, U.S.N., M. Am. Soc. C. E., M. Am. Geographical Society. With maps, diagrams and about 800 illustrations. In two volumes. Frederick A. Stokes Co., New York. Cloth, 9 × 6¾ ins.; pp. 520 and 625.

This story of adventure and discovery in North Greenland is remarkable among narratives of its kind, as illustrating what one man can do,almost unaided by others, in extending our common knowledge of geography, and of a remote and peculiar people. Though Mr. Peary has devoted twelve years of his life to Arctic explorations, has made six expeditions to the North, and for nearly four years of that time remained within the Arctic Circle, the government has never appropriated, nor been asked to appropriate one dollar towards this purpose, nor has any scientific or geographical society, as a body, provided funds for furthering his efforts. Fully two-thirds of all the money expended has been earned by Mr. Peary and by his wife, by lectures and publications issued. Some few individuals have been generous in their personal contributions, though none of these latter exceeded $1,000, except the aid extended by Mr. Morris K. Jesup, in assisting to send a ship after Mr. Peary in 1895. Mr. Peary, evidently, did not propose to be open to the charge of "wasting other people's money on useless Arctic exploration," and he reduced the risk of human life to a minimum, the chief risk being to himself.

In the introduction to this work, Mr. Peary gives full credit by name to those who assisted him in his efforts, describes his outfit, and gives a sketch of those who accompanied him to the North. He then takes up in detail his several expeditions, from the reconnoissance of 1886 to his latest voyage. In the first volume the chief interest centers upon his 1,200-mile march across the Greenland ice-cap to Independence Bay and back, with but one companion—the faithful Eivind Astrup. Aside from the details of camp-life and the experiences on the ice-cap and the rocky moraines, very considerable information is given relating to the geological structure of the region visited, and to the peculiar Smith Sound tribe of Eskimos and their manners and customs. The many illustrations are chiefly reproduced direct from photographs, and in their way tell a graphic story of the difficulties encountered and surmounted and the curious and interesting people met with.

The second volume is devoted to the North-Greenland expedition of 1893-94, and 1894-95, and to the summer voyage of 1896-97 after the Cape York meteorites. Here again we have detail, but very interesting detail, of the almost daily doings of the party in building and fitting out their winter home, in passing the weary winter in preparing for the long marches across the ice-cap and in actually making the several journeys towards the North. This part must be read to be appreciated as no abstract will do justice to the strange conditions encountered.

Mr. Peary gives a detailed history of the Cape York meteorites, of exceptional size, purity and homogeneous composition. He traces this history to 1818, when Captain Ross found the natives in possession of rude implements edged with iron which they said came from an "iron mountain" near Cape York. Various expeditions sought this iron mountain, but it remained for Mr. Peary to discover the true source of these nickel-alloyed fragments of iron. Having gained the confidence of the Eskimos, in 1894, he was led to the long-sought-for "mine" and found it to be three great masses of true meteoric iron, the "Woman," the "Dog," and the "Tent," as the natives termed them. The first named weighed 5,500 lbs., and this was secured in 1895 after much trouble in getting it aboard the "Kite," and it and the "Dog," a smaller mass of 1,000 lbs., were transported to New York. The great meteoric stone, the "Ahnighito," or the "Tent," was partly removed from its bed in 1896 and finally secured in 1897. This mass, the largest of the meteorites, was irregular in shape and had a maximum length of 11.2 ft., a maximum width of 7.6 ft., and a maximum thickness of 6 ft.; its estimated weight is between 90 and 100 tons. Etchings show the characteristic Widenannstätten figures, and analyses show the typical meteoric nickel-steel alloy of about 92% iron and 8% nickel. Final analyses of the three masses indicate that they were three fragments of one original mass. In answer to objections made that the specimens obtained were not of meteoric origin, Mr. Peary produces certificates from three of the highest authorities upon this branch of mineralogy—Prof. L. Hetcher, of the British Museum; Dr. E. A. Weinschenk, of the Institute of Minerals of Munich, and Professor Bezina, Director of the Natural History Museum of Vienna. The book itself is handsome in appearance and it includes a map of the Arctic regions, showing the most recent explorations of Robert E. Peary, Fridtjof Nansen and F. Jackson; the map being made by Prof. Angelo Heilprin, who accompanied Mr. Peary.

Duty Record of the Indianapolis Pumping Engine.

THE MATTER OF WATER FILTRATION AT PHILAdelphia was referred to Mr. John C. Trautwine, Assoc. Am. Soc. C. E., Chief of the Bureau of Water, on Aug. 3, requesting that by Sept. 1, or in just four weeks, he submit plans and estimates for the "filtration of all the water used by the city." Mr. Trautwine submitted his report to Mr. Thos. M. Thompson, Director of Public Works, on Sept. 9, and the report has just been made public. The report first mentions the inadequacy of the time available for its preparation, and states that on that account no general plan can be recommended for adoption. In deference to the wishes of Mr. Thompson and Mayor Warwick the estimates are based mostly upon slow sand filtration, with suggestions for mechanical filtration at one station. Owing to the vast amount of water wasted in Philadelphia, two sets of estimates are submitted, one for water used, and the other for water used and wasted, both in the year 1900, the quantities per capita being 100 and 300 gallons, respectively. The figures for construction and operation are as follows:

Cost of Installation.

	For water used in 1900.	For water used and wasted in 1900.
Filtration plant	$2,398,500	$7,195,500
Real estate	100,000	300,000
Meters, $500,000 to..............	1,000,000	0
Total incidental to filtration......	$3,498,500	$7,495,500
Immediate requirements for other extensions and improvements...	1,107,000	5,014,000
Total	$4,605,500*	$12,509,500†

Annual Expense of Operation.‡

Filtration plants	$200,000	$600,000
Meters	90,000	0
Total annual additional expense.	$290,000	$600,000

*This would give an ample supply of filtered water for the entire city in 1900, and a surplus of pumping capacity of about 100%.

†This would furnish sufficient water (filtered) to meet the demands of the year 1900, but without surplus capacity.

‡This, in the case of water used, would undoubtedly be more than covered by the reduction due to restriction of waste.

The report also includes an estimate for the cost of mechanical filters for the whole supply, submitted by the New York Filter Manufacturing Co. These figures were $2,052,387 and $6,149,849, respectively, for water used and for water used and wasted in 1900, the total daily quantities in each case being 130,000,000 and 390,000,000 gallons, as in the estimate for slow sand filtration. In conclusion, Mr. Trautwine strongly urges that no measures be adopted for the filtration of the whole supply until a filter plant large enough to supply a whole district has been built and operated. He recommended the appropriation of $300,000 for the restriction of waste and a filter plant for the Roxborough district, and that experts be appointed to co-operate in the design of the plant. The information given has been taken from an authorized abstract of Mr. Trautwine's report. Unofficial abstracts of the report of Mr. Thompson indicate that he favors the immediate construction of filtration plants to the extent that the money available will allow, recommending slow sand filtration at Lardner's Point, on the Delaware River, and at Belmont, on the Schuylkill River. Regarding the restriction of waste, Mr. Thompson is reported as saying in one place that he is in favor "of increasing our facilities to supply a greater abundance of water," and in another, "the adoption of such legislation as may result in the curtailment of the excessive waste of water."

THE COVERING OF THE FILTER BED connected with the water-works of Lawrence, Mass., has been recommended by the Massachusetts State Board of Health. This is deemed necessary to prevent the formation of ice on the bed and insure the proper working of the filter and the ability to clean it in winter.

◆

PROGRESS ON THE CLEVELAND WATER-WORKS tunnel, described in our issue of Aug. 11, 1898, has been as follows, up to Oct. 1: The steel intake crib has been brought to within 0.11-ft. of a level position, the steel work is nearly finished, ready to begin on the parapet, and the work of filling the crib with stone is in progress. As an additional protection against floating ice a belt of concrete 4 ft. wide and 8 ft. high, 4 ft. above and 4 ft. below the water line, is being placed on the inside of the crib. Shaft No. 3, in which there has been trouble with water, has been sunk to its full depth, and 14 ft. of tunnel driven. After having been shut down several weeks for repairs to the contractor's plant, it was proposed to pump out the shaft early this month and calk leaks preparatory to going on with the headings. From Shaft No. 2 there has been completed 2,024 ft. of tunnel in the East drift and 2,056 in the West. From the shore shaft, or No. 1, no work has been done since the second explosion, last July. The contractors talk of finishing the remaining tunnel between shafts Nos. 1 and 2 entirely from Shaft No. 2, but the matter has not been decided. These facts were obtained by a representative of this journal, while in Cleveland, from Mr. M. W. Kingsley, M. Am. Soc. C. E., Chief Engineer of the work, and Mr. C. F. Schulz, First Assistant Engineer.

◆

THE ABOLITION OF GRADE CROSSINGS in Newton, Mass., has been reported on by Mr. H. D. Woods, City Engineer. The estimated cost of abolishing all such crossings now remaining is $987,000, of which it is stated the city would pay about $100,000.

◆

THE TOTAL DEATHS in the United States Army from May 1 to Sept. 30, inclusive, are reported as follows by the Adjutant-General's office:

	Officers.	Enlisted men.
Killed	23	257
Died of wounds	4	61
Died of disease	80	2,485

This makes an aggregate of 2,910 deaths out of a total force of 274,717 officers and men, or a death-rate of 10.59 per thousand for the five months. We understand that deaths of officers and men on furlough are not included in these totals.

◆

THE LOSS IN THE U. S. NAVY, in the war with Spain, was only 17 men killed and 67 wounded, and of the latter 54 returned to duty. Surgeon-General W. K. Van Reypen, U. S. N., Chief of the Bureau of Medicine and Surgery, has handed in his official report. He shows that the U. S. Navy, before the war commenced, secured competent surgeons from civil life to meet the possible demand for them on auxiliary vessels and commissioned 37 as Assistant Surgeons out of the 2,000 applications received. The Bureau fitted out as a hospital ship the "Solace," a steel vessel of 3,801 tons, a speed of 16 knots, and comfortable accommodations for 200 patients and the medical staff. She was ready to take the wounded at the bombardment of San Juan. The "Solace" made numerous trips to northern ports and went back loaded with all manner of supplies for the sick. The medical officers of the "Solace" first introduced antiseptic surgery at sea. Throughout the report there is evidence of careful and intelligent preparation for all emergencies, by the naval medical staff; and the small percentage of loss of life from wounds and the general good health of the navy is proof of the efficiency with which the medical officers discharged their duties.

◆

CORN-PITH CELLULOSE, for the protection of warships against leakage from shot-holes, was officially tested in Russia, on July 19. The cellulose was furnished by the Marsden Co., of Philadelphia, and was handled by experts of that company. It was packed in a coffer-dam 6 ft. long by 6 ft. deep and 3 ft. thick, and subject to a head of water of 5 ft., and compressed until it weighed 8 lbs. per cu. ft. This dam was then perforated by a 6-in. solid shot striking 20 ins. from the bottom and less than half a pound of cellulose was carried out by the shot. In one-half hour after the water was turned on back of the dam a moist spot appeared on the front, but this was proven to come along the bottom of the packing and not through the shot-hole; in four hours no water came through the shot-hole and only 6 gallons passed under the packing. The test was pronounced a complete success by the Russian naval authorities present, according to the statement of U. S. Consul-General W. R. Halloway, of St. Petersburg. He says it opens up an immense market for Indian-corn pith.

◆

A NEW SYSTEM OF SIGNALING at night has been tested on the steamer "Kaiser Wilhelm der Grosse," at her pier in Hoboken, the signals being read from the pier of the American Line in New York, over two miles distant. The system consists in throwing the letters of the international code, one at a time, on a screen by means of a reflecting lamp. The inventor proposes to use instead of a fixed screen, on which to display his signals, a rotating canvas-covered wind wheel, or screw, which will not flap in the wind as a sheet would do. The letters used in the test were 15 ft. high.

◆

THE MANCHESTER SHIP CANAL was designed for ships of not over 3,000 tons and drawing 22 ft. of water. The steady increase in the capacity and draft of ocean steamers is now giving trouble for the canal owners, as the present channel will not accommodate even the later class of ocean tramps. As a direct trade in cotton with American ports was one of the chief objects of the original promotors of the canal, the deficient depth of channel presents a grave problem for solution. More docks and warehouses are also needed for handling and storing the cotton; and the want of these taken with the comparatively shallow channel, are hindering the growth of the canal business. In the first half of 1898 the increase in canal revenue was about $45,000, as compared with an increase of $80,000 in the corresponding half of 1897, and $90,000 in 1896.

◆

THE DRAINAGE OF THE CALUMET DISTRICT lying to the south of the main business section of Chicago, Ill., and comprising South Chicago and the neighboring territory, is discussed in a special report recently made to Mr. L. E. McGann, Commissioner of Public Works, by a commission of engineers appointed to investigate the subject. At present the Calumet River receives a large amount of Chicago sewage, which in time of high water is swept out into Lake Michigan to pollute the water supply. To remedy this the report recommends constructing a canal from the river to a connection with the Drainage Canal at the Sag, which will divert the flow from the lake westward. The canal recommended is to have a capacity of 50,000 cu. ft. per minute, and is estimated to cost $1,621,000.

◆

THE CHANGE OF GAGE from 3 ft. to 4 ft. 8½ ins. on the Port Austin division of the Flint & Pere Marquette R. R. was effected on July 17. This division extends from Port Huron to Grindstone City, Mich., a distance of 92 miles, and the work was done by 274 men during a long, hot day. A considerable amount of preparatory work was done in advance to enable the change to be made in one day. This consisted in planing the ties by machinery attached to a car, the ties being planed for a space wide enough to receive the rail and spike. This was done before any spikes were driven. Then, by means of suitable gages, all the outer spikes were set for the new position of the rail, and were driven nearly home. On July 16 a large number of the old spikes were drawn. The old rails were used almost entirely, joints being unbolted at suitable intervals to facilitate the sliding of a length of rails to the new line of spikes. The rails were then spiked on the inside at the joints, centers and quarters, to make the track safe for the passage of trains. The railway company had been putting standard ties in the track for two or three years, about one-fourth of the ties being new and put in during May and June. The rails weigh from 35 to 45 lbs. per yd., and the traffic is light. Trains passed over the line on July 18, the only delay being for three hours on one section, where a green man blundered and failed to notify the division roadmaster in time to receive aid. Mr. Wm. B. Sears, M. Am. Soc. C. E., is Consulting Engineer; Mr. Geo. M. Brown, Chief Engineer, and Mr. E. Treadwell, General Roadmaster.

◆

ELECTRIC LIGHTING FROM THE CAR AXLE has been adopted on the limited train of the Atchison, Topeka & Santa Fe R. R., running between Chicago, Ill., and Los Angeles, Cal., a distance of 2,209 miles. The aggregate candle power generated will be about 4,928 candle power, including, besides the regular train lights, lamps in all berths and the locomotive headlight.

◆

A FAST RUN was made by a special train on the Lehigh Valley Ry. on Oct. 9. From Buffalo, N. Y., to Rochester Junction, 69 miles, the time was 67 mins., and the first 105 miles were covered in 102 mins. The run to Ithaca, 148 miles, was made in 2 hrs. 46 mins., including 12 mins. lost in stops.

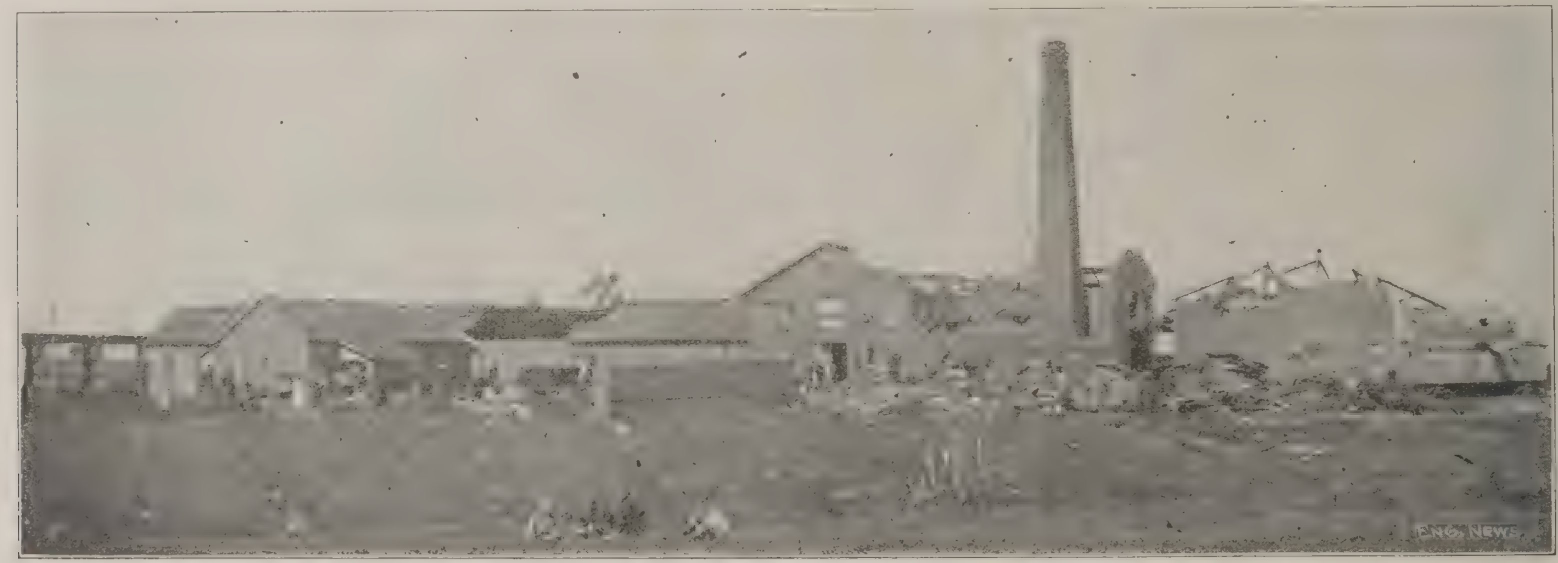
◆

THE CHINESE NORTHERN RAILWAY, as built by the state and open for traffic, includes the Tiensin-Tonghu-Chunghouso line, 214 miles long, and the Tiensin-Pekin line, 80 miles long. These roads are said to be the cheapest yet built in China, and cost $25,500 per mile, not including large bridges, but including the heavy fees demanded by Chinese officials. On the Pekin section the only heavy work is the lattice bridge over the Peiho River, 984 ft. long. There are heavy embankments and many small bridges. The roadway and station buildings on these lines are American in type; ballast is very scarce and not used at all on some sections, and the American pine ties cost 81 cts. each. The rails are of Belgian make and the locomotives were made in England and America; the rest of the rolling stock was built in the shops at Tongshaw. The line is single track, but roadbed and bridges are built for double track. The Viceroy Chi Li is the head of the railway department, and excepting a few Europeans at the head of each secondary department the staff is Chinese. These notes are taken from an article in the Proceedings of the Austrian Society of Engineers and Architects for 1898.

THE MERRITTON TORNADO.

By Orrin E. Dunlap.

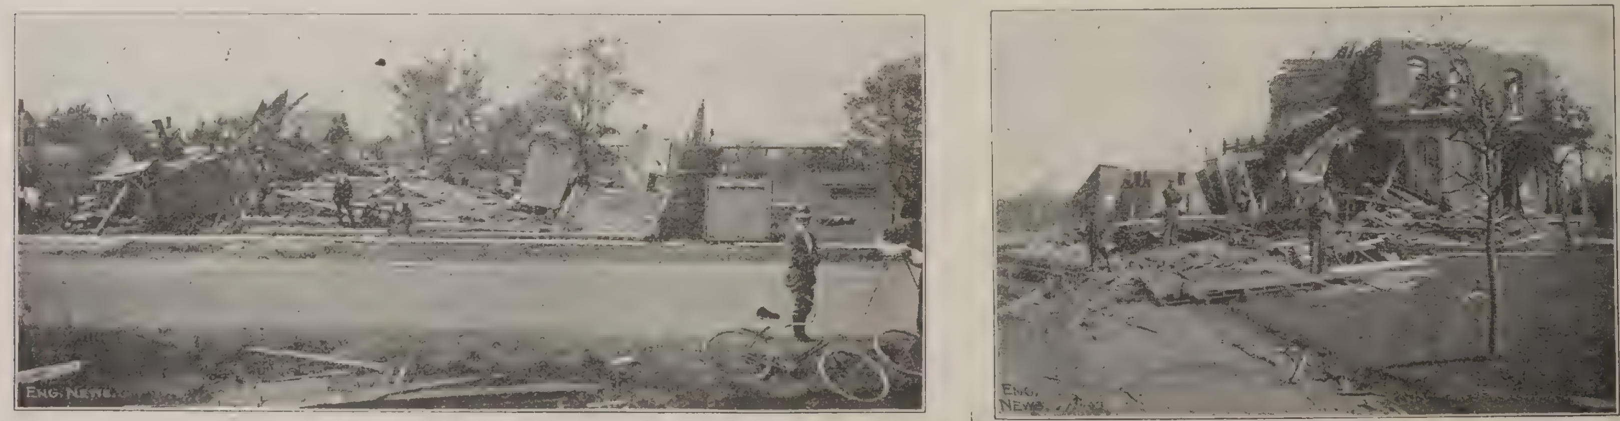
One of the most severe tornadoes that has ever been recorded east of the Mississippi Valley swept through St. Catharines and Merritton, Ont., and Niagara Falls and the Tonawandas, N. Y., on the afternoon of Monday, Sept 26. The destruction of life and property during the brief period while the storm lasted was something awful, and while pictures and words may in part describe the result in this storm-swept territory, they cannot give to the reader a full realization of the terrible nature of the disaster. The people living in the vicinity of the storm of September 26 had read of the destruction done by tornadoes on the Western prairies, but it was only when they themselves found the storm upon them that they realized the power and terror of such a visitation. With loved ones dead or injured, and with their homes swept out of existence, the full truth came home to them.



WRECK OF THE LINCOLN PAPER MILLS, MERRITTON, ONT.

The early part of the afternoon of Sept. 26 was beautifully bright until after 3 o'clock, when a dark, peculiar-looking cloud made its appearance in the northwest sky. Many noticed it, and watched it, and remarked its unusual appearance. This strange-looking cloud grew in size, and distant thunder announced an approaching storm. The cloud changed its shape; gathered itself like a balloon, and then was seen to send out two funnel-shaped tails earthward. One of these tails touched below Welland Ave., between Lake and George Sts., in the city of St. Catharines, Ont., and traveled in a direct line from this point to the southerly limit of the city. Its course was marked by ruin. The drill shed was practically demolished, the western arch being blown in on the gun sheds, breaking them in, and the roof of the hall being carried away. The cloud appeared to rise and fall; in some places destroying houses and barns, unroofing others and carrying away chimneys. Trees were uprooted and tossed about like paper, and the roads were rendered impassable.

It was the village of Merritton, Ont., that suffered most from the cyclone, however, for there it struck with greatest fury. About the first building it struck was the Lincoln paper mill, and it is evident from the wreck it made here that its force was fresh. The buildings were most substantial, of heavy stone and brick construction, but after the storm had passed over them they presented the appearance of a shell-riddled fortress. Roofs and parts of the wall were carried away, as shown in the photograph, but the tall brick chimney withstood the storm. The rain that followed the wind damaged the stock and the interior of the buildings, as well as some of the machines. There were 80 employees at work when the storm struck the mill. One girl was killed outright, and many were injured. Cars on the mill siding were picked up and dropped into the canal. Two men at work loading pulp into a car from a wagon were swept into the water, but were rescued. The wagon was wrecked and the horses were killed. Parts of the mill were carried long distances.



The Presbyterian Church. Residence of Samuel Smith.

SCENES IN MERRITTON, ONT., AFTER THE TORNADO OF SEPT. 26, 1898.

The destruction in and about the public school house was remarkable. When the teacher saw the storm approaching she gathered her little pupils to the number of 40 in the southwest corner of the room. The wind struck the building, and in an instant it was a mass of debris. The children were almost buried, but, after all were taken out, it was found that only one was killed. The school was located on a street running east and west, and next to it on the west was Orange Hall, a frame structure. West of Orange Hall stood the residence of James Bradley, and across the street, directly opposite it, stood the new residence of R. Thompson. The storm first caught the Thompson house, carried it across the street against the Bradley house, which it struck with great force. The two dwellings were then carried onward under the storm's power against Orange Hall, which was in turn swept against the school house. At this point the force of the cyclone seemed to be at its highest. One woman was killed in the wreck of the Bradley house. The Willson carbide plant was damaged, as were also the power houses.

The Presbyterian Church was razed to the ground. A person unacquainted with the conditions before the storm would not have known a building once occupied the site. John Hogan's house, a frame structure, was picked up and tossed against the brick dwelling of Samuel Smith, both being badly wrecked, as shown in one of the photographs reproduced herewith.

In one instance a man was blown out of his buggy. In another case a child was blown from its mother's arms and killed. In several instances boards were driven into the ground, and in one place the ground had the appearance of having been plowed.

After leaving Merritton the cloud seemed to divide, one end rushing over Niagara Falls and the other southward to Tonawanda. At Niagara Falls a severe hailstorm occurred, some of the hailstones weighing 2 oz. and measuring from 7 to 9 ins. in circumstance.

In Tonawanda the scenes at Merritton were repeated, though the force of the storm was not so great. Houses were leveled to the ground, and in one instance a barn was carried 300 ft. Piles of timbers represented what before the storm were three dwellings. In Tonawanda it was also noticeable that the storm jumped about, striking here and there. One strange fact in connection with the storm is that near Merritton there is a highway called Hurricane Road. It is said on good authority that many years ago the locality was visited by a storm which swept a path through the woods, which was continued as a road and given the name Hurricane Road.

THE WORK OF THE ENGINEERS IN THE SANTIAGO CAMPAIGN.

By Eduardo J. Chibas, Assoc. M. Am. Soc. C. E., late Assistant Engineer to the Chief Engineer of the Fifth Army Corps.

(With maps showing position of troops at Santiago.)

The echo of the heavy cannonading from our war ships—which from early dawn had taken their position in front of Daiquiri—had hardly died away, and clouds of smoke from the bombardment were still hanging here and there over the landscape, when the advance guard of the Fifth Army Corps landed on Cuban soil on June 22 without any opposition from the enemy. Among the transports near shore waiting for orders to unload her troops was the steamship "Alamo," with the Fifth Army Corps' Battalion of Engineers, which was composed of two companies of the U. S. Engineer Corps of the regular army —Company C and Company E, of 100 men each. The latter company started from West Point for Tampa on April 30, and the former went from Willett's Point on May 14. Both companies were organized into a battalion in Tampa, under the command of Capt. Jas. L. Lusk, who was relieved before the sailing of the expedition by Capt. Edward Burr, afterwards Lieut.-Colonel of the Second Volunteer Regiment of Engineers. The officers of Company E were Capt. Edward Burr, First-Lieut. E. E. Winslow, now Captain, and Second-Lieutenants H. B. Ferguson and L. Brown. The officers of Company C were Capt. G. D. Fitch, afterwards Major of Volunteer Engineers, Lieut. T. H. Rees, now Captain, and Second-Lieutenants G. M. Hoffman and S. A. Cheney.

On board the "Alamo" were stowed a large amount of square timber of various sizes, 12 pontoons and 15 completed trestles, susceptible of adjustment to any height from 3 to 12 ft. for military bridges; and all the tools and material that any possible emergency might have called into requisition. All the contingencies that might arise had been considered in Tampa, before sailing, and under the personal supervision of Brigadier-General William Ludlow, Chief Engineer of the Army in the field, all the necessary material had been provided. Through his efforts also, many photographs of the Spanish blockhouses and forts had been secured.

The work performed by the engineers in the Santiago campaign may be subdivided into "Reconnoissance," "Piers," and "Road and Bridge Work."

Reconnoissance.

On the morning of June 22, shortly after the first troops had landed, Lieutenants G. M. Hoffman and S. A. Cheney, with four men each, were detached from the Engineer Corps for reconnoissance work under Lieut.-Colonel Geo. McC. Derby, Chief Engineer Fifth Army Corps. They followed close to the advance, taking topography and mapping roads and foot-paths, noting their condition with reference to the transportation of artillery and supplies. They reached the Siboney landing, six miles away, on the next day. The two parties had kept separate, doing work along different roads They reported every evening to the Chief Engineer's office at headquarters—which for the first week was kept on board the steamer "Seguranca," that lay first in Daiquiri and then in Siboney Bay. After the troops passed beyond Las Guasimas, three miles from Siboney on the road to Santiago, where the first skirmish of the war was fought by the Cavalry Division, on June 24, four line officers were added to the reconnoissance party under orders of Major William D. Beach, Division Engineer of the Cavalry Division, through whom they reported to Lieut.-Colonel Derby, Chief Engineer of the Fifth Army Corps. These line officers were Lieut. Guy H. B. Smith and Lieut. D. P. Cordray, of the Infantry, and Lieutenants G. P. White and M. A. Batson, of the Cavalry. After July 3 they reported direct to the Chief Engineer. During the six days of rest and preparation that followed the first battle, and while the troops were camped on either side of the road to Santiago, the reconnoissance party kept constantly at work, very often venturing considerably beyond our outposts and going into the very heart of the enemy's country. The quiet and unostentatious manner in which the work was performed failed to bring it into general notice, and very little has been known by outsiders of the many risks incurred by individual members of the party, and of the commendable and valuable services rendered by them. After looking back over the excellent work accomplished by that small number of men, the only regret is that a much larger party was not placed in the field so that it could have covered the whole country around Santiago before July 1. The information we started with was very meager, as the Spanish government has never made a topographical map of Cuba, and the maps we had for reference showed merely a general outline without topographical features.

On June 27, when the American outposts were located at La Redonda, near where General Shafter established his headquarters three days later, and the Cuban outposts were a mile farther on the road to Santiago at El Poso, Lieut.-Colonel Derby and Lieut. Hoffman pushed the reconnoissance work half a mile beyond on the same road.

On June 28, Lieut. Hoffman went three-quarters of a mile beyond the outposts on the road to Caney, and Lieutenants Batson and Smith, from another direction, approached within less than a mile of the forts around that village.

The writer, on that morning, was ordered to measure a base line and make triangulations at the front to find distances to the City of Santiago, and to locate the prominent points of the surrounding topography. The positions we were able to secure on the hills near our outposts were not advantageous enough for the purposes intended; and on the next day, after having secured an additional force through Major Beach, Engineer of the Cavalry Division, we ventured with Lieut. Batson to within less than a mile of Caney and close to the road connecting it with Santiago, Without the use of field glasses we could see the Spanish sentinels pacing back and forth in front of some of their block-houses. The other members of our party, on that day, were Mr. E. M. Bane, official photographer, one sergeant and two Cuban privates, and one sergeant and five privates of the Ninth Dismounted Cavalry. A peculiar incident of the day was that, without firing a shot we returned to our lines after our work had been performed, with ten prisoners and a horse, captured by our small force. It is fair to explain, however, that they were not soldiers, but civilians, who claimed they had come out of the city to get mangoes and other fruits, and were on their way back to Santiago when we detained them. From them we obtained information as to the number of Spanish troops in Santiago, their condition and the nature of the barbed-wire entanglement around the city. On that same day, Lieut.-Colonel Derby and Lieut. Hoffman had gone scouting with a detachment of six Cubans beyond El Poso and almost to the San Juan River crossing. Later on, they proceeded to Marianage, which the Spaniards had evacuated the day before, and climbing a tree they observed the Spanish position on San Juan hill. On June 30, Lieut. Cheney had completed his reconnoissance along the coast line, and venturing within sight of the Spanish sentinels of Aguadores, reconnoitered their strong position. On that same day Lieut.-Colonel Derby continued reconnoitering the country towards San Juan and went again far beyond our outposts.

On July 1, Lieut.-Colonel Derby, Chief Engineer, and Lieut. Maxfield, of the Signal Corps, made their balloon ascension, which has been so much criticised. The opponents of the balloon claim that its presence at the front betrayed the position of the troops, and that the deadly fire poured upon it by the Spaniards was the cause of unnecessary casualties. On the other hand, the observers in the balloon, who certainly deserve credit for their unflinching valor while exposed to a most severe fire, argue that their discovery of the trail running parallel and to the left of the main road, through which General Kent swung his division as soon as Colonel Derby notified him of its existence, saved many lives by relieving the congestion of the main road through which the troops had been advancing. The results proved, however, that the usefulness of the balloon in warfare must be confined to the rear, or far enough from the enemy to insure it a fair chance of escape from the fire that will be directed against it, while it must be kept far enough from the main body of the troops to prevent the spent bullets from causing losses that might be avoided.

While the fighting was going on, nearly all the officers attached to the reconnaissance party were out with the troops at either Caney or San Juan in the line of fire, noting the position of the different regiments and brigades.

The instruments used in the reconnaissance work were the prismatic compass, cavalry sketching case, and often a hand level. The distances were estimated by pacing. The average daily distance covered by each individual varied, according to the nature of the country and the width of the belt sketched, from one to ten miles. The different parties reported every evening to the office of the Chief Engineer where the works were compiled, fitted together and added to the map of the previous day. A tracing was made, and then blue-prints were issued to the commanders of divisions, brigades and batteries, and other officers as far as the available number would permit. The first blue-print issued in the field was on July 3, and they continued to be issued from that time on nearly every other day, showing all additional information and changes in the position of the troops.

The Chief Engineer's office was moved from the "Seguranca" to headquarters in the field, on June 30; but soon after the capture of San Juan, the office was moved to San Juan hill, just behind our intrenchments for convenience in receiving the daily reports. The mapping and all the field office work was performed by Lieut. Geo. M. Hoffman, of the Corps of Engineers, and the writer, or by either one of them when the other was in the field. Mr. R. S. Porro had charge of the compiling on board the "Seguranca," and continued attached to the office of the Engineer Corps till July 8, when he was transferred to another branch of the service.

The blue-printing was done by means of an improvised field outfit, as the glass of the blue-printing frame was broken while being unloaded at Siboney, and we were unable to secure another one of the same size to replace it. We were fortunate enough, however, to find two pieces of window-glass about 24 × 30 ins. each. Our improvised frame consisted of the cover of one of the packing boxes around headquarters, over which was stretched a blanket folded to make three or four thicknesses. The blue-print paper and the tracing were unrolled, placed on the blanket and kept in contact by the weight of the two pieces of glass resting on it. For a tray for washing the blue-prints, we used a rubber blanket.

The trenches in the Santiago campaign were not laid out by the engineers, but were dug on the nights of July 1 and 2 by the troops of the line, under the direction of their own officers. After the capture of San Juan hill, however, a line officer from each brigade was appointed as Brigade Engineer, under the direct orders from Lieut.-Colonel Geo. McC. Derby, Chief Engineer, and his duty was to look after the trenches and to report daily to the Chief Engineer's office, through one of the members of the reconnaissance party, the changes in his own line of intrenchments, or any changes or extensions he might have observed in the enemy's positions. Some of the trenches that were hastily thrown up during the nights of the first and second of July, were improved later on by orders of the Chief Engineer, and a few had to be changed so as to place them on the military crest, that is, the point from which the defender can sweep with his fire the whole line over which the enemy must advance.

Piers.

On the morning of the first landing at Daiquiri, the engineer battalion was ordered to put ashore a large quantity of intrenchment tools, which were afterwards distributed to the troops of the line; also pontoon material and sufficient lumber to repair the small pier that had been partially burned by the fire started by the Spanish forces as they evacuated the place in the early morning. The damage had been mostly confined to the approaches, and before midnight the repairing was ended. On the next day the main portion of the engineer battalion, under the direction of Brigadier General William Ludlow, was ordered to proceed on the "Alamo" to Aserradero, twenty miles west of Santiago, to build a temporary pier to facilitate the embarkation of the Cuban forces, under General Calixto Garcia, which were to be transferred to the eastward to co-operate with the American forces. The wharf built at Aserradero consisted of two rows of piles of 5 × 5-in. timber driven by a heavy wooden maul 8 ft. apart longitudinally, and 4 ft. between the rows. The caps were spiked to the side of the pile, to do away with the labor of leveling and cutting them off, and on them rested the flooring of three or four planks.

On June 25, the 3,000 Cuban troops were transferred from the landing at Aserradero, to the three transports, about a mile away, by means of twelve large ship-boats and two navy launches. On the next morning we arrived at Siboney, and the battalion was immediately ordered to proceed to the building of a boat landing at that place. Before dark the work had been completed. The landing consisted of a crib 7 × 7 ft., sunk in 6 ft. of water, and connected with the shore by an approach 45 ft. long. On that day Brig. Gen. Wm. Ludlow, now Major Gen. U. S. Vol., was detached from the Engineer Corps and given active command of troops in the field; the 1st Brigade of the 2d Division. A portion of the battalion was detailed to begin work on a much larger pier from June 27 to July 1, when the whole battalion was ordered to the front and did not return to Siboney to resume its work till July 5. This pier consisted of three cribs. The first one was 10 ft. square, built of 5 × 12-in. timber, and sunk 30 ft. from the shore in three or four ft. of water. This portion of the approaches was finished about July 1, and began to be used shortly afterwards. The next two cribs, one of which was partially built by the 33d Volunteer Michigan Regiment while the battalion was at the front, were built of 12 × 12-in. timber. They measured 30 ft. deep and 10 ft. wide, and were sunk in 6 and 10 ft. of water, respectively. The spans between the cribs were 15 ft., making the total length of the pier about 130 ft. It was completed on July 12 after many difficulties, due to the heavy surf constantly beating aginst the shore, had been encountered and overcome.

Road and Bridge Work.

The portion of the battalion which was not detailed for the pier construction worked on the road from June 27 to July 1, when both sections were combined, and, as before stated, were ordered to the front. On July 2 the whole battalion worked all day under fire, improving the road near the crossings of the San Juan and Aquadores Rivers, and rendering those fords passable by wagons. On the next day, July 3, the battalion was marched to Sevilla, and on that day and the succeeding one they worked on the road from there to Siboney, where they went to resume the pier work. At that time Lieut. Brown was detached from the battalion and placed in charge of road repairing. Under his orders he was authorized to draw details of two battalions, or about 600 men, from Division Commanders. These details were generally taken from the volunteer regiments, and many men from the 71st New York were assigned to this work. These men made wide clearings on both sides of the road to allow the sun's rays to penetrate and dry the road beds. They corduroyed the swampy portions, improved the drainage, and opened up new roads on either side of the old road, along portions which had been rendered impassable, and extended them so that all portions of the line along which the besieging army was located could be reached by pack mules or wagons. These men also built some bridges and culverts, using such material as was at hand, which was often bad and difficult to procure. Lumber from the landing could not be had on account of lack of transportation.

After the surrender the Battalion of Engineers continued at work until August 16. From July 19 to July 22 they repaired the Aquadores Railroad bridge, one of whose piers and the two spans resting on it had been blown up by the Spaniards. The completion of this work allowed the trains to run from Siboney to Santiago Harbor. Later they repaired portions of the railway from Santiago to San Louis that had been partly destroyed; rebuilt about 300 ft. of a high trestle over Purgatorio Creek, which had been partially burned, and a smaller bridge near Boniato that had also been damaged.

General Remarks.

The Engineer Corps has been widely criticised for not doing work that they were expected to do during the Santiago campaign; but the critics certainly ignore the difficulties under which the Battalion had to labor, not difficulties of nature, which they were fully able and prepared to meet, but difficulties arising from the peculiar manner in which the campaign was conducted. Had the Engineers been furnished with two or three wagons to transport to the front some of the material that was safely stowed in the hold of the S. S. "Alamo" while she rode on the waves in front or Siboney, they could have bridged every single ford in a short time. They could have improved many portions of the road, and its carrying capacity would have been greatly increased. But the Engineers were dependent on other Departments for transportation which they could not secure. They had three wagons for their own use while camping in Port Tampa, and although, I understand, they asked to be allowed to take them with them to Cuba, their request was refused.

The Battalion of Engineers is equipped and drilled as Infantry. The enlisted men in it are trained and drilled as infantrymen, and besides have special drills in building pontoons and military bridges; in laying out and building fortifications; in sapping and mining; in planting and operating submarine mines, etc., and although they accomplished a great deal at Santiago with the means at their command, they were certainly fit to have performed a much greater service than they were given a chance to perform.

In conclusion, it may not be out of place to refer to what was one of the most impressive lessons of the campaign, to every intelligent observer, that our troops were under a great disadvantage on account of their use of black powder. Whenever our cannons and small arms poured forth their shots such a dense cloud of smoke hung around them as to furnish an excellent target for the enemy. On the other hand, when the Spaniards fired it was almost impossible to detect their position, and it was only after considerable watching on our part that their artillery could be located at all.

POPULAR ERRORS ABOUT WATER METERS.*

By John C. Trautwine, Jr.†

The water-works of Philadelphia are pumping more than twice as much water as would furnish to all its people a lavishly bountiful supply at good pressures; yet from all sides come well-founded complaints of beggarly supply and low pressure. The Bureau of Water appeals in vain, year after year, for millions of dollars for new pumps and new mains, and private companies improve the opportunity by suggesting the expenditure of many more millions for prodigious facilities which the city does not need.

The reason is not far to seek. It is perfectly well known that more than half of all the water pumped is wasted, flowing off into the sewers without benefiting even those who waste it—or the sewers. If the waste, or even the major part of it, were stopped, the capacity of our works would be practically doubled, and there would be plenty of water for all. The cost of installation of filter plants, or that of bringing water from a distance, would be cut in two. Even without the adoption of means for purifying the water, the quality of that furnished would at once improve, for pumping could then be stopped during seasons of muddy or coal-polluted water, and the water in the reservoirs would have longer time for sedimentation.

The experience of other places leaves no doubt whatever that the proper use of the water-meter is a radical cure for the evil of waste, and the only one. In other words, upon the meter depends the salvation of our city's water supply. It is therefore most unfortunate that, through ignorance of the facts of the case, the public seems to be standing in its own light by a reluctance to sanction the increased use of meters.

Many of our people appear to be under the impression: (1) That the proposed use of meters in dwellings is intended to restrict the use of water. (2) That the charge for water by meter is excessive. (3) That the waste is exaggerated. (4) That the wasted water helps to cleanse the sewers.

To correct the first error it ought to suffice to say that it is not desired to charge by meter for water used in families. In the first place, it is not proposed to apply the meter to all dwellings, but to those only where outrageous waste is found to be going on.

In the second place, every metered supply, however little the meter shows, pays a minimum charge, established for the express purpose of discouraging economy in the use of water, and in most cases the consumer will have drawn all the water he can possibly use and enjoy, and will have done a fair amount of wasting besides, long before the meter reading equals this minimum charge. The meter thus charges only for water wasted (and not for all of that), not for water used.

There is therefore, as a rule, no inducement to be even careful in the use of water from a metered dwelling-house supply, and this is as it should be. Otherwise undue economy might lead to filth and disease. Gas may properly be so charged for as to induce care in its use, but this is not the case with water. It is better to have a gallon of water wasted than to discourage the proper use of a pint.

The present meter rate (after the minimum charge has been exceeded) is 30 cts. per 1,000 cu. ft., or about 4 cts. per 1,000 gallons, or 1 ct. per 2,000 pints, or 1 ct. per ton. One cent's worth of water would supply from five to ten liberal baths, even if it were proposed to charge by meter for water used for baths in dwellings, or for other domestic purposes.

My bath-room faucet recently began leaking, and I placed the stopper in the tub, in order to measure the loss. The faucet was merely trickling, yet a measurement showed that it was passing about 70 gallons per day. Even so trifling a leak, if it existed in each dwelling-house in the city, would amount to 6% of our total consumption, and would require an engine pumping 20,000,000 gallons a day to supply it; and it is notorious that thousands of houses have numerous leaks, in comparison with which the one in question is insignificant.

An investigation of the consumption of the district bounded by Broad, Seventh, Chestnut and Spruce Sts. showed that 63% of the water furnished to that district was wasted, and by only 17% of the population, the other 83% paying for the wasted water.

A similar examination of a district consisting of two intermediate streets in the northwestern section of the city, where 142 seven-room houses built in 1893 were inspected, gave the following results:

Number of inhabitants	539
Number of appliances	782
Number of appliances leaking slightly	22
Number of appliances turned on continually	32
Average consumption per capita per day, gallons	222
Water consumed during 24 hours, gallons	119,800
Water used, gallons	16,120
Water wasted, gallons	103,680

In other words, of the 222 gallons per head per day consumed, 30 gallons were used and the other 192 gallons wasted.

The only hardship inflicted, even upon those wasteful consumers whose supplies should be metered, would be that of seeing that their plumbing was in good order, and that no considerable quantity of water ran to absolute waste. In short, in order to keep their bills within bounds, they must take care to use most of what they draw.

As regards hardship to manufacturers, it is to be hoped that no Philadelphia manufacturer is in such straits that he would find it a hardship to pay one cent per ton (or but little more than bare cost) for the water supplied to him by the city; but, if it is considered advisable to give water to any or to all manufacturers at less than cost, the city can do this as well with meters as without them. The meter does not fix the rate. It simply substitutes payment by the ton in place of payment by the year. It encourages and rewards care, where the present method puts a premium on the vice of prodigality.

It is a mistake to suppose that wasted water aids in keeping our sewers clean. This water flows through the sewers with too little velocity to accomplish any good in this respect; but the use of meters would render the supply (with our present means) so ample that water could easily be spared for proper flushing of the sewers by jets introduced at high velocities.

I quote as follows, from correspondence and from publications, respecting the experience of other towns:

> Atlanta, Ga.—There never was a better illustration of the duty so constantly pressing upon municipal authorities to save and protect the unthinking public against themselves and against the consequences of their own want of knowledge as in this instance. The reform was met by a storm of protests, and so great was the opposition that nearly 400 consumers ordered the water cut off. Soon, however, finding that the pressure and service was so greatly improved and the rates with meters really less than they were without, they all came trooping back, admitting their error and full of thanks and praises.
>
> It was a fight and a sharp one at first, when we put in the meters and filters. Such, however, has been the effect of experience and education, with demonstration of success, that now I make bold to say it would not be merely a fight, but a revolution, if we attempted to abolish meters and filters.
>
> In 1885, with about 2,000 consumers, we pumped about the same amount of water per day as we now do in 1895 with over 6,000 consumers. Our experience is that, with a minimum rate, consumers use nearly the full amount of water allowed them. The sanitary conditions of our city has not suffered by reason of scarcity of use of water.
>
> We had been pumping 6,000,000 gallons per day, but

---

*Abstract of a paper presented to the Engineers' Club of Philadelphia, Oct. 1, 1898.

†Chief of Bureau of Water, **Philadelphia**, Pa.

when meters were put in the daily pumpage immediately fell to 1,250,000 gallons, and the pressure rose to such an extent that we could throw ten or more streams from the street hydrants over the tallest buildings without using the fire engines at all.

It was the adoption of meters that made it possible to filter the total supply.

Atlantic City, N. J.—One leaky hopper closet (or one that is allowed to run continuously) in some small property that paid perhaps $6 or $8 per year on the assessed rate will waste water enough to supply half a dozen fine residences and sprinkle an acre or two of lawns besides. In cheap houses, or where there is cheap plumbing, by letting the water run to prevent freezing in cold weather, enough is wasted to furnish baths galore to the whole population.

* * * * * * * * *

The per capita pumpage has been reduced from a maximum of 260 gallons per day to about 75 gallons per day.

* * * * * * * * *

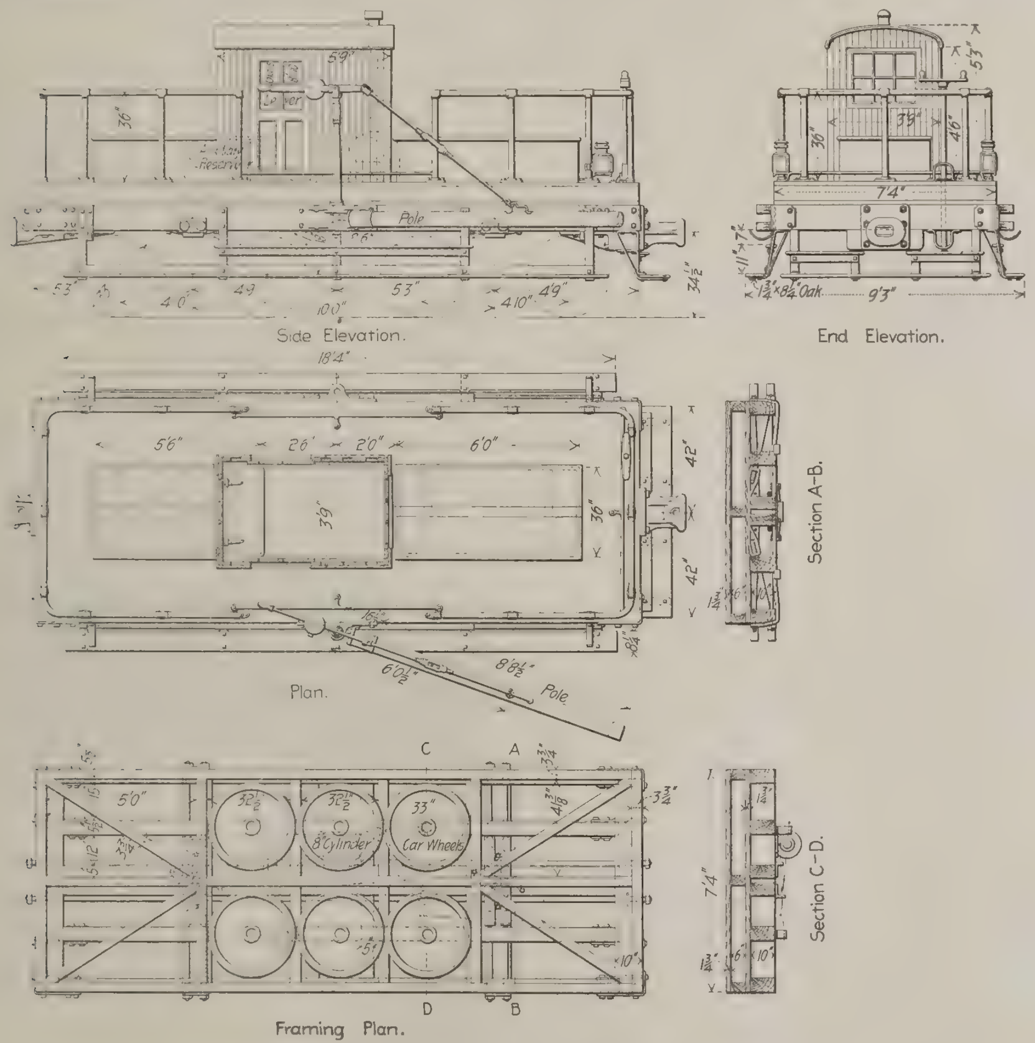
Richmond, Va.—At the commencement of this year we had about 1,400 meters in use. I have, so far, set about 500 meters this year, with the result, taken with those previously placed, that the pressure has increased five pounds at the high points, enabling many consumers who had no water on their second floors during the hours of the day to use water on those floors. Our pumpage has been decreased about 25% from what it was four years ago, and we have a larger number of consumers.

Harrisburg, Pa.—We overcame popular objection by teaching people that the only objectors to meters were those who wanted to get water without paying for it. You know, of course, that more than half of your pumping plant would be idle if you supplied water equitably by meters.

(Besides the opinions quoted, the paper contained others, all in favor of meters, from Utica and Poughkeepsie, N. Y.; Providence, R. I.; Milwaukee, Wis., and Lexington, Ky.—Ed.)

STANDARD POLING CAR; PENNSYLVANIA R. R.

For the handling of cars in railway freight yards, in making drilling movements, two different systems are in general use. In the first, each car or cut of cars is hauled or pushed direct by a switch engine on the same track as the cars. In the second, the cars are pushed by means of a horizontal pole seated in a socket on a switch engine or poling car running to and fro on a track parallel with that on which the cars move in passing to the classification tracks. Operating the pole from the locomotive is usually more or less inconvenient and unsatisfactory, especially in a busy yard, and for such yards poling cars are in many ways preferable. The car is, of course, attached to a switch engine, and runs to and fro on the poling track. One great advantage of the poling system is the rapidity with which the work can be done, there being no time lost in coupling or uncoupling the switch engine, while there is of course far less chance of injury to the yard men than when such frequent coupling and uncoupling movements have to be made.



STANDARD POLING CAR; PENNSYLVANIA R. R.
F. D. Casanave, General Superintendent of Motive Power.

The accompanying cut represents the latest type of poling car in use on the Pennsylvania R. R. We are indebted to Mr. F. D. Casanave, General Superintendent of Motive Power, for the blue prints from which our illustration is made.

The poling car is essentially a short flat car, 20 ft. long over the end sills and 7 ft. 4 ins. wide over the side sills. There are two end sills, 10 × 10 ins., and six longitudinal sills, the side and intermediate sills being 5½ × 10 ins., and the two center sills (only 2 ins. apart) 5 × 10 ins. At the middle of the car are two rows of transverse blocking let into the sills. The body bolsters are flat steel plates, let into the sills and having their ends turned up against the outside faces of the side sills, being supported by heavy truss rods which pass through the turned up ends and are attached to loops on a strap resting on top of the center sills. Two heavy tie-rods pass longitudinally through the frame, close to the center sills, and each longitudinal sill is attached to the end sill by a bolt having a flattened strap end, this flat end being bolted through the sill. The design was prepared with a view to the racking and twisting strains to which the car is subjected in service. The car is mounted on two four-wheel trucks with 33-in. wheels, the truck wheelbase being 4 ft. 10 ins., and the total wheelbase 14 ft. 10 ins.

Over the sills is a decking of 1¾-in. planks, upon which is a framing of timbers 3¾ × 6 ins., carrying the floor of 1¾-in. planks. In the middle of this 6-in. space between the two floors are placed six 33-in. car wheels to weight the car down upon the track, while the end panels have horizontal diagonal bracing, as shown. A railing runs around the ends of the car, and a cabin or house is built in the middle and fitted with a stove and locker. This cabin is 5 ft. 3 ins. high, 5 ft. 9 ins. long, and only 3 ft. 9 ins. wide, leaving a gangway on each side for the men handling the pole. Two oak footboards, 1¾ × 4½ ins. and 1¾ × 8¼ ins., are placed along each side and end of the car, 17 and 28 ins. below the tops of the sills, and to each end sill is bolted a heavy coupler head, while at the front end are two large marker lamps. The car is fitted with air and hand brakes.

At the middle of each end sill is a heavy casting with two lugs having holes for the vertical standard which supports the pole lever. The pole is 6 ins. diameter and 10 ft. 1 in. long, its heel being pivoted to the vertical standard, between the two lugs. The pole is handled by a horizontal lever pivoted at the top of the standard, the inner end of the lever being counterweighted to balance the weight of the pole, and the outer end being connected to a shackle near the end of the pole by a tie-rod and turnbuckle. The pole can thus be swung round horizontally to engage with or clear the poling sockets attached to the corners of the freight car frames, and its end can be raised or lowered to adjust it to the varying heights of the cars. The platform is about 4 ft. 6½ ins. above the rails, so that the men are well placed for handling the pole. A curved arm supports the end of the pole when it is not in use. There is only one pole, with its operating standard and lever, but a socket casting is placed on each side of the car, and the pole can be transferred from one side to the other when necessary.

A NEW SYSTEM OF SEWER ASSESSMENTS IN BOSTON.

After trying a great variety of plans for raising the money required for sewerage purposes in Boston, and finding it next to impossible to secure sufficient funds to carry on the work under any of the methods tried, an entirely new system is just being put in operation. The system seems rather complicated, at first, but a very slight study of it will show this appearance to be largely due to the bringing together of several methods of raising money which have heretofore been carried on separately. The only innovation seems to be the raising of three-fourths of the cost of maintenance in the form of sewer rentals, and the other fourth by general taxation, instead of securing the whole amount by taxation.

The law which made this method possible was enacted by the Massachusetts legislature in 1897, through the efforts of Mr. Josiah Quincy, Mayor of Boston. It was drawn by Mr. Andrew Bailey, Corporation Counsel. It provides that there shall be annually determined, before the first day of July, just and equitable sewerage charges to be paid by estates in said city for the construction, maintenance and operation of the sewerage works of said city, taking into consideration the necessity of the works as caused by each estate, the amount of the use thereof, if any, by the estate, or its occupants, the benefit received therefrom by each estate, the amount of any assessments for a sewer paid by any owner of the estate, the length of time which has elapsed since such payment, and the use, if any, that has heretofore been made of the sewerage works by the occupants of the estate, and such other matters as shall be just and proper.

In working out the details of the new system, Mr. F. Herbert Snow, Assoc. M. Am. Soc. C. E., of Snow & Barbour, Sanitary Engineers, Tremont Building, Boston, acted in the capacity of consulting engineer to Mr. Benj. W. Wells, Superintendent of Streets, and his deputy, the Superintendent of the Sewer Division, Mr. C. R. Cutter. These gentlemen were assisted by Mr. J. Frank Williams, Assistant Engineer in Charge of the Record office, and by the Chief Engineer of the Sewer Department, Mr. E. S. Dorr. Mr. Cutter was selected to supervise the investigation of various methods for Mr. Wells and to report his findings.

Under the plan adopted, the total sum appropriated by the city council each year for the maintenance and operation of sewers is to be divided into two parts, of one-fourth and three-fourths, respectively. The one-fourth is to be raised by general taxation of all the land in the city and the three-fourths on the basis of water charges on an amount of water used by each estate in the city.

The interest and sinking fund requirements for all sewerage bonds issued since June 21, 1897, are to be met in three ways, as follows: (1) By an assessment of $1.25 per ft. frontage on all land abutting on lateral sewers, using the word "lateral" to include all sewers with which house connections are made; (2) the cost of lateral sewers in excess of $1.25 per ft. frontage and of all district trunk sewers not used as laterals is met by general taxation of all the land in the district; (3) all the remaining charges for interest and sinking funds are to be raised by general taxation of all the land in the city. The bonds in question, it appears, run for 30 years.

The various sums chargeable, as described above, against any property are to be included in the regular tax bills and collected like other taxes.

We are indebted to Messrs. Wells and Snow for the information given. By referring to our issue of July 19, 1894, it will be seen that the new Boston plan is similar in principle to that recommended by Mr. Snow for Brockton, Mass., and adopted by that city. Besides Mr. Snow's exhaustive report for Brockton, which was abstracted in Engineering News of the date given above, those interested may consult with profit a symposium on the subject, giving the practice in six cities, published in the Journal of the Association of Engineering Societies for January, 1897.

◆

TEST OF AN ELECTRIC STREET RAILWAY POWER PLANT AT BROCKTON, MASS.*

This test was made to determine the performance of some new machinery installed in the power house of the Brockton Street Railway Co., and included tests to determine the following data:

Boilers.—Evaporative performance, commercial horse power, rate of combustion and rate of evaporation.

Engine.—Speed regulation, power and efficiency.

Generator.—Efficiency and capacity. The engine is a 700-HP. cross-compound condensing engine built by the E. P. Allis Co., of Milwaukee, Wis., with cylinders 20⅛ and 38 × 48 ins. The flywheel weighs 60,000 lbs., the rated speed being 110 revolutions per minute. A 24 × 12-in. Reynolds independent steam air pump and a jet condenser are also used.

Two specially designed vertical water-tube boilers rated at 200 HP. each are used. These have 222 tubes 2½ ins. in diameter and 15 ft. long and furnish steam at about 115 lbs. gage pressure.

Boiler feed water was taken from the city water mains and pumped through the main feed-water heater, which utilized the engine exhaust steam, thence through an auxiliary heater, which received the exhaust steam from the pumps and condenser, to the boiler.

Coupled directly to the engine is a 10-pole 500-K-W. railway generator built by the General Electric Co., of Schenectady, N. Y.

Generator Tests.—The armature resistance was obtained by the "Fall of Potential" method; that is, the armature was put in series with a water resistance and the bus-bars of the old part of the station, which were connected with the other generators. The resistance was adjusted to allow 100 amperes to flow through the armature. The drop in pressure between the terminals of the armature, as shown by a low-reading voltmeter, divided by the current flowing (100 amperes), according to Ohm's law ($R = \frac{E}{C}$), gave an average value of 0.0189 ohms. In the same way the series or compound winding gave 0.0026 ohms and the shunt field 47.1 ohms; the resistance being measured in each instance while the machine was hot.

To obtain the "External Characteristic" or curve which shows the variation of the voltage of the machine under different loads, the engine speed was maintained constant and the load varied from 0 to 800 amperes by means of a water resistance. At zero amperes the voltage at the machine terminals was 500, at 800 amperes 510 volts and at 910 amperes, 550 volts.

The "Electromotive Force Curve," or the curve showing the different values of electromotive force between the brushes, was obtained by the third brush method, one terminal of a voltmeter being attached to one of the brushes and the other to a movable brush which was slipped around the commutator towards the other machine brush, readings being taken at frequent intervals from the voltmeter. In this case the plotted values gave almost a true sine curve.

The efficiency of the generator was obtained by running it as a motor, to do which it was necessary to disconnect the connecting rod at the crankpin and the valve rods at the rocker arms, leaving the armature, flywheel, shaft, crank-disk, eccentric strap and rocker arms as the only moving parts. The shunt field was then excited from the station bus-bars. The armature was also connected to the bus-bars in series with the water resistance, already mentioned, which was gradually cut out until finally the armature was directly on the bus-bars and running at full speed. It was then found that the no load voltage at the machine terminals was 569; current through shunt field, 9.5 amperes; current through armature and series field, 47.5. This gave 569 × 47.5 = 27,027, say 27,100 watts, as the power required to turn the armature over at full speed without any external load. In other words, the amount of power necessary to overcome the internal losses of the machine, not, however, including C^2R losses, was 27,100 watts. The machine was rated at 500 K-W. and 550 volts at full load, or

$$\frac{500 \times 1{,}000}{550} = 910 \text{ amperes}$$

at full load.

$$\text{The efficiency} = \frac{W}{W + w + m}, \text{ in which}$$

W = useful output, or available output.
w = unavailable but used energy.
m = wasted energy, C^2R and other losses.

Using this to calculate the full load efficiency, we have

$$\frac{910 \times 550}{(910 \times 550) + [(550 \times 10) + 27{,}100] + [(910 + 10)^2 \times 0.0215]} = 90.8\%.$$

The stray losses (waste energy) and power required to magnetize the shunt field are practically the same for all loads, and the efficiencies for ½, ¼ and 1-10 load were calculated in the same way, using ½, ¼ and 1-10 the total current output.

The efficiencies found were lower than those guaranteed by the manufacturers, as shown in Table I.

TABLE I.

Load.	Per cent., efficiency. Found.	Guaranteed.	Corrected.
Full load	90.8	95.0	94.6
½	87.0	93.0	94.3
¼	78.7	91.5	91.8
1-10	60.4	...	...

This apparent discrepancy is explained by the fact that from 35 to 40% of the friction of a steam engine is due to the bearings and the air resistance to the flywheel's motion. The general value allowed for total engine friction is about 10% of the rated power, and this is practically constant for all loads. If the full load horse power be taken as 750, then 750 × 10% × 40% = 30 HP., or the amount of power absorbed by the bearings and air resistance to the flywheel.

Deducting 30 H.P., = 30 × 746 = 22,380 watts from the sum of the terms W + w + m in the efficiency calculations, the values given in the last column of Table I. will be obtained. These agree very closely with the guaranteed efficiencies.

The following table gives the results of the tests of boilers and engines.

The Boiler Test.

Date of trial	June, 1897
Duration of trial	10 hrs.
Number of boilers in use	2
Dimensions and Proportions:	
Grate surface of each boiler	33.18 sq. ft.
Grate surface, total	66.36 "
Water heating surface of each boiler	1,648 "
Water heating surface, total	3,296 "
Superheating surface of each boiler	502 "
Superheating surface, total	1,004 "
Ratio of water heating surface to grate surface	50
Ratio of total heating surface to grate surface	65
Average Pressures:	
Steam pressure in boiler, by gage, per sq. in.	112.3 lbs.
Atmospheric pressure per sq. in.	14.5 "
Absolute steam pressure in boiler per sq. in.	126.8 "
Force of draft in colm. of water beyond damper.	0.40 "
Average Temperatures:	
Of external air	85 degs.
Of fire-room	88 "
Of feed-water before entering 1st heater	68 "
Of feed-water before entering 2d heater	137.3 "
Of feed-water before entering boiler	197.1 "
Of escaping gases after leaving boiler	554 "
Of steam	384.4 "
Fuel:	
Moist coal consumed	10,149 lbs.
Moisture in coal	2.4%
Dry coal consumed	9,966 lbs.
Wood consumed	458 "
Coal equivalent of wood	183 "
Total dry coal consumed, incl. wood equivalent	10,149 "
Total dry refuse	817 "
Total dry refuse	8%
Total combustible	9,332 lbs.
Dry coal consumed per hour	1,015 "
Combustible consumed per hour	933 "
Quality of Steam:	
Number of degrees superheated	39
British Thermal Units:	
Heat units absorbed by boilers per lb. of steam generated	1021.4 B. T. U.
Factors of Evaporation:	
Factor of evaporation for boilers	1.06
Water:	
Total water pumped into boilers	98,119 lbs.
Water actually evaporated, corrected for quality of steam	100,007 "
Equivalent water from and at 212° F.	106,007 "
Equivalent water from and at 212° F. per hr.	10,601 "
Evaporation Performance:	
Water actually evaporated per lb. dry coal	9.85 lbs.
Equivalent per lb. of dry coal from and at 212° F.	10.44 "
Water actually evaporated per lb. of combustible	10.72 "
Equivalent per lb. of combustible from and at 212° F	11.36 "
Commercial Horse-power:	
On basis of 34½ lbs. of water from and at 212° F. per hour by boilers	307.3 H.P.
No. sq. ft. of total heating surface per horse-power	14
No. sq. ft. of water heating surface per horse-power	10.72
Rate of Combustion:	
Dry coal actually burned per sq. ft. of grate surface per hour	15.3 lbs.
Rate of Evaporation:	
Water evaporated per sq. ft. of total heating surface per hour from and at 212° F.	2.47 lbs.
Water evaporated per sq. ft. of water heating surface per hour from and at 212° F.	3.16 "

STEEL DOME AND SPIRE OF ST. PAUL'S CHURCH, CHICAGO, ILL.

The new St. Paul's Church, recently erected at the corner of Orchard St. and Kemper Place, Chicago, presents an interesting feature in the use of a structural steel skeleton framework for the dome and spire. The architects of the church were Messrs. Hill & Woltersdorf, and plans were invited for designs for a steel-framed dome and spire over the center of the church, one condition being that the members must be concealed by and not interfere with the domed ceiling provided for in the architect's design. This condition prevented the use of horizontal members between the masonry walls supporting the roof construction. The building is cruciform in plan, with the dome and spire over the center, and four gable roofs over the wings. Several designs for the steel framework were submitted, and the one selected was that prepared by Mr. Carl Binder, C. E., 903 Schiller Building, Chicago, by whom the work was carried on, and to whom we are indebted for plans and other information.

Fig. 1 is a view of the completed framework, showing the posts or columns of the spire resting upon one of the rings of the flat dome. The four roof trusses next to the dome are of steel, and to these trusses are attached the ribs of the dome, as shown in Fig. 2. The hip and valley beams are also of steel. Fig. 2 is a general plan and elevation, and clearly shows the character of the design. The base of the structure is formed by four A trusses which rest on the walls and have inclined bottom chords above the line of the ceiling. It will be seen that the horizontal member of these trusses forms also a part of the dome, and extends beyond the dome truss to the roof trusses. These members form an octagonal tension ring, to the corners of which are attached the ribs and bracing of the dome. Above this ring are an intermediate and an upper compression ring, the latter being 11 ft. above the tension ring, while from the former spring the eight ribs or columns of the spire, each of which is formed of channels connected by lacing bars. The height of the walls at the truss seats is 49 ft. 6 ins., and the top of the dome is 74 ft. 5 ins. above the ground. The belfry floor is 18 ft. 4 ins. higher, and above this the spire rises 127 ft. 3 ins., the total height from the ground to the top of the spire being 201 ft. 8 ins.

The eight ribs of the spire are connected by eight horizontal frames or bents, and unite at the top in a cap ring, above which rises the steel flagstaff. All the side panels, except those near the top, have diagonal bracing. Angle iron rafters attached to the main frames support the slate covering.

The loads and wind pressure assumed for the design are as follows:

	Lbs. per sq. ft.
Roof, including covering and steel framing	28
Church ceiling	15
Ringing floor	100
Belfry floor	250
Wind pressure (horizontal) for main members	30
Wind pressure (horizontal) for anchorage and connections	45

The ironwork was manufactured by the Universal Construction Co., of Chicago, and had to be shipped in small pieces, the work of connecting and fitting being all done in place. For the trusses and the dome a square wooden trestle tower, about 60 ft. high, was used, but above this no falsework was employed. Very little adjustment was required in erection. The work occupied about 25 days, and cost about $8,400.

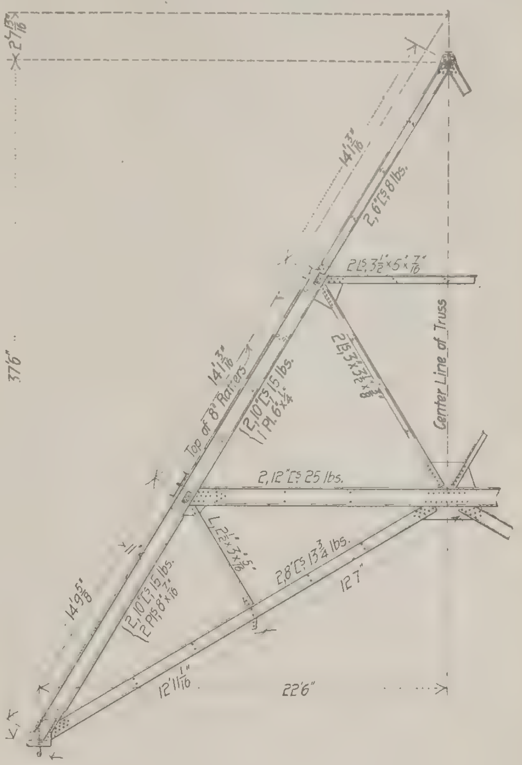

Fig. 3.—Details of Roof Truss.

THE RAILWAY SYSTEM OF PORTO RICO needs reorganization. Some years ago a line was projected making a circuit of the island along the coast line, and the provincial authorities finally made terms with a French company for its construction. This company promised to complete the belt system in six years, and the government gave the company the exclusive franchise for all railway construction for 99 years and guaranteed 8% on the cost of construction. Neither promise has been kept. Only three parts of the system are completed. The longest line is the 62 miles between San Juan and Camuy, on the north coast, with one train per day each way, besides two covering a part of the distance. Proceeding westward the finished work begins again at Aguadilla, and proceeds southward, 36 miles, to Hormigueros. At Yauco the line again begins and leads to Ponce, about 22 miles distant and on the south coast of the island. The company has also built a line, 14¼ miles long, from San Juan to Carolina. The three coast-line sections mentioned were built, equipped and put into operation within the time and in accordance with the terms of the franchise, as distinct parts of the general system. The provincial government accepted them under these terms, and recognized the obligation to pay the 8% interest; but the Carolina line has not been accepted by the government as complying with time and other conditions. When the first section was accepted the government began appropriating money annually to pay deficits and bring the interest-earning power up to 8%. Finally the people protested that the railway company was under obligations to build more railway and was not meeting its obligations, and payment on interest was stopped. Both of the French companies—one a construction company and the other holding the stock—have failed, and the charter has lapsed by its own terms, but has not been declared forfeited. No reports of operation are available, but freight rates are so high that transportation by ox-carts is said to be cheaper. The roadbed and equipment are in fairly good shape, all the latter being French in design and build. The gage of the road is 1.2 m., or nearly 4 ft., and the maximum speed is about 13 miles per hour. In addition to the lines named the same company has built a branch, of one meter gage, from Anasco, on the west coast, to San Sebastian, a distance of 21.7 miles. There is also a local tram-line, from San Juan to Rio Piedras, 6.8 miles long; and another tram from Catano to Bayamon, 6.2 miles long. This list includes all railways actually in operation on the island; and in this connection it is noted that most maps of Porto Rico show lines as in existence which are only projected.

The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number 328 *means that subscription is paid to the* 32d *week (that is the issue of Aug.* 11) *of the year* 1898; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line. Want noticees special rates, see page* 18. *Rates for standing advertisements sent on request. Changes in standing advertisements must be received by Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

Engineering News takes pleasure in presenting to its readers with this issue the first complete and official map to be published of the district surrounding Santiago, Cuba, and of the positions of the United States and Spanish forces during the investment and capture of the city. We are also able to give the first published statement of the work done by the engineer division during the advance upon Santiago. This statement is of no small interest at this time, since several well-known magazine writers and newspaper correspondents in their accounts of the Santiago campaign have taken occasion to criticise the engineers of the army for failing to do their part in the work of the campaign.

In his paper on another page of this issue, Mr. E. J. Chibas, of the engineering staff of the 5th Army Corps, shows that, despite published statements to the contrary, a thorough reconnoissance was made of the country lying between the Spanish and American forces prior to the advance of July 1. In the building of piers, everything seems to have been done that the exposure of the shore and the limited material and time available for the work would permit. In the work of building roads and bridges, the engineer battalion appears to have labored heroically and well; and the only reason why the rivers had to be crossed by fords instead of bridges was that there was no means of transporting the sectional bridges and other material which were taken to Cuba in the hold ot a transport, to the site where they were needed.

It will be borne in mind that the engineer troops which did service in the Santiago campaign were not the volunteer engineers, but the engineers ot the regular army, who have had long drill in the especial work that falls to their lot, and the officers engaged in the work were almost entirely commissioned officers of the engineer corps. These men knew their business as well as the regular infantry and cavalry regiments knew theirs; and from Mr. Chibas' account it seems evident that, so far as the engineers at Santiago failed to do the engineering work that was needed, it was due to circumstances beyond their control.

The Nominating Commitee of the American Society of Civil Engineers, appointed at the Detroit Convention, has presented a full list of officers to be voted for in January next, and it heads this list with the name of Mr. Desmond FitzGerald, of Boston, as the candidate for President. We believe the committee has made a wise choice, both in the selection of an engineer who deserves the honor, and in awarding the office to a locality which has hardly had its proper share in the selection of the Presidents of this Society.

Mr. FitzGerald, during his many years of service in connection with the Boston water supply and other important engineering works, has won for himself an enviable professional reputation; and his name ranks high among the engineers whose original research and whose contributions to professional literature have brought hydraulic engineering in this country to its present position.

Besides the question of personal fitness, however, it is certainly important that in a truly national society like the American Society of Civil Engineers, the highest honor which it can bestow should be given with some regard to the representation of all sections of the country. The Society now has members in every state and territory of the Union, except Nevada, North Dakota and Oklahoma. Of course in many of these the members are very few and widely scattered. Under these conditions the equitable selection of a President by location is a somewhat delicate task, especially as precedent requires that the selection of candidates should be made from the engineers who have become prominent by a long and distinguished professional career. As a natural result of the last condition, candidates must be generally selected from the older sections of the country, where engineering works of magnitude are most plentiful, and where alone employment in the highest grade of professional work is to be found. In looking over the list of Past-Presidents of the Society and classifying them by location at time of election, we find, that New York State has furnished 11 Presidents out of a total of 28. This is almost half of all the Presidents, but it is accounted for by the original organization of the Society in this city and by the fact that for a long time the bulk of its membership came from this section of the country. As the interest in the Society spread, Presidents were selected from other states, and the general list to date, and excepting New York, reads about as follows: Pennsylvania, four Presidents; Missouri and Illinois, two each; Louisiana, Kentucky, Wisconsin, Ohio, New Jersey, Maryland, Massachusetts, Canada and the Corps of Engineers, U. S. A., one each.

It will be seen from the above that New England has furnished but a single President for the Society; yet a very large membership is located there. Massachusetts alone has 128 members of the Society, in all grades, and at least 70 of these belong to the City of Boston. The only President ever selected from Massachusetts, or, in fact, from the New England States as a whole, is the late James B. Francis, who was elected in 1880. The nomination of Mr. FitzGerald, therefore, is not only the bestowal of the highest professional honor on a worthy candidate; but it is an appropriate recognition of a geographical section, which, both in the number and quality of its members, is a most important component part of the American Society of Civil Engineers.

We desire to call attention to the new plan of sewerage assessments recently adopted at Boston, and described elsewhere in this issue. The plan is similar in principle to that in vogue at Brockton, Mass., reviewed at length in our issue of July 19, 1894. It is based on the fact that since a sewerage system confers both public and private benefits upon a community, its cost should be divided between the municipality as a whole and individuals; or, in other words, that a portion of the expenses should be raised by general taxation and the balance be met by individuals who are benefited. The private benefits are divided into two classes, the actual use of the sewers, and the increased value of property because of the mere fact that sewers are available. Under the Boston plan, of the total cost of maintaining the sewerage system, one-fourth will be raised by general taxation and three-fourths by rentals for the privilege of using the sewers. The cost of sewer extensions and improvements is to be met partly by assessments on frontage, and partly by taxation, thus recognizing both the private and the public benefit. To carry out this plan, all sewerage construction is divided into three classes, namely, lateral, district and main trunk sewers and works, and the cost is distributed among these classes, as explained elsewhere. The plan is one of the comparatively few attempts which have come to our attention. to distribute the cost of the construction and maintenance of sewerage systems in a way that shall be really equitable to all parties concerned. The use of water charges as a basis of determining rentals for the use of the sewers has the double advantage af apparent equity and of tending to prevent the waste of water. The new plan will probably add somewhat to the clerical work of the city, sewer and tax departments, but not so much as might be thought at first, since for years past the cost of most of the new sewers has been distributed between frontage assessments and general taxation, and the charge for maintenance has also been raised by general taxation. Once the various charges are computed, they are added to the regular tax bills and collected in bulk with the other taxes, thus doing away with the separate collection of special sewerage assessments. In cities where sewer extensions are made only on private initiative, and where sewer connections are not compulsory, the Boston plan might retard the development of sewerage systems, since the placing of a lateral sewer in front of one's property means an assessment, and a sewer connection means a yearly rental. But, as we pointed out in our review of the Brockton report, the system is so arranged as to place a part of the burden of sewers upon all real estate, and having this to bear already there is an inducement to take the next steps and secure the full benefit of the system.

For over thirty years the Mississippi River has been the scene of extensive and costly experiments in removing the shifting sand-bars which impede navigation during the season of low water, but within recent years there have been adopted two general systems of improvement. The first of these is the establishment of permanent bank-protection works to rectify and improve the channel. The second is the use of hydraulic dredges of enormous capacity to cut channels through the bars which develop at every season of low water.

A peculiar feature of this dredging is that the entire benefit from it is reaped in the few weeks, or sometimes months, that the low-water season lasts. As soon as the depth of water in the river increases again, the shifting sands of its bottom are again set on their interminable travels, and long before the water comes again every vestige of the season's dredging work is wiped out. The same thing would be true even if dredges of ten times the size of the huge machines now at work were to undertake the task.

Beside the power to carve its way of the Mississippi in flood, man's largest machines are puny indeed. A very full and detailed account of the machines used, the work done, and the conditions under which the work is done, is given in a paper by Mr. J. A. Ockerson, M. Am. Soc. C. E., which was presented at the recent annual convention of the American Society of Civil Engineers, at Detroit. We give an abstract of Mr. Ockerson's paper in another column, but the paper is so comprehensive and so long that we are compelled to abbreviate it greatly. We would advise every engineer and contractor interested in dredging work and machinery to procure a copy of the complete paper, which is published in full in the June number of the "Proceedings" of the Society.

The paper forms a worthy addition to the list of remarkably good papers which have been recently presented to the Society on the bank-protection and levee building on the Lower Mississippi by Major Starling, Mr. Coppee and others.

UNIVERSITY OF ILLINOIS

THE COOLGARDIE PIPE LINE; A REMARKABLE ENGINEERING PROBLEM.

In our issues of Feb. 12 and 17 we described at some length the project for furnishing a water supply to the Coolgardie gold mining district in Western Australia, and criticised in some particulars the plans proposed for this work by an English Commission of Consulting Engineers. Since that time bids have been asked for the pipe to be used on this work, amounting to 246 miles of steel riveted pipe of 31 ins. diameter, and 3-16 to 5-16-in. thickness, and 82 miles of welded pipe of 26 to 29 ins. diameter and ¼-in. thickness. These bids were opened on Aug. 23, and no authentic statement of the award of the contract has yet been made; "The Iron Age," of Oct. 6, prints rumors that the contract has been awarded to two Australian firms, Mephan Ferguson, of Melbourne, and Hoskins Bros., of Sidney. Mr. Ferguson is the inventor of a novel longitudinal joint for steel pipes, which was illustrated and described in Engineering News of June 9 (p. 373), and which has been used on 8¾ miles of pipe for the Adelaide Water-Works. The above-mentioned rumor, however, still lacks confirmation, and our last direct advices were that to some extent, at least, the details of the conduit are still an open question.

We have also received, since we made our former comments on this scheme, the final report of the Board of Consulting Engineers (Messrs. Carruthers, Deacon and Unwin), upon the plans for this work, and very interesting reading it is.

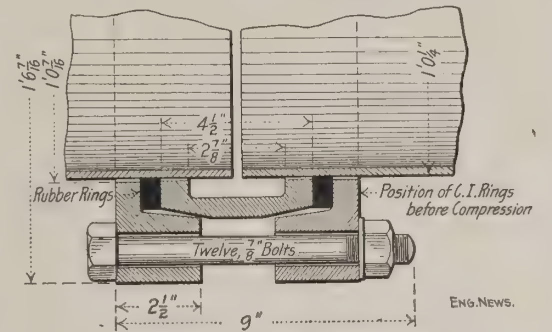
As our readers will recall, the project proposes the delivery of 5,000,000 gallons of water per day at a point in the interior of Australia, 328 miles from the reservoir in the mountains near the coast where it is impounded. To force the water through a pipe line for this long distance, not only must its friction be overcome, but it has to be actually raised a total vertical distance of 1,330 ft. Further, the district through which the pipe line passes is a desert whose soil is impregnated with salts, which are said to be so corrosive to iron that it is deemed safest not to bury the pipe in the ground at all. Another reason for leaving it exposed is that in a pipe line of such great length avoidance of leaks is essential. If an ordinary pipe line leaks a thousandth part of its flow in a mile, the loss may be a trifling matter; yet even so small a loss in a pipe line of this length would amount to nearly a third of its flow. In the arid desert through which this pipe line will pass, it is thought that the soil might absorb small leaks, so that they would not show at all on the surface of the ground if the pipe were buried. Facility of inspection, therefore, is another important reason for keeping the pipe above ground instead of burying it. Besides this, the ordinary reasons for burying water pipes—to get them out of the way, and to keep them from freezing in winter—do not obtain at all in the region over which this pipe line will pass; and as the cost of excavating and backfilling a trench 328 miles long will be saved by placing the pipe on the surface, the decision not to bury it seems, on the whole, a wise one.

The one great difficulty which is involved in keeping the pipe on the surface is the necessity of providing for expansion and contraction. In an ordinary line of pipe buried in the earth, the variation of temperature to which it is subjected is so small that the internal strains caused by the change of temperature do not reach serious proportions. To explain this more clearly! The modulus of elasticity of steel is about 30,000,000. That is to say, if a piece of steel of 1 sq. in. section be put under a tensile stress of 1 lb., it will be stretched $\frac{1}{30{,}000{,}000}$ of its length. The coefficient of heat expansion of steel per degree Fahrenheit is 0.0000065. That is, if a bar of steel be heated one degree Fahrenheit, it will be increased in length by $\frac{65}{10{,}000{,}000}$ of its original length. Dividing this coefficient by the one above given for the elasticity of steel, and we have a quotient of 195, as the stress per square inch that will be set up in a steel rod or plate by heating it or cooling it 1° F., and at the same time preventing it from changing its original length. Since the above coefficients are not exact, however, we may as well take the stress per square inch per Fahrenheit degree as 200 lbs., a quantity which is worth memorizing, as it is often convenient to use in calculations.

In an ordinary continuous steel conduit, buried in the earth in a temperate climate, the extremes of temperature of the water passing through it will probably not exceed 35°. If we suppose that the conduit is under no strain when at its mean temperature and is under compression during warm weather, and under tension during cold weather, the maximum internal stress will be:

$$\frac{35}{2} \times 200 = 3{,}500 \text{ lbs. per sq. in.}$$

Turning now to the Coolgardie conduit, to be laid unprotected on the surface of the ground, and with a distance between pumping stations as great as 75 to 80 miles, it is evident that the water confined from evaporation and exposed in a steel pipe to the fierce rays of the Australian sun, may reach a very high temperature in its passage from one pumping station to the next, which in the case of the longest conduits will require nearly three days. The English engineers estimate the range of temperature which will occur in the pipe line at 75°; and we should think this rather an under estimate. It will be seen at once that with such a range of temperature, internal strains would be set up in the pipe which might become so great as to cause movement and leakage at the circumferential joints. Expansion joints are, therefore, essential to the safety of the pipe; and the English engineers propose that such joints shall be placed at intervals of about 120 ft. for the whole length of the conduit, which would make a total of about 15,000 expansion joints in the length of the conduit.



Section of Expansion Joint for the Coolgardie Water Supply.

The engineering problem presented then (and one which we need hardly say is without precedent) is the design of an expansion joint for a pipe of 26 to 31 ins. diameter, which shall provide for a motion reaching ⅝-in., which shall sustain pressures reaching 200 lbs. per sq. in., which shall be and remain tight, with little or no attention, and which shall be as nearly as possible a permanent part of the pipe line. Our readers will be interested, we are sure, in learning what solution Messrs. Carruthers, Deacon and Unwin recommend for this problem. We, therefore, print this portion of their report in full:

> Expansion Joints.—If the Coolgardie main is placed above ground, it is of the highest importance to have durable and efficient expansion joints. The amount of expansion to be provided for is large, about ⅝-in. per 100 ft. length, for a change of temperature of 75° F. So far as we know, no case has previously occurred in which the general expansion of a water main has required to be met by an extensive use of expansion joints. We have, therefore, been driven to consider and to recommend what is essentially a new expedient in such a case. It appears that, with such a range of movement, some form of stuffing-box joint must be adopted. After considering various forms, we have come to the conclusion that a joint on the principle of that used on the more recent Paris compressed air mains is well adapted to this purpose. (This joint is described in Reuleaux "Der Constructeur," 1869, as the joint of Normandy.) No form of expansion joint which has come under our notice, or which we have been able to devise, is simpler, cheaper, or likely to be more efficient than the Paris joint, although, so far as we can ascertain, it has not, up to the present time, been used for water mains, except for the joints of a 59-in. steel pipe, subject to a head of about 262 ft., recently constructed in connection with the water supply of Paris. The materials on which it depends have, however, been so used for a long time past, and we have no doubt whatever that a joint of this kind can be so designed as to be and remain perfectly watertight for such a time as would amply justify its adoption. Such a joint was constructed at our suggestion by Mr. Cleminger, the representative of Mr. Mephan Ferguson, patentee of the seamless pipe. We saw this joint tested on one of the seamless pipes several times up to a pressure of 500 lbs. per sq. in. It appeared so far to be quite satisfactory.
>
> We next thought it necessary to carry out prolonged tests of the joint in such a manner that the movements due to expansion and contraction of the pipes would be imitated. We send with this report a drawing and description of the joint so experimented with. It is substantially the same as that used in Paris. The trials, which were carried out under the direction of Mr. Deacon, indicated that the details of the design could be improved, but notwithstanding some defects of the experimental apparatus, which on the whole were unfavorable to the endurance of the joint, the results of the trials are excellent, and, in our judgment, fully warrant the adoption of a joint on this principle.
>
> The apparatus consisted of a 12-in. welded steel pipe, about 5 ft. long, divided transversely into three pieces, the two end pieces being fixed, and the middle pieces—3 ft. long—being free to move axially to the extent of about ¾-in. The joints shown and described on the drawing were placed round the open spaces between the three pieces. The pipe was charged with water maintained at a head of from 300 to 400 ft., and the central pipe was so connected with a steam engine that an approximately harmonic reciprocating motion in an axial direction, with periods of three to the minute, could be given to it.
>
> We believe that if expansion joints are placed at every 120 ft. in the Coolgardie pipes, the maximum annual motion which ought to be allowed for will not exceed ⅝-in., and we think that this range is only likely to occur if the pipes are emptied during extremes of local temperature. We, therefore, made ⅝-in. the maximum range of motion at each joint, and we have imitated the smaller and more usual annual movements by ranges of about ⅜-in., and the diurnal movements in an exaggerated way, by ranges varying from ¼ to 1-10-in.
>
> Four different qualities of vulcanized India-rubber were experimented with, and the general result was to show that the dearer qualities were not the best for this puruose. With medium qualities, used in two rings, the full range of ⅝-in. was repeated 990 and 1,420 times, respectively, before any leakage occurred, while 13,000 and 16,000 double strokes, respectively, of ⅛-in. were given with another quality of rubber of the same price before any leakage occurred.
>
> It is to be observed, moreover, that, on tightening up the bolts of the joints subjected to the ⅝-in. strokes, when the leakage amounted to about two drops per minute, they were further subjected to more than 13,000 double strokes of 5-16-in. each, during and after which no leakage occurred. We are satisfied that the diurnal contraction and expansion will not amount to anything like 5-16-in., and we therefore think that this may be regarded as a very severe test of diurnal work.
>
> The above observations apply exclusively to the two rubber rings encircling the two ends respectively of the central moving pipe. But, owing to the construction of the apparatus, the two joints themselves move through smaller ranges, but more or less in proportion to the difference of recorded motions between the central pipe and the joint. In one of these, made with a ring of the lowest quality of rubber used, this motion of the joints in relation to the two fixed end pipes, varied from about ⅛-in. to about 5-16-in., during the first 2,500 strokes, and subsequently from about 1-10-in. to ⅛-in. throughout the remaining tests, covering 37,605 double strokes. The motion of the other ring, with the medium quality of rubber, varied from about ⅛-in. to 5-16-in., during the first 2,500 strokes, and subsequently from about 1-10 to 1-16-in. throughout the remaining tests, covering 37,605 double strokes. During the whole 40,105 strokes, both these outer rings remained perfectly watertight, and were still watertight after the experiments had ended.
>
> It is believed that, unless leakage occurred, no sliding of the rubber took place, but that the whole of the displacement was satisfied by distortion of the rubber. It must not, of course, be expected that the rubber will endure for the number of years corresponding with the number of repetitions of double strokes of the longer ranges, each of which was completed in one-third of a minute. Other elements will probably conduce to the deterioration of the rubber, before the mechanical strains to which it will be subjected cause the joint to leak. But it is one advantage of this joint that the replacement of the packing is not a very serious matter. Other advantages are the lateral flexibility of the joints, which permits of considerable angular movement of any two adjoining pipes, and the facility with which any length of pipe may be rapidly removed and replaced.
>
> On the whole, we regard the result of these experiments as most satisfactory, but the larger joint required for the Coolgardie main must be carefully and specially designed. In the case of the riveted pipes, a seating must be pro-

vided at the ends of the pipes to receive the expansion joints. This must be a steel ring with countersunk rivets.

The joint which was subjected to the tests above described is shown in the accompanying cut. It is a simple form of double stuffing-box joint. The details of the experiments upon it we do not reproduce, as they seem to us absolutely inconclusive. An expansion joint might work very well on a 12-in. pipe, and very poorly on a pipe of nearly three times the diameter. More important than this, however, is the fact that the tests ignored the element of time. The movement of the joint was effected by the deformation of the rubber packing rings, and not by their slipping on the surface of the pipe. Now, soft and elastic rubber has a very short life, especially in such a hot and dry climate as that of West Australia. The engineers, indeed, hint at this in one of the paragraphs above quoted; but they seem to think that the replacement of the packing rings will be no serious matter. Perhaps this may be true, if the packing can be renewed while the conduit is in service, and if the rings have a reasonably long life, say two or three years. It is by no means clear to us, however, that the packing rings could be renewed without emptying the conduit; and if the rings should require renewal every few months, it would very seriously interfere with the usefulness of the whole water supply plant.

At last accounts the question of the design to be finally adopted for these expansion joints was still open. The specifications on which bids were received Aug. 23, did not require the contractor to furnish the expansion joints, although a clause provided for the receipt of designs in which the longitudinal seams of pipes were made by other means than welding or riveting, accompanied by designs for expansion joints suitable for such pipes. Whether any such designs were received, we are not yet informed.

In searching for previous instances of the use of expansion joints on long lines of pipe of large size, the only example we have been able to find is the system of underground mains of the New York Steam Co. In this system, expansion joints made of thin corrugated copper plates are used; and have proved eminently successful. The joints were fully described by the late Chas. E. Emery, their inventor, in Trans. Am. Soc. C. E., Vol. XXIV., p. 188. The largest of these pipes, however, are about half the diameter of the Coolgardie conduit, and the application of joints of this type to pipes of such large size might involve some difficulties. The advantage of an all-metal expansion joint, with no parts depending on a sliding contact, or on the elasticity of perishable materials, is evident enough, and would be worth considerable added first cost to secure.

Turning now to some other features in connection with this project, we note that the specifications require all plates and pipes to be dipped in a bath of dilute sulphuric acid and scrubbed if necessary to remove the mill scale, followed by a bath of lime water. The plates must then, before exposure to the weather, be dipped in a bath of Trinidad asphalt and creosote of a composition satisfactory to the engineer. The pipes must be heated to about 300° F., before dipping in the bath.

The Commission of English engineers, in their report, remarked that the asphalt coating on the exterior of the pipes, if unprotected: "Will soon dry and become brittle by exposure to sunshine, and lose those properties which cause it to adhere to steel." To prevent this they recommended that, after laying, the pipe should be given a coat of lime whitewash with enough size to make it adhere firmly.

Steel for the pipes must be open-hearth acid steel, with ultimate strength between 25 and 29 tons, elongation in 10 ins. of 20% and reduction of area of 45%. A drifting test is also required as follows: A ⅝-in. hole punched within 1¼-in. of the edge of the plate must drift cold to 1⅛-in. without signs of fracture. Hot and cold bending tests may also be made to the satisfaction of the engineer.

The welded pipes are to be made in lengths of 9 ft. 2 ins., and these are to be riveted up at Midland Junction, West Australia, into 27½-ft. lengths. The joining up of these lengths into the 110-ft. lengths, which will be joined by stuffing-boxes, is to be done by the Colonial government. The unit lengths for the riveted pipe is 7 ft., and these will be joined up into 28-ft. and 112-ft. lengths. Longitudinal seams in riveted pipe will have two rows of rivets. The joinings of the rings will be on the telescopic plan, every alternate ring being of smaller diameter than the rings on either side by twice the thickness of the plate. All rivet holes may be punched except those in the circumferential seam by which the 28-ft. lengths are joined together.

To prevent creeping of the pipe, an anchorage will be provided at the middle of every 112-ft. length. Here two of the 7-ft. rings are joined by a butt joint and cover ring, and three pieces of angle iron are riveted on for attachment to the anchorage.

In our review of the project in our issue of Feb. 17, we suggested that the use of wood stave pipe for the Coolgardie pipe line would solve the many difficulties from contraction and expansion and corrosion by the soil. We are informed, however, that the pressures on most of the line will be so great as to make this class of pipe inadmissible. Its use is under consideration, however, for a large mileage of smaller pipes which will be necessary in distributing the water from the main reservoir at Coolgardie to the various towns and mining camps in the district. A question in connection with its use on which more information is desired is to what extent water is lost from existing wood stave pipes by small leaks and by evaporation from the surface of the pipe. The latter, it is thought, might be a source of considerable loss in a climate so dry as that of West Australia, if the pipe line were exposed to the sun for long distances. If any of our readers can furnish us information upon this point we shall be pleased to receive it.

LETTERS TO THE EDITOR.

Duty Record of the Indianapolis Pumping Engine.

Sir: I notice in your issue of September 29th an abstract of a report made by me to the Indianapolis Water Company upon a test of the 20,000,000-gallon Snow pumping engine recently installed at Indianapolis, in connection with which you refer to the performance of the Leavitt pumping engine at the Chestnut Hill Station, Boston, as published in the edition of Peabody's Thermodynamics, just issued. You note that while the duty, on a heat unit basis, of the Indianapolis engine is higher than that of the Leavitt engine, the steam consumption per horse-power per hour of the Leavitt engine is lower. I would add, as a fact which is of interest in this connection, that it appears from the data to which you refer that the Leavitt engine worked under a steam pressure of 175.7 lbs., which is 20.1 lbs. higher than the pressure available for the Snow engine.

Respectfully, W. F. M. Goss.

Purdue University, Lafayette, Ind., Oct. 8, 1898.

NOTES AWHEEL IN BOSTON AND VICINITY.

(Editorial Correspondence.)

For some years past Boston and vicinity has been the scene of a large amount of interesting engineering work, much of which is still in progress. A large part of this work is being carried out to meet the municipal wants of what may be called the metropolitan district. Most of it has been described in Engineering News at some stage of its progress. The following notes relate chiefly to work in the metropolitan district. They were secured on a bicycle trip made the latter part of September. The writer found a wheel a most excellent means of getting about the metropolitan district, the distance between points of interest being short, the grades generally easy and the roads for the major part of the 250 miles traversed most admirable. The days were long ones, but they need not have been so long, nor the total distance so great had not the writer wished to make his headquarters at picturesque and historic old Concord.

In recording what he saw and heard, no attempt will be made to follow the order of the trip. Instead, facts bearing on the different pieces or systems of work will be brought together.

The Metropolitan Water System.

Enough work on this system had been accomplished early this year to permit the introduction of water from the Nashua River, supplementing the supply from the Sudbury River and Lake Cochituate and cutting off the Mystic supply, which was objectionable in quality. The water from the Nashua River is diverted by a temporary dam, just above the site for the permanent one, into the Wachuset aqueduct, which changes to an open channel and empties into what was formerly known as Basin No. 5 of the Boston water-works, but is now the Sudbury Reservoir of the Metropolitan System. From here on, the waters of the Nashua are mingled with those of Boston's earlier sources of supply, passing through the old aqueduct. From the Chestnut Hill reservoir the mingled waters are pumped for the high service of the district. Some of it goes to Spot Pond, the former supply of Malden, Melrose and Medfield, and part of this will again be repumped to a high service reservoir described later on, both Spot Pond and the new reservoir being in the beautiful Middlesex Fells Reservation of the Metropolitan Park System.

At the Chestnut Hill pumping station a 30,000,000-gallon Allis high duty pumping engine is now being erected, and three 35,000,000-gallon low duty Allis pumps, working under a head of some 60 ft., are to be placed in a new pumping station. The high duty pump is a fine piece of workmanship. Its pump cylinders will support the rest of the machine.

It is hoped that the contract for the new dam at Clinton will be let next spring. About 1,000 wash drill and 30 diamond drill borings were made at the site of the dam in 1895 and 1896. Connected with this reservoir there will be two immense dikes, the North one being about 9,500 ft. long and the South one, about 4,000 ft. long. The latter will have a core wall, but the former will not. The contract for the eastern part of the North Dike was let on Aug. 22 to Joseph Genarro, of Boston, and work was already well under way when the writer visited Clinton. The maximum fill on this section will be about 85 ft. Preliminary wash drill borings were taken on every square of 100 × 100 ft., and on the center line of the dike the same kind of borings were taken at intervals of 50 ft. Some of these were 265 ft. deep and their average depth was about 110 ft. The location of the North dike will be about 100 ft. nearer Clinton than that recommended in the special report of the Massachusetts State Board of Health. A cemetery is included in the site, from which the remains must be removed. The contract for the western portion of this dike and for the whole of the South dike have not yet been let. The dikes will have outer slopes of 4 to 1, and will be composed principally of the soil which is to be stripped, as a sanitary precaution, from the site of the reservoir. The central part of the North dike will be constructed of selected material, and there will be a secondary wall of selected material some distance down the slope, outside of the first one. These precautions are being taken to prevent the possibility of sliding which might occur if water should get into the soil composing the dike and change it to a somewhat pasty mass.

The new reservoir at Clinton will have a storage capacity of over 60,000,000 gallons, or about double that to be formed by the New Croton Dam. It will have a length of 8½ miles and a shore line of 35½ miles. New highways will probably be constructed around the reservoir, about one-third of this having already been done.

One of the most interesting features of the new reservoir is the blotting out of a large part of two towns and the destruction of the water power of the Lancaster Gingham Mills, employing 2,500 hands, when working full force. The mills have been paid about $500,000 for their water power, and are spending some $600,000 for improvements, most of which will be for the installation of a steam and electric plant. The mills will hereafter be operated by electricity, in 100 to 150-HP. units, thus doing away with long lines of shafting. Mr. Chas. H. Richardson is agent for the Lancaster Gingham Mills.

Altogether millions of dollars will be spent for the sanitary protection of the waters of the new reservoir at Clinton. The bulk of this will be for stripping the site of organic matter. In addition, a sewage disposal system for the city of Clinton will be built. Contracts have been let for this work and construction started. It includes about a mile of intercepting sewers, having a maximum diameter of 30 ins., a 600,000-gallon receiving reservoir, a pumping plant and 23½ acres of filtering area divided into 25 beds. The reservoir will have a bottom and roof of groined arches, built of Portland cement concrete, 4 parts screened gravel, 2½ parts sand and 1 of cement. The centering of all arches is to be placed before any are built, the desirability of which practice seems to have been impressed upon Boston engineers by the recent failure of the reservoir roof at Wellesley, Mass. The bottom of the reservoir is designed to sustain the upward pressure due to a 12-ft. head of water, the reservoir being close by the river. For about a half month each year the ground water level may be 5 ft. higher. To provide against this, that is, to keep the head at 12 ft., instead of 17 ft., underdrains are to be laid beneath the bottom and a relief pipe carried up through it, with its top at such a level as to draw off 5 ft. of ground water. The reservoir is to be 100 ft. in diameter, with elliptical groins at the top, and circular at the bottom, the bottom to be filled in as desired to facilitate draining and cleaning.

The high service reservoir in the Middlesex Fells, mentioned above, will have a storage capacity of 38,000,000 to 40,000,000 gallons. It will be formed partly by excavation, much of which is in rock, and partly by five dams. The dams have concrete core walls, plastered with cement. The bottom of the reservoir will be covered with 4 ins. of Rosendale cement concrete, and the inner slopes of the dams, to 4 ft. below low water, with 4 ins. of Portland cement concrete. The inner slopes of the dams will be 2 to 1, as far as the lining extends, and 4 to 1 above that, gravelled. In rock excavation the slopes will be given no treatment, unless on trial it proves necessary to prevent leakage, or unexpected fissures develop as the work progresses. There will be a division wall formed partly by natural rock, the balance being of concrete. The water surface, when the reservoir is full, will be at elevation 271, Boston datum, and its bottom will be 17 ft. lower. Two pockets of muck are being removed, one going down 12 ft. below the bottom. The reservoir, as stated above, will be filled from Spot Pond, not far distant, by pumps yet to be placed in a station not yet built. Spot Pond has a high water surface of 154 ft., or 20 ft. above the Chestnut Hill Reservoir, from which water is now pumped to supplement the yield of the drainage area of the pond. A 36-in. force main will lead from the Spot Pond pumping station to and through the new reservoir, so the service may be direct, if desired.

Mr. F. P. Stearns, M. Am. Soc. C. E., is Chief Engineer of the Metropolitan Water System, with Messrs. Jos. P. Davis and Alphonse Fteley as Consulting Engineers. The heads of the several departments are as follows: Distribution, Dexter Brackett; Sudbury, Desmond FitzGerald; Dam and Aqueduct, Thos. F. Richardson; Reservoir, Hiram A. Miller. Mr. Reuben Shirreffs is Principal Office Assistant. All of these gentlemen, it is hardly necessary to say, are members of the American Society of Civil Engineers.*

The New State Road in Concord, Lincoln and Lexington.

The state road work of the comparatively few states that have taken it up with vigor and intelligence has now been in progress long enough to show most admirable results, both in state roads completed and in the stimulus given to improved road building by local authorities. Naturally, with limited appropriations available and large mileages demanding attention, the work must be done piecemeal. But after a few years stretches of fair length are developed in some sections. One of the longest of these in Massachusetts, and a fine example of road work, too, extends for some seven miles in the towns of Concord, Lincoln and Lexington, on the route from Concord to Boston. The work was begun in 1895 and has been continued each year since. A missing length has just been completed, and a start is just being made on a section continuing on well into the center of Concord.

Under the statutes authorizing this work, the towns in which it is done have the privilege of taking the contract for it. At first each of the three towns took the contract, Concord subletting it, but this year none of the work is being done directly by the towns. The towns were thus compelled to buy stone crushers, rollers and other road building plant, one of them after having voted down such a proposition yearly for many springs in the town meeting. This town has since been building some improved road on its own account, thus fulfilling one of the great objects of the state work and of letting the towns take the contracts for it.

On the stretch of road being finished there were in use a Buffalo Pitts Co. steam roller, of about ten tons net weight, and a Studebaker sprinkler, with very wide tires and wheels gaged to overlap, thus acting as rollers. The improvement consists of 15 ft. of macadam, with 5-ft. shoulders, making a total width of 25 ft. The macadam is 6 ins. deep at the center and 5 at the sides, in three layers. The first layer is of 2½-in. stone 4 ins. deep; the second of 1¼-in. stone 2 ins. deep; and the last is of dust from the crushers. The gravel shoulder is 6 ins. deep. The gravel is paid for by the yard, spread, blue gravel hauled some distance costing 60 cts. per cu. yd., on this year's contract. Most of the stone is of trap rock, from ledges along the road, but some is field stone, hauled by farmers. The crushed stone cost $1.45 per ton, in place. There is but little competition. For culverts, the inside masonry is of rubble, and the outside is laid in Portland cement. Where there is only 2 ft. of dirt fill above the culverts iron pipe is used for the channel; where more than this, sewer pipe, the diameter generally being 12 ins. Sometimes a stone channel is used. The roads are drained with tile pipe, where necessary, and always when they abut upon banks or hillsides.

The crown of the roads is ¾-in. per ft. of width for macadam and 1 in. for the gravel. This brings to mind one of the greatest faults of the ordinary road; it is allowed to sag so that that water runs in it on grades and stands in it on level stretches, to the destruction of the road in either case.

Fences are placed where necessary for safety. They consist of 6-in. chestnut posts, 8 ft. c. to c., with the upper edge of the top rail 3½ ft. above the ground. This rail is 4 ins. sq., set with corner up, being notched half its width into the post and having joints formed by halving the ends onto each other. Half way between the rail and the ground is a 2 × 6-in. plank, generally let into the post from 1 to 2 ins. The rail and plank are of spruce, planed, and given one coat of white paint. The rails and plank are in 16-ft. lengths, and break joints. This fence costs about 15 cts. per lin. ft.

At intervals along the state roads notices, printed on cloth, are posted, warning the public that

> any person who injures or defaces trees, guard rails or other structures, or disturbs or removes road material or other property of the Commonwelth on any State road will be prosecuted.

The placing of placards, signs or advertising devices within the limits of state roads is also prohibited. Quotations are also made from the Acts of 1893, Chap. 476, Sec. 14; Acts of 1894, Chap. 497, as amended by Acts of 1897, Chap. 355, Sec. 1, all bearing upon the making of openings in and repairs to the state roads. These roads are placed under the police jurisdiction of the local governing bodies.

Most of the information given above was obtained from Mr. F. P. Cutter, of Lexington, Mass., Resident Engineer on the road work described. Mr. Mills is Chief Engineer of the Massachusetts Highway Commission.

The Metropolitan Park System.

Only a part of one day could be devoted to the park system. The start was made from Concord, Mass., over the seven miles of state road already described, then through Arlington to the Mystic Parkway, extending along the Mystic Lakes. At Winchester a turn was made into the Middlesex Fells, crossing here over a causeway dividing the Winchester reservoir and passing along Spot Pond, up and down hills and out on the Malden Boulevard. The Mystic Parkway is an example of engineering and landscape work carried to a high state of perfection, but without over-elaborateness or too much ornamentation. In the Fells, science and art have attempted little or nothing except to make the beauties of nature accessible to man. Men were at work raking stones from the roads and clearing up tangled underbrush. The roads were mostly in good condition, but with rather heavy grades, which last could not be avoided, perhaps, without making too deep gashes in the hills.

One rather startling thing that met the eye in these woods was a piece of bagging tied around nearly every tree, a few feet from the ground. The vast amount of work involved in this is a good example of what the carelessness of one man may cost a whole state or nation. Years ago a naturalist brought home some Gypsy moths to this country as specimens, and allowed them to escape. They have so multiplied and proved so destructive that the state of Massachusetts is now spending some hundreds of thousands of dollars annually in the endeavor to exterminate them.

From Malden the course taken led on through several towns to the Revere Beach Reservation, a strip of ocean front which has been provided with an immense bath-house and a grand boulevard a mile or more in length, connecting with a fine piece of state road. During the past season 140,400 bathers patronized this bath-house, the greatest number in a single day being 5,508 on a Sunday. The total number would have been greater had it not been for a fire on Sept. 6, caused by overheating in the drying room. This was confined to the upper floor of the bath-house, but damaged the drying room and offices to the extent of some $30,000. The establishment was in operation again in two days, the work, where necessary, being done by hand. The beach is accessible from Boston in a very few minutes' time, and the fare each way is only 5 cts., by either the electric cars or the Boston, Lynn & Revere Beach Ry. Thus Boston has provided what is, perhaps, an unparalleled seaside resort, available for the humblest.

The curbstones and gutters along the boulevard are of concrete, made in sections, in place. The curb is about 7 ins. wide at the top, 9 at the bottom, and 18 ins. deep. The gutter is some 2 to 2½ ft. wide. Tar paper is placed between each joint. The curbs are of ordinary concrete, faced with ¼-in. of neat Portland cement. All the stonework around the shelters is of the same material, which was all built by the Murdoch Parlor Grate Co.

Mr. Chas. H. Howes is the Resident Engineer at the Beach, and Mr. Wm. T. Pierce is the Chief Engineer of the Metropolitan Park Commission.

The Massachusetts-New York Boundary Line.

A remarkable piece of instrument work in the way of long sights was described in our issue of Dec. 23, 1897, in connection with a re-establishment of the boundary line between the states of Massachusetts and New York. Subsequent surveys have verified the accuracy of this line, which was 38 miles between points, and it has been officially adopted by the State of New York, through its state engineer, Mr. Campbell W. Adams. The engineers of 1787 stated in their report that they had run the line as closely as possible with the instruments available, and the recent work shows that they did remarkably well, considering their facilities.

Boundary posts are now being set along the line at all highway and railway intersections, mile posts and important summits. Of these posts 44 are of 12 × 12-in. × 9-ft. New Hampshire granite, at highways; 38 are of 12 × 12-in. × 5-ft. Connecticut granite, at mile points or summits; and 29 are iron posts of 97 lbs. weight, 5 ft. long, about 4 ins. in diameter, with small oval heads. On one side of each head are the letters MASS, and on the other N. Y. The posts are set in concrete and their exposed portion is painted white, with the letters in black. Mr. Henry B. Wood, M. Am. Soc. C. E., is Engineer of the Massachusetts Topographical Commission, and we are indebted to him for the information given.

Improvements to the Water-Works of Winchester, Mass.

A high service system is now being added to these works, with Mr. F. L' Fuller, M. Am. Soc. C. E., 12 Pearl St., Boston, as engineer. A 20-HP. oil engine will drive a 500,000-gallon triplex Gould pump, lifting water to a stand-pipe 40 × 40 ft. With a full stand-pipe the lift will be about 125 ft.

---

*Previous articles on the Metropolitan Water System may be found in Engineering News for March 7 and April 4, 1895, and Feb. 25 and March 4, 1897.

The engine is of English design, known as the Hornsby-Akroyd, made by the De La Vergne Refrigerating Co., of New York.

* * *

DREDGES AND DREDGING ON THE MISSISSIPPI RIVER.*

By J. A. Ockerson, M. Am. Soc. C. E.

About 1870 the use of temporary expedients for improving the channel of the Mississippi River gave place to a system of permanent improvements, consisting of the closing of chutes, the contraction of wide places by means of jetties or dikes, and the revetment of banks. The inauguration of this policy, to the exclusion of temporary expedients, was evidently a mistake, due probably to the fact that the length of time required before tangible results could be realized by the so-called permanent method was very much underestimated.

In the meantime, competition of railway lines along the banks of the river, and difficulties of navigation, threatened to annihilate the river traffic. Immediate temporary relief must be found, or the river as a great commercial highway must be abandoned. In response to the appeal of the steamboat men, temporary channel improvements were again taken up, and were made obligatory by Congress, for the lower river, in the River and Harbor Bill of June 3, 1896.

In 1883 a plant was provided for dredging in the Mississippi River above the mouth of the Illinois River. This plant consisted of an Osgood dipper-dredge and six dump-scows, the whole plant costing $29,348. It was used with good results.

In 1887, a contract was entered into for a hydraulic dredge and decked flat-boats to support 500 ft. of discharge pipe, to be used in the district above named. Experience had shown that a dipper dredge could do good work under favorable conditions, but for opening temporary channels through bars it was found to be too slow in its operations and hence too expensive. A dredge provided with a centrifugal pump for pumping sand and water from the channel and delivering the same through pipes far enough away to clear the channel was manifestly an improvement. This hydraulic dredge was equipped with a Van Wie pump with a 14-in. intake and a 12-in. discharge. The pump was run at 330 revolutions per minute and the material was lifted about 9 ft. above the surface of the water and discharged from 300 to 800 ft. from the pump. The intake nozzle was provided with a jet supplied by a Worthington pump, to aid in stirring up the material so that the suction could take hold of it.

While this dredge was evidently a move in the right direction and was very useful in the upper river, its capacity was entirely inadequate to meet the requirements of the lower river. Here the dredging required at a single bar often exceeds 100,000 cu. yds., and the time permissible to remove this large amount of material is very short. To successfully accomplish this result machines were required of far greater capacity than any heretofore used or known.

In November, 1891, the representatives of steamboat transportation lines below St. Louis appeared before the Mississippi River Commission and urged immediate relief for low-water navigation. They stated that if such relief depended on the completion of the permanent improvement work, by the time it came, there would be no traffic. In response to this appeal, the Commission appointed a committee of two to study the subject of the construction and operation of such appliances for dredging as can be applied to the deepening of the Mississippi River over the bars in extreme low water; . . . and to prepare and report a project for the construction of a dredging boat of as large capacity as can be handled in the channel of the Mississippi River at low water with safety and convenience.

Col. Chas. R. Suter and the late Henry Flad, both members of this Society, were designated to serve on this committee. After a thorough investigation of the matter, the committee concluded that among the various devices for temporary relief, dredging was the only means which held out a reasonable promise of success. The problem involved so many new features in the way of the enlargement and combination of devices heretofore used, that the construction of an experimental dredge was recommended. Drawings and specifications for an experimental dredge were prepared under the direction of this dredging committee, and contracts for the construction of the various parts were let at the close of 1892.

Dredge "Alpha."—This experimental dredge was equipped with an Edwards centrifugal pump having a curved drag-suction at one end, and an Allis-Reynolds screw pump having a straight suction with jet agitators at the other end, the object being to make practical tests of the efficiency of the different devices. The pumps, engines and boilers were designed by their respective manufacturers. The Edwards pump runner was 6 ft. 4 ins. in diameter, and was operated by a compound non-condensing, vertical engine with cylinders 15 and 27 ins. in diameter, and 20 ins. stroke. The suction and discharge were each 30 ins. diameter. The Allis-Reynolds pump was operated by a similar engine, with cylinders 8 and 16 ins. diameter and 12 ins. stroke. The suction and discharge pipes were each 30 ins. in diameter. The jet pump was of the Allis-Reynolds pattern, with 15-in. suction and discharge. This pump operated six jets 2½ ins. in diameter under a head of about 20 ft. By this means the material was loosened and divided up so as to enter the suction of the sand pump thoroughly mixed with water.

The machinery was mounted on a wooden hull 130 ft. long, 36 ft. wide and 8 ft. deep. The dredge in working order drew about 4 ft. of water.

The material pumped was discharged through a floating pipe-line made up of sections of pipe 33 ft. long, connected by means of strong rubber joints and iron coupling bars. An air chamber on each side of the discharge pipe served to float it when loaded with 10% or less of sand. In order to operate the dredge, two hydraulic piles are set about 25 ft. apart, near the upper end of the bar to be excavated. A wire rope about 1,000 ft. long is attached to each of these and to the hauling drums on the dredge. If the wind does not deflect the dredge from its proper place, it is allowed to swing freely in the current with the discharge pipes trailing below it. If necessary, side piles are set, and by means of lines attached to them, the dredge can be hauled into such position as may be desired. In dredging, the boat is pulled ahead up-stream at rates varying with the depth of the material taken out, the average movement being about 60 to 75 ft. per hour. After one cut is finished, the dredge is dropped down again to the lower end of the bar, the head piles are moved over about the width of the cut and another cut is made near by and parallel to the first. This process is repeated until a channel of the required width and depth has been secured.

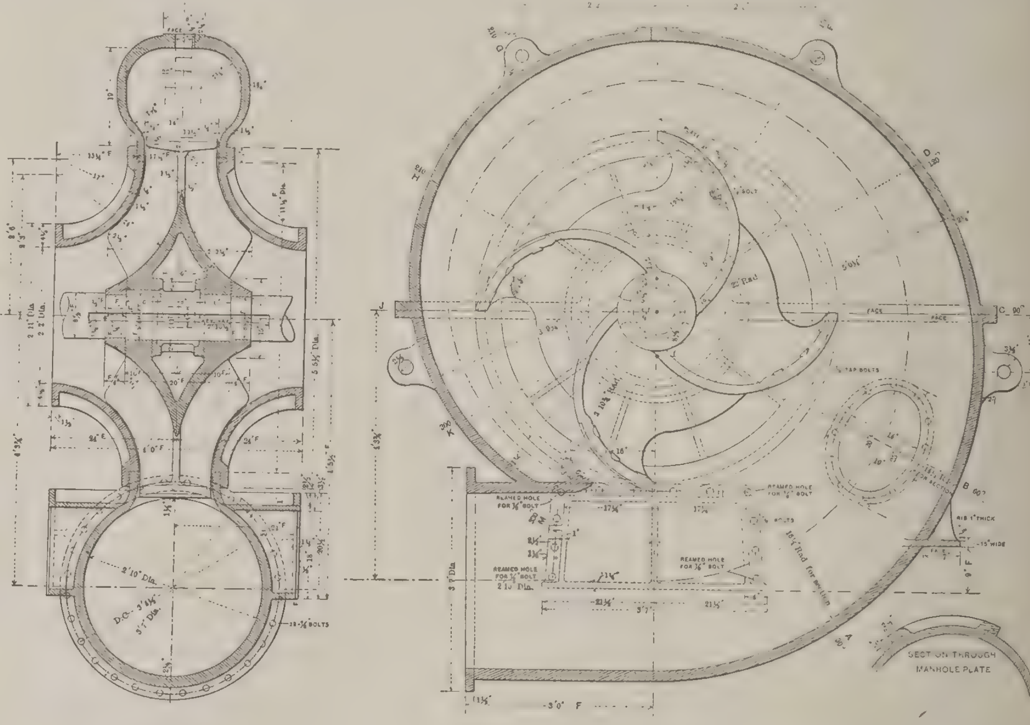


FIG. 1.—CENTRIFUGAL PUMP OF THE HYDRAULIC DREDGE "GAMMA"; MISSISSIPPI RIVER.

There is perhaps no single feature which facilitates this method of dredging as much as the hydraulic mooring piles.* The ease with which they can be set and withdrawn, and their great holding power, make them really indispensable where dredging is done in strong currents. They are sunk 15 or 20 ft. deep in the sand, and the head lines are attached to a shackle down at the surface of the sand, and consequently there is little danger of bending.

In the fall of 1894 the first attempt to aid navigation was made near Cape Girardeau, Mo., where there was a bar about 1,600 ft. long with from 3 to 4 ft. of water. Work began on Oct. 19, and by Oct. 26 a channel 6 ft. deep had been made and this channel remained good throughout the season.

With a view to get the benefit of the best dredging experience available, a circular was sent out in August, 1894, to engineers, contractors and builders of dredges, inviting "informal plans and suggestions as to the methods and machinery best adapted to the work." The capacity of the required dredge was to be 1,600 cu. yds. of sand per hour. Several replies were received, and three firms were requested to prepare detailed drawings and specifications of the plant they proposed to furnish. These were submitted in December, 1894, and a contract was let to the American Hydraulic Dredging Co., of Chicago, for the construction of the dredge "Beta," at a cost of $172,775. The dredge was completed and ready for testing in January, 1896.

Dredge "Beta."*—This dredge has two independent dredging machines complete from suction to end of discharge pipes. The sand pumps are of the centrifugal pattern with runners 7 ft. diameter and with 8 arms in each runner. The suction for each pump is 33¾ ins. diameter, and is split near the pump so that the water enters the casing from both sides. The discharge for each pump is from a single 33-in. pipe leaving the pump chamber from the top. The suction for each pump divides near the forward end of the hull into three sections, each 19½ ins. in diameter. A cast-iron elbow is riveted to the hull at the bow for each of the three branches, which are provided with elbows of hammered copper ⅜-in. thick, and these work in the iron elbows and form a radial telescopic joint. The axis of rotation is the center of a 7-in. shaft supported on brackets at the bow of the boat. These three suctions are framed together and can be raised or lowered, as one piece, through a depth of 20 ft.

Each of these suctions is provided with a vertical revolving cutter, 5 ft. in diameter, and 5 ft. long, with 12 nickel-steel blades on each cutter. These serve to loosen up the material so that it will readily enter the suction. There are six of these revolving cutters for the two pumps. They are spaced 6 ft. apart, c. to c., and are driven, through a system of spur gearing, by a cross-compound, non-condensing engine with cylinders 14½ and 29 ins. diameter and 18-in. stroke. The engines make about eight revolutions to one revolution of the cutters.

To support a portion of the weight of the cutter machinery, a pontoon is provided for each set of suctions. This pontoon is made of steel plates, and is built around the various pipes and frames. Each pontoon has a displacement of 1,000 cu. ft.

Each pump is operated by a direct-connected, triple-expansion, vertical, inverted, four-cylinder, tandem engine provided with jet condensers. The cylinders are 20½, 33, 38 and 38 ins. in diameter, and 24-in. stroke, with the cranks set at right angles. These engines are run at a speed of about 130 revolutions per minute, each being of about 1,250 I. HP., with boiler pressure of 175 lbs. Each engine is provided with a Worthington duplex air pump and jet condenser, with cylinders 14 and 19 ins. and 15-in. stroke. They are also arranged to exhaust without condensing. The steam is supplied by four Heine boilers, and mechanical filters are provided to free the boiler feed from water sediment.

The winding engines are placed near the bow of the boat. There are six drums, operated by a double cylinder, link-motion, reversing engine with cylinders 12¼ ins. diameter and 15-in. stroke. Four of the drums are 24 ins. in diameter and 40 ins. long. Two of these drums are used for side warping, and are geared 25 to 1. The other two are used for pulling the dredge ahead, and are geared 30 to 1; 1,200 ft. of ⅞-in. wire rope is used for this purpose. The two end drums, 30 ins. diameter and 28 ins. long, are used for raising and lowering the suctions.

At the stern of the boat is a steam capstan and a spud hoist. There are also two vertical anchor-spuds and one push-spud at the stern of the boat. The anchor-spuds are of oak, 24 ins. square and 40 ft. long. These were intended mainly as pivots on which to swing the boat, so that a wide cut could be made by moving the suction on the arc of a circle, but this method is not well adapted to streams with a strong current.

The machinery is mounted on a steel hull 172 ft. long and 40 ft. wide. It is 7 ft. 2 ins. deep in the waist, and for 36 ft. from the forward end and 16 ft. from the after end it is

---

*We are obliged to condense largely this long and interesting paper, which was presented at the annual convention of the American Society of Engineers at Detroit, in July. The paper is published in full in the June number of the Society's "Proceedings."

*A similar mooring pile, used on a later dredge, was illustrated in our issue of July 22, 1897.

*Illustrated and described in Engineering News of April 23, 1896.

10 ft. 10 ins. deep. These deep portions are decked over, as are also the guards, for the entire length.

The requirements of the contract fixed the limit of draft at 4½ ft., and the width at 40 ft. When the dredge was completed, the draft was found to be about 6½ ft. The total displacement when running, with suction and discharge pipes, boilers, filters, heaters, etc., full of water, and a supply of coal on board, is about 1,175 tons.

The discharge consists of two independent pipe lines, each 1,000 ft. long. A deflecting baffle plate is provided for the end of each line. Eight of the sections of each line are 100 ft. long, and four sections are 50 ft. long. When the pipes are empty, the pontoons draw about 14 ins. of water.

A number of defects were developed in the use of this dredge, many of which were remedied. At first the cutters all worked in the same direction, and the result was that the dredge was pulled sidewise out of the cut. This was remedied by changing one set of cutters to work in the opposite direction. The breaks in the gearing of the cutter machinery were frequent, although the spur gears were made of nickel-steel, and the pinions of phosphor bronze. The 6-drum hoist also gave considerable trouble. The cutters were found to be very much longer than necessary, and their operation drew heavily on the boiler capacity. The unexpected draft developed difficulties in coaling, and in manœuvring the dredge over the shoal bars.

The preliminary tests of the dredging machinery began in January, 1896, and continued until March. Of the 400 working hours embraced in this period, 255 hours were used in repairs and changes, and 74 hours in actual pumping. The capacity tests were begun on March 10 and continued for about a month. The tests show an average capacity of 4,920 cu. yds. per hour, and, therefore, according to the terms of the contract, a bonus of $86,387 was earned by the contractor.

During the low-water seasons of 1896 and 1897, the enormous capacity of the "Beta" was fully demonstrated. Before the dredge is again put into service for the low-water season of 1898, numerous changes will be made. The hull will be widened to 56 ft. and lengthened, so as to reduce the draft to 4½ ft. About $41,000 has been retained from the contract price to do this work, as the specifications required that the draft should not exceed 4½ ft. The cutter engines, cutters and other parts belonging to the present suction will be replaced by a jet suction and pumps. This is done because it has been found in actual practice that mechanical agitators are unnecessary in the sands of the Mississippi River. The wear and tear of the cutter machinery is a very large item of expense, to say nothing of the power required. The jet agitators are quite efficient, are much more economical in point of repairs and power required, and are more simple in manipulation. The push-spud and one anchor-spud will be discarded. The other anchor-spud will be moved to the bow of the boat, and the spud-hoist will be discarded. The forward battery of boilers will be turned end for end in order to properly distribute the weights under the new arrangements, and to improve the facilities for coaling. Much of this work would probably be deferred were it not that the boat must be put into dry dock to make the hull repairs, and this opportunity is seized for making the changes outlined.

Dredge "Gamma."—The Act of Congress of June 3, 1896, was the first to formally recognize and require the use of dredge boats and other devices as an adjunct to the permanent improvement of the lower Mississippi River. The act requires that as much of the money appropriated as may be necessary

> shall be expended in the construction of suitable dredge boats and other devices and appliances, and in the maintenance and operation of the same, with a view to ultimately obtaining and maintaining a navigable channel from Cairo down, not less than 250 ft. in width and 9 ft. in depth, at all periods of the year, except when navigation is closed by ice.

This formal recognition of the necessity of temporary relief for low-water navigation resulted in the construction of four more dredges.

The contract for the "Gamma" was let in July, 1896, to the Bucyrus Steam Shovel & Dredge Co., of South Milwaukee, Wis. The capacity required was 800 cu. yds. of ordinary river sand per hour, delivered through 1,000 ft. of pipe with a single centrifugal pump.. The price paid was $85,530, and the time fixed for completion was nine months. This dredge was used in actual work throughout the low-water season of 1897, and was found to be very satisfactory, both in capacity and economy. The hull is of steel, and is 128 ft. long over all, 38 ft. wide and 8 ft. deep. There is a well at the bow, 32½ ft. long, in which the suction is placed.

The main dredging pump is a centrifugal pump, with a 24-in. suction inlet on each side and a 34-in. discharge at the bottom. The runner is 5 ft. 9 ins. in diameter, and has four blades. It revolves at a speed of about 150 revolutions per minute. The pump is driven by a cross-compound, condensing engine with an independent condenser. The high and low pressure engines are horizontal, and are connected to two disk cranks set at right angles and keyed to opposite ends of the pump shaft. The cylinders are 18 and 32½ ins. in diameter, and 22-in. stroke. The high-pressure cylinder has an adjustable cut-off, with a hand adjustment to regulate the point of cut-off. Expansion relief-valves are provided for the low-pressure cylinder. These engines develop about 500 HP., with a boiler pressure of 140 lbs. The jet pump is of the centrifugal type, with 18-in. suction and discharge. This pump supplies the water to stir up the sand at the suction head. The runner has four arms, with steel tips, running as close as practicable to the casing, to obtain the greatest available pressure. This pump is shown in Fig. 1.

The main hauling winches are located on opposite sides of the boat near the bow. They are driven independently and are provided with fast and slow feed controlled by clutches. The drums are 42 × 42 ins., giving space for 1,200 ft. of ¾-in. wire rope. Each drum is driven by a pair of 7 × 7-in. double cylinder engines, with cam reverse, and the power is transmitted through a combination of worm and spur gearing. The movement is controlled by means of a brakewheel and strap. The speed ratio is 81 to 1 for fast, and 493 to 1 for slow speeds. The hoisting engine for raising the suction pipe has a drum 24 × 24 ins.

The anchor-spud is hoisted by means of an upright, single-acting, steam cylinder, 18 ins. in diameter and 6-ft. stroke. The piston is attached to a cam clamp at its upper end, which grips and holds the spud against the slides. Steam enters at the bottom of the cylinder through a three-way valve, raising the piston and spud to the height of its movement. When the valve is turned to the exhaust port the piston and clamp descend, the spud being supported by a rack and pinion. The pawl locking the pinion is hinged between its center of movement and point, and the tripping is effected by making the pawl buckle on itself so that the point turns under. This releases its hold and allows the spud to drop.

Steam for this plant is furnished by six boilers 48 ins. in diameter and 28 ft. long, with five 11-in. flues in each. They are designed to carry a pressure of 140 lbs. In front of the fire doors are coal bunkers having a capacity of 40 tons.

The two intake pipes at the pump casing run forward to the suction head. They are hinged to the boat at the bow by two flanges connected by a pivot pin on the lower side and provided with a circular stuffing-box, making a radial joint that will allow the suction to be lowered to a depth of 15 ft. Outside of the joint the pipe and suction head are framed together and rigidly connected so as to form essentially one piece. At the suction head the pipes are 11 ft. apart, c. to c. The suction head for each pipe is 8 ft. long and they are 3 ft. apart, forming one suction head 19 ft. long over all. The suction head proper has two inlets, one for the upper and one for the lower intake, and between the two is a triangular pressure chamber running the whole length of the head. This connects directly with the jet pump. This chamber has nine 2¼-in. nozzles through which the water from the jet pump is forced with sufficient pressure to loosen the sand in front of the suction. The discharge pipe is 34 ins. in diameter. The floating discharge pipe is 1,000 ft. long, divided into 20 sections, each 50 ft. long. They are made of ¼-in. tank steel, and the pipes are floated by means of 40 cylindrical pontoons, each 23 ft. 9 ins. long and 30 ins. diameter.

This dredge was tested near St. Louis, Mo., in August, 1897, and, after the completion of the tests, was used in actual dredging between Cairo and Memphis until early in December of the same year. The general efficiency test, called for by the contract, required that the dredge should be operated 60 working days of 12 hours each in water from 5 to 15 ft. deep, and with sand of such different degrees of coarseness as will be found on the low-water bars. After this had been done and the machinery found satisfactory, then 20 capacity tests were required to be made with the suction at different depths. This last requirement was considered filled when the total amount pumped per hour divided by 20 was equal to or exceeded the required capacity of 800 cu. yds. per hour.

The total weight is 1,019,623 lbs., and the working draft of the dredge is about 46 ins.

Construction was begun in June, 1896, and the dredge was practically completed in March, 1897.

Dredge "Delta."—This dredge was constructed under contract with the New York Dredging Co., which sublet the construction of different parts to various manufacturers and builders of machinery. The contract price for this dredge was $124,940. It differs from the "Gamma" chiefly in having a mechanical agitator instead of jets, in its hoisting and hauling winches, and in the form of pump. Its capacity is also somewhat greater. Its construction was begun in June, 1896, and it was practically completed by the end of June, 1897. After the tests were finished, this dredge was used in removing sand bars below Cairo throughout the low-water season of 1897.

The hull is of steel, 175 ft. long, 38 ft. wide, and 8¼ ft. deep.

The dredging pump is different from those on the dredges heretofore described, in the shape of the casing and the runner, Fig. 2. The runner has five blades 22 ins. wide, and is 7 ft. in diameter. The edges run close to the casing, but the runner is not concentric with the casing, hence the outer ends of the arms are nearer one side of the casing than the other, the widest space being at the bottom, and the space being nearly cut off by a projection in the casing at the upper side of the discharge opening. The axis of the pump is parallel to the axis of the boat and lies over the center line of the same. The shaft has one long bearing through the aft side of the casing, and is provided with water bushing under pressure to keep the sand out of the bearing. The sand pump is driven by a vertical, inverted, two-crank, compound-condensing engine, with cylinders 22 and 48 ins. diameter and 24-in. stroke. It is fitted with a piston and slide valve and has an adjustable cut-off for the piston valve. This engine was designed to develop 800-HP. at 140 revolutions per minute, with a boiler pressure of 160 lbs. and a vacuum of 25 ins.

The engine which drives the cutters is horizontal, two-cylinder and non-reversible, attached to a sliding steel frame, which moves back and forth in guides as the cutter is raised or lowered. This is necessary because the shaft which drives the sprocket chain is not in the axis of motion, on which the suction and cutter revolve. The whole engine, with its frame, follows the motion of the shaft, so that the gear and pinion are always engaged. To admit of this motion, the steam pipes are provided with slip joints. The cylinders of this engine are 12¼ ins. in diameter and 15-in. stroke, with the locomotive type of slide valve.

There are two winding drums located forward of the sand pump, one on the starboard and the other on the port side of the hull. These drums are provided with clutches and brakes, and are driven by two independent double-cylinder, horizontal engines with cylinders 10 × 12 ins.

The ladder hoist for raising and lowering the suction, and the spud hoist for raising the spud, each have drums 24 × 24 ins. The cables from these drums lead to the roof and thence out through sheaves to the ladder and spud. These drums are operated by the same engines that operat the winding drums.

Steam is supplied by four Heine safety water tube boilers rated at 250 HP. each.

The intake of the sand pump is from one pipe 34 ins. in diameter, entering in the axis of the pump at the forward side of the casing. This single pipe runs 25 ft. to the forward bulkhead and there branches into two pipes, each 24½ ins. in diameter, which separate and pass through the bow of the boat below the water-line, 9 ft. apart. These two pipes turn to the right and left square along the outside of the bow and then turn forward again and each branch separates into two pipes 17½ ins. in diameter, which connect with the suction head. The whole is framed together so that the four pipes, suction head and cutters are raised and lowered together as one piece. Instead of a radial slip joint for the suction pipes, as used on the dredges already described, there is a vertical flanged joint in the horizontal part of each pipe next to the bow, and the revolving pins that sustain the weight of the aft end of the suction are placed in the prolonged axes of these pipes.

The cutter for loosening up the material is placed at the outer end of the suction head. It has 22 cast-steel wheel cutters, each having four blades mounted on a steel shaft 6⅞ ins. square. This shaft is driven by the cutter engine by means of two steel sprocket chains, at a rate of about eight revolutions per minute.

The floating discharge pipe is 1,000 ft. long, with the usual rubber couplings at intervals of 50 ft. There are pontoon floats on each side of this pipe, U-shaped in section, with the flat side closed, and they sustain the pipes in yokes which are firmly attached to the floats. There is a baffle plate at the end of the pipe line. The dredge is provided with sixteen hydraulic piles, six of which are 10 ins. in diameter and 38 feet long, and ten are 6 ins. in diameter and 25 ft. long.

The total approximate weight is 1,375,608 lbs., and the weight of the floating pipe line is 221,477 lbs. This dredge was launched on Feb. 20, 1897, and the tests were completed Aug. 11, 1897.

Dredges "Epsilon" and "Zeta."—The construction of these dredges was begun early in January, 1897. They were built under contract with the Springfield Boiler & Mfg. Co., of Springfield, Ill. The work done by this company at its own shops was confined chiefly to the hulls, floating pipe lines, boilers and other plate work. The pumps, engines, etc., were sublet to other manufacturers.

The stipulated capacity of these dredges is 1,000 cu. yds. of ordinary river sand per hour, dredged from a maximum depth of 15 ft., and delivered through 1,000 ft. of floating pipe.

The dredges are alike throughout, except that the "Epsilon" has water jet agitators, and the "Zeta" has mechanical agitators. The contract price of the "Epsilon" is $102,000, and of the "Zeta," $106,000.

The hulls are of steel, 157 ft. long, 40 ft. wide and 7½ ft. deep. There is a well at the bow 35 ft. long, 18 ft. wide at the hull, and 22½ ft. wide at the forward end. There are two open spaces in the hull, one for the engine and pumps, and one for the boilers and coal bunkers. All other parts are decked over. It is divided into 11 water-tight compartments by two longitudinal bulkheads and five cross bulkheads.

The main sand pump, Fig. 3, is located on the axis of the hull, in the forward part of the engine pit. It is similar in form to that on the "Gamma," having a divided suction, consisting of two 24-in. pipes, admitting the water on both sides of the casing, and the shaft of the runner extends through the casing with a bearing at each side. The main bearings of the pump runner are protected from sand by means of a ring of water under pressure supplied by the fire pump. The discharge is from the bottom of the casing and is 32 ins. in diameter. The pump runner is 5 ft. 9 ins. in diameter and has seven blades 11⅝ ins. wide at the outer ends. It is run at a speed of about 160 revolutions per minute. Pressure gages are provided to show the suction and delivery heads.

The main engines which operate the pump are connected to the ends of the shaft passing through the pump runner by means of flange couplings. There is a tandem-compound engine at each end of the shaft, each having cylinders 16 and 26 ins. in diameter and 18-in. stroke. The cranks are set at right angles with one another. These engines are balanced in a horizontal direction, and automatic governors are provided to regulate the speed. They are designed to develop 650 HP. at about 180 revolutions per minute, with a boiler pressure of 150 lbs.

The "Epsilon" has a 15-in. centrifugal jet pump operated by a vertical cross-compound engine with cylinders 12 and 22 ins. in diameter and 12-in. stroke. The engine is on the same base as the pump, and is directly connected by a flanged coupling.

The winding engines and the hoisting and hauling drums are located near the bow of the boat. The drums are 42 × 42 ins., and hold about 1,200 ft. of ¾-in. wire rope in two laps. Each drum is operated by an 8 × 8-in. double cylinder engine provided with a link reverse and suitable clutches and brakes giving fast or slow motion, as may be required. The suction hoist drum is 14 ins. long, and 42 ins. in diameter, operated by a double engine with 8 × 8 ins. cylinders. The spud hoist is located just behind the anchor spud, and is also operated by an 8 × 8-in. double engine. It is used for raising or lowering the anchor spud. The drum is 21 ins. long and 42 ins. in diameter. The operator stands on an elevated platform behind the winches and controls their movements by means of vertical levers.

On the "Zeta" the jet pump is omitted and a mechanical agitator for stirring up the material is used. This agitator consists of a vertical scraper or harrow attached to the front end of the suction head, which is given an up and down motion by means of a bell crank. It is divided into two parts, which are suspended in front of the suctions. A connecting rod or pitman extends from each agitator back to the rear end of the well, where it connects with a second oscillating crank operated by an engine with cylinders 10 × 14 ins. These engines are connected through gearing to a common shaft extending entirely across the boat. In order to lessen the danger of breakage from snags or other solid obstructions, a shearing pin is provided at the angle of the forward crank, which is so arranged as to shear off before sufficient strain can come on the agitator to break it. Mechanically considered, its movements are quite satisfactory. In the tests, however, it was demonstrated that the capacity of the pump with this agitator was not much over half the capacity of the pump with jet agitators. It will, therefore, be taken out, and jets will be put in. This device is the invention of Edward Flad, M. Am. Soc. C. E.

Steam for the various machines is derived from six boilers, 48 ins. in diameter and 28 ft. long, with three 11-in. and two 13-in. flues. They are designed for a working pressure of 140 lbs.

The two suction pipes run forward from the pump casing, separating gradually until 12 ft. apart at the bow. At this point a tight radial joint is provided, which connects the pipes in the hull with the pipes from the suction head, and admits of the vertical motion necessary for dredging at different depths. The suction can be lowered to a maximum depth of 15 ft. Outside the hull the two suctions are framed together rigidly and are handled as a single piece. The raising and lowering is accomplished by means of sheaves and tackle attached to a derrick

frame located over the forward end of the suction well. A straining frame is provided so that when the suction is lowered to a suitable depth it can be locked; it thus relieves the tackle of the weight, and maintains the suction at a constant depth. Each part of the suction head is 10 ft. long, making the suction 20 ft. wide over all.

The "Epsilon" suction head has a pressure chamber on the under side at the front end connecting with the jet pump. Ten 3-in. jet nozzles are screwed into the front side of this pressure chamber and serve to loosen and stir up the sand and induce the flow of material to the suction.

The discharge pipe passes straight aft from the pump between two central keelsons, and rests on the floor beams for a distance of about 52 ft. From this point it rises gradually for a distance of 22 ft. until the center of the pipe is 4 ft. above the bottom of the boat. Then it runs horizontally straight out through the stern, projecting far enough to couple on the floating pipe line. The pipe is flattened out near the pump casing so as to depress it below the water-line and thus facilitate priming, which is done by using a steam syphon at the top of the casing. The floating discharge pipe is similar to those previously described, except that greated buoyancy is provided, and the shape of the float is somewhat flatter.

A velocimeter is provided for showing the velocity of flow in the discharge pipe. This consists of two vertical tubes whch pierce the discharge pipe. They are set in the vertical plane passing through a longitudinal axis of the discharge pipe. About 5 ins. below the upper inner surface of the pipe, ¼-in. tubes, 6 ins. long, are inserted horizontally; the one nearest the pump being open toward the pump to receive the pressure of flow and the other turned in the opposite direction. The upper ends of the vertical tubes connect with glass tubes attached to suitable scales. The difference in the height of the columns of water in the two tubes, when water is flowing through the discharge pipe, gives results from which the velocity of flow can be deduced.

Weighing apparatus, designed to show the percentage of solid matter passing through the discharge pipe, is also provided. To accomplish this, a suitable length of the pipe is connected at each end by rubber thimbles, which leaves the joints flexible. One end of this pipe is then supported by a weighing apparatus properly counterbalanced. An indicator is located where it can be readily seen by the engineer. The pointer is set so that it reads zero on the dial when water only is pumped. When sand is pumped the pointer will show on the dial the weight of the same at any moment, and consequently the percentage of solid matter.

The total approximate weight of each dredge is 1,057,118 lbs.; weight of floating pipe line, 325,000 lbs.

The efficiency tests of these dredges were begun about the middle of January. Owing to delays occasioned by high water and some minor modifications that were required, the capacity tests were delayed until the latter part of March, 1898.

The specifications and plans of all the dredges of the Mississippi River Commission have been prepared under the direction and subject to the approval of the Committee on Dredges, consisting of Major Thomas H. Handbury, Corps of Engineers, U. S. A.; Henry Flad, M. Am. Soc. C. E., and B. M. Harrod, Past-President, Am. Soc. C. E. The dredges "Gamma," "Delta," "Epsilon" and "Zeta" were constructed under the direction of Capt. H. E. Waterman, Corps of Engineers, U. S. A.

Table No. 1 gives the leading features of these five dredges, working below Cairo, Ill. Table No. 2 gives some particulars of the tests, showing the minimum and maximum capacities of these dredges:

Another dredge has been designed for work on the river below Cairo, and the contract for its construction will be let during the present year. This will be a single-pump dredge, similar in form to the "Epsilon," but will be provided with side wheels and propelling machinery.

Two dredges for use on the Mississippi River between the Missouri and Ohio Rivers are now under construction, and are practically completed. They were designed and constructed under the direction of Major Thomas H. Handbury.* They will be ready for use during the next low-water season. It is expected that a navigable channel 6 ft. deep can be maintained with these dredges, aided by the temporary jetties and the jet dredge.

The hulls of these dredges are of steel, 160 ft. long and 40 ft. wide, with 6½ ft. depth of hold. Their working draft will be about 3½ ft.

Each dredge is provided with two centrifugal pumps with a single 20-in. suction in the axis of the pump, discharging from the lower side of the casing. The discharge at the pump is 20 ins. diameter, but is expanded to 24 ins. at the discharge pipe. The casing of the pump is 48 ins. in diameter and 28 ins. across the inside.

Each pump is operated by a direct-connected, horizontal, compound, non-condensing engine, designed to run 200 revolutions per minute and develop 300-HP. at a boiler pressure of 140 lbs. This speed is to be regarded as the average work of the engine, and is expected to maintain through the suction and discharge pipes the velocity necessary to carry at least 20% of sand and 80% of water under a maximum head of 30 ft.

A jet pump is provided with each main pump, which serves to loosen up the material at the end of the suction and thus facilitate its passage into the suction pipe. The jet pump has two high-pressure cylinders 8 ins. in diameter, two low-pressure cylinders 12 ins. in diameter, and two water plungers 12 ins. in diameter; all having 10-in. stroke. The capacity of the pump is 1,200 gallons per minute against a water pressure of 65 lbs. when running compound under a steam pressure of 150 lbs. These pumps discharge through 8-in. pipes terminating in three bronze nozzles 1½ ins. in diameter, their extremities radiating to a distance of about 30 ins. apart and just beneath the suction of the main pump.

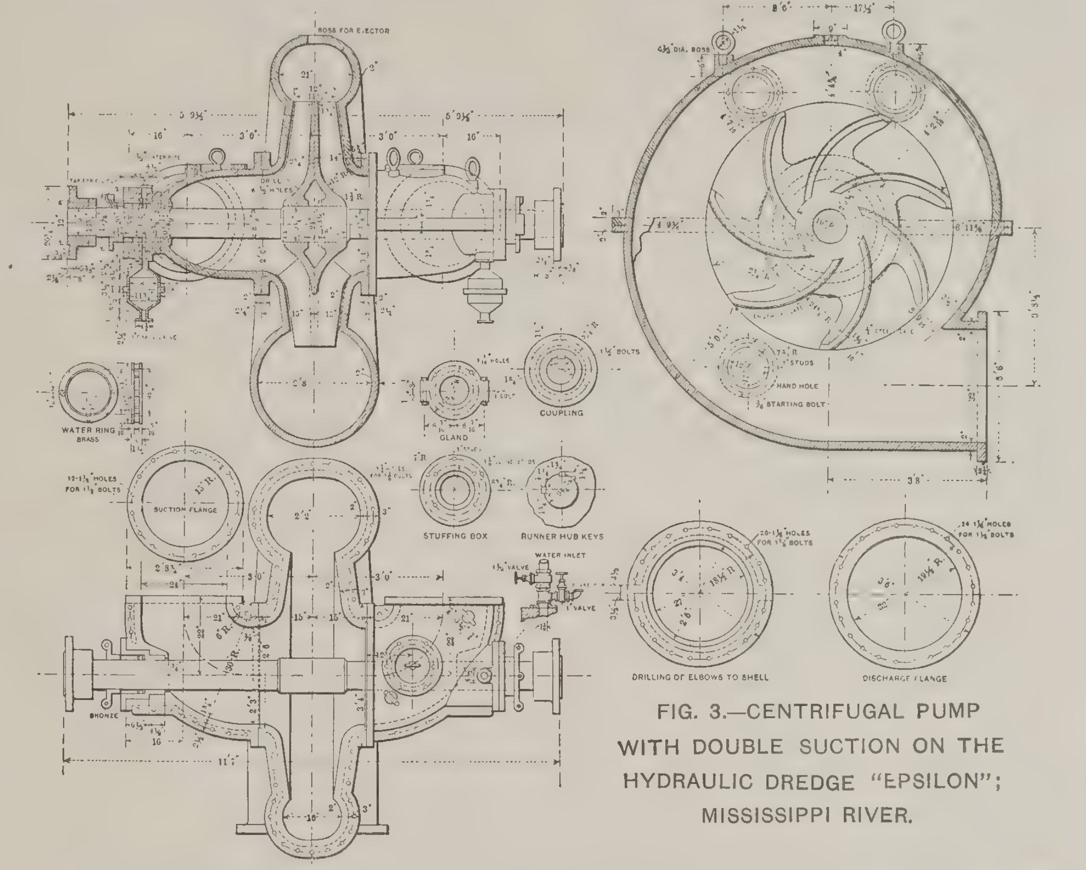

FIG. 3.—CENTRIFUGAL PUMP WITH DOUBLE SUCTION ON THE HYDRAULIC DREDGE "EPSILON"; MISSISSIPPI RIVER.

Steam is supplied by six boilers of the Mississippi River steamboat type.

Dredge "Ram."—In the fall of 1893 the dredge "Ram" was completed by the Bucyrus Steam Shovel & Dredge Co., for use in keeping open the channel from the Mississippi River into the Red and Atchafalaya Rivers. It was built under the direction of Capt. John Millis, Corps of Engineers, U. S. A., and cost $69,500. The capacity is about 300 cu. yds. of mud per hour, delivered through 300 ft. of pipe. It is provided with propelling machinery such as commonly used on stern-wheel steamboats. The hull is 95 ft. long, 27 ft. beam and 7½ ft. deep. The dredging pump is an Edwards centrifugal, with 15-in. suction and discharge. The pump is run through a belt connection by a horizontal, compound-condensing engine, with cylinders 14½ and 26 ins. diameter, and 20-in. stroke.

This dredge can work in any depth up to 30 ft. It is so arranged that material can be discharged on either side at will. A vertical anchor spud is provided in the stern of the boat, on which it swings by means of kedge anchors laid out from either side of the bow and maneuvred by winding drums. In this way a wide cut can be made by swinging the cutters from side to side.

The cutter and suction is supported by an A-frame, the inner legs of which are pivoted to the sides of the bow. The frame is raised or lowered with wire rope tackle attached at the upper end to suitable shears and operated by winding drums. The cutter is a conical steel casting with eight steel blades forming a cutter 24 ins. in diameter at the end and 54 ins. in diameter at the base. This cutter is at the outer extremity of a 5-in. steel shaft, which is revolved by gear wheels at the bow of the boat, and operated by a sprocket wheel and chain. The suction proper starts at the base of the cutter.

This boat has been quite successful from the start. During the low-water season of 1894 she dredged 265,000 cu. yds. of material at a cost of a trifle over 4½ cts. per yard. The material was largely mud and clay. The material is generally delivered through about 50 ft. of pipe suspended from a derrick and attached to the boat. This boat has also been used with considerable success in building levees. It is estimated that under favorable conditions a levee 10 ft. high can be built at a cost of about 6 cts. per cu. yd.

Menge Dredges.—In 1888 two dredges of the elevator type were procured, one for use in Vicksburg harbor and one for the mouth of the Red River. These were called the 'Menge" and the "Pah-Ute."

In actual work the "Menge" has dredged 4,000 cu. yds. in 10 working hours. This dredge cost about $18,000. The "Pah-Ute" has about half the above capacity, and cost $10,000. These dredges, as generally equipped, deliver the dredged material in dump scows, which are towed to the desired point and dumped. In some favorable situations the material is delivered through sluice boxes supported on barges. These dredges, if properly constructed, are very successful when operated in soft material.

Dredge "Bayley."—This was built by Carroll & Co., of Pittsburg, for use in South Pass. It arrived at Port Eads in the fall of 1877. It is constructed of iron throughout. The hull is about 200 ft. long over all, 32 ft. wide, and 10 ft. depth of hold. With fuel on board, it draws about 5 ft. of water. It is self-propelling by means of side-wheels 25 ft. in diameter, with buckets 11 ft. long. These wheels are operated by two engines with cylinders 21 × 84 ins.

This dredge has a centrifugal pump of the Andrews' cataract pattern, with a runner 6 ft. in diameter and 3 ft. wide, mounted on an 8-in. steel shaft. It is operated by two independent condensing engines, placed forward of the pump, having cylinders 24 × 20 ins. The wrought-iron suction pipe is 27 ins. in diameter. The suction is supported on a flat plate resting on the sand to prevent the scraper from cutting too deep. This scraper takes in a slice of sand about 8 ins. deep and 4 ft. wide. A stream of water of about half the above depth and the same width enters the suction at the same time.

The movable part of the suction, when in operation, in 26 ft. of water, stands at an angle of about 35°. When not in use it is lifted above water, under the extension of the main deck, the end projecting about 15 ft. aft of the stern post. The discharge pipe is 30 ins. in

TABLE No. 2.—Summary of Tests of Mississippi River Dredges.* (Showing minimum and maximum capacity.)

‡The sand weighs about 100 lbs. per cu. ft. when dry; and has about 35% of voids when wet.

---

*These dredges were described and illustrated in our issue of July 22, 1897.

diameter, and is arranged so that the spoil can be deposited in the spoil bins on board, or delivered on either side of the boat through pipes swung from derricks.

The four spoil bins stand forward of the engines. They are 60 ft. long, 19 ft. wide and about 20 ft. deep, and have a capacity of about 512 cu. yds. of dredged material. These tanks are filled in about 7 minutes, when the suction is raised and the boat proceeds to the dumping ground. Two-thirds of the available time is occupied in unloading. Overflow gates are provided so as to allow the water to escape while the sand settles to the bottom, thus insuring a greater load of solid matter. In a working day of 13 hours the average amount of solid matter removed is 1,309 cu. yds. The tanks are divided into compartments, each of which terminates in a hopper having a 4-ft. opening through the bottom of the hull. These openings are closed by valves operated by hydraulic jacks with a capacity of about 12½ tons. The sand is washed out of the tanks by means of two jets in each hopper.

The capacity of the dredge when delivering the material as described is about 350 cu. yds. per hour. If the material is simply delivered overboard, the capacity is about 1,000 cu. yds. per hour. When dredging, the boat moves down stream, with the suction lowered, at the rate of about 2½ miles per hour.

This dredge cost about $150,000. It was designed by Jas. B. Eads, M. Am. Soc. C. E., for the special purpose of working in deep rough water with strong currents.[*] This boat is now over twenty years old, but is still serviceable.

The foregoing descriptions cover a fleet of eight hydraulic dredges of large capacity and five other dredges, all of which are now available for use in improving the low-water navigation of the Mississippi River. The "Alpha" has been operated for three seasons, the "Beta" for two seasons, and the "Gamma" and "Delta" for one season. They have all demonstrated the practicability of moving economically immense quantities of material in a short space of time. They have also shown that good navigable channels can be opened through the reefs that obstruct navigation.

As far as the machines themselves are concerned, they seem to meet the requirements fully. The value of these dredges as aids to navigation depends far more on the proper location and direction of the cuts to be made than on the efficiency of the machinery. Experience may show that in some cases the dredges can be made more efficient by filling side chutes and thus throwing the water into one channel, rather than attempting to enlarge one of the channels by dredging out the material. It may also be found desirable in some cases to discharge the material at the sides of the proposed channel rather than to deliver it at a distance through long discharge pipes.

The volume of material rolled along the bottom is so great as to far outweigh the greatest possible capacity of any dredge. To those who are not familiar with this phenomenon it will seem incredible that a dredge with a capacity of over 1,000 cu. yds. per hour may be operated for days and leave scarcely a trace of the cut. Or, on the other hand, if the cut has been so located as to meet the requirements of the current, a channel will be scoured out and an amount of material removed which would probably exceed the capacity of the dredge many times. It is by no means certain that the channel will always follow the line of the cuts. It sometimes happens that after some days of diligent dredging, a channel develops without assistance on a line quite remote from the dredged cuts.

Whatever is done during one low-water season is generally obliterated by the succeeding high-water. The successful location of a cut during one low-water season does not necessarily imply that a similar location during the following season will give like results. In fact, a new problem is presented by each bar every season.

In a stream of this character it is, of course, extremely difficult to determine in a particular case justs what share of the channel should be credited to the dredging and what proportion to natural causes. Enough bars have been dredged, however, to fully demonstrate that the dredging at least induces the scour which eventually results in a wide and deep channel.

During the low-water season of 1897, four dredges were at work on the bars below Cairo, and the cost of operating them was as follows:

Labor	$26,704.53
Fuel	13,474.23
Subsistence	7,586.99
Lubricants	970.79
Lighting supplies	215.05
Miscellaneous supplies	1,527.79
Office supplies	145.10
Hire of tow boats for moving plant	10,115.50
Preparation and moving into field	3,269.44
Moving to winter quarters at end of season	4,637.03
Cost of inspection and supply boat	10,554.75
Cost of operating two survey boats	8,674.10
Total	$87,875.30

There was a conspicuous sand bar at Lazelles, some 82 miles below Cairo. When the survey of this bar was made, just before dredging, the distance from the 9-ft. depth in the upper pool to the same depth in the lower pool was 1,400 ft. At that time the amount of excavation required to make a 9-ft. channel 250 ft. wide at the datum stage was 61,000 cu. yds. The dredge "Gamma" was at work on this bar ten days, and the actual dredging time was 178 hours. Taking the capacity of the dredge at 800 cu. yds. per hour gives the total amount dredged as 142,400 cu. yds. Thirty-one days after the dredging was completed there was a 10-ft. channel clear through the reef, except for a distane of about 225 ft., where the depth was only 8 ft.; 76 days after the dredging was completed the channel was found to be 350 ft. wide at the narrowest point, over 1,000 ft. wide for more than nine-tenths of the length, and with a least depth of 9 ft., and an average depth of 11 ft.

At President's Island, just below Memphis, the dredge 'Delta" was employed in opening a channel through a reef which was causing much trouble to navigation. In the bed of the river in this locality there is a considerable quantity of conglomerate rock and lignite to be found. The mechanical agitators of the "Delta" were, therefore, put to a very severe test. One solid piece 3½ × 4½ ft. was caught in the cutters. It had to be broken into small pieces to dispose of it. When work began there was barely a 5-ft. navigable channel across this bar. After 15 days' work, during which period much time was lost in clearing the cutters of débris, leaving only 80 hours actual dredging time, a 9-ft. channel 100 ft. wide and 1,300 ft. long was completed. This channel remained intact throughout the season, although a wider channel broke through the bar lower down.

These bars do not all develop at the same time, and they do not necessarily develop at the same places during successive seasons. There are, however, certain general localities that have long been recognized by steamboatmen as liable to develop bad navigation during any low-water season. Now and then, even these places pass through a season without developing any serious obstructions, and at such times dredging below Cairo will be unnecessary. Seasons having good navigation throughout are, however, not frequent.

Dredging operations will, in the main, be confined to the same general localities from year to year, although wrecks, snags and bank erosions may occasionally develop new bars that will require dredging.

The season of 1895 was one of extraordinary low water. At one time during that season there were 57 crossings between St. Louis and Cairo, where the water was 6 ft. or less in depth. During ordinary seasons about as much dredging would be required between St. Louis and Cairo to secure a 9-ft. channel 250 ft. wide as is required below Cairo for a similiar channel. The supply of water above Cairo at extreme low stages is too limited to readily admit of 9-ft. channel depths. The requirements of river traffic on this reach would be satisfied fairly well by 7 or 8 ft., and it is doubtful whether these depths can be materially exceeded by means of dredges or other temporary devices at an expense justified by the value of the results obtained.

It is evident from the foregoing that the problem of keeping navigation open in the Mississippi River during the low-water season is very far from being a simple one. The magnitude of the plant described is sufficient evidence that strenuous efforts are being made to "improve and give safety and ease to the navigation" of the river, and the experience gained thus far justifies the belief that these efforts will be successful.

The writer is indebted to Gen. John M. Wilson, Chief of Engineers, U. S. A., M. Am. Soc. C. E., to Maj. Thomas H. Handbury, Capt. H. E. Waterman and other officers of the Engineering Corps for free access to records and drawings. He is also indebted to his associates, engaged in the improvement of the river, for valuable assistance in the preparation of drawings and tabulated data.

◆

THE RAILWAYS OF NEW SOUTH WALES, which are owned and operated by the government, aggregated 2,691 miles in length on June 30, 1898, or 52 miles more than in 1897. Several light or pioneer railways have been built and have given satisfactory results. The traffic aggregated 8,340,338 train-miles, with gross and net earnings of $1.81 and 84 cts per train-mile. The total earnings were $15,133,740, and the balance after paying operating expenses was $7,060,715, the operating expenses being 53.34% of the gross revenue. The freight traffic aggregated 4,561,943 tons, with an average haul of 56.63 miles per ton, and earnings of 2.76 cts. per ton per mile. Improvements of grades and curves are being made, the work being done by the Railway Commissioners and not by contract. The Commissioners also control and operate 65 miles of street railway, operated by steam, cable and electricity.

◆

AN ELECTRIC RAILWAY TRAIN SERVICE has been put into operation between Berlin and Zehlendorf, 7.5 miles distant. The train is made up on nine carriages of the type used on the Berlin elevated railway, weighing 210 metric tons. The carriages at the head and rear of the train are equipped with electric motors, and one or the other hauls the train, according to the direction of motion. All shifting of cars at terminal stations is thus avoided. The run occupies 27 minutes including four stops, and there are 15 trains a day each way. Each motor car is equipped with two electric motors of 100 HP., mounted over the two end axles. The two motor cars are so connected, electrically, that both may be used in case of need, and the four motors may be employed in braking. Besides the electric brakes on the motors, all the carriages in the train are equipped with electro-magnetic and Westinghouse brakes. The current is distributed by the third-rail system at a tension of 550 to 600 volts.

◆

THE ELECTRIC TRAMWAYS OF SWITZERLAND, on July 1, 1898, had a total length of 69 miles in actual operation, and 64 miles under construction; concessions for 200 miles more had been granted to different companies. Water power is usually available for generating the current. The usual gage is one meter. The overhead system is generally used with copper wires 6 to 9 mm. diameter, elevated from 16 to 20 ft. above the road surface. In the establishment of new lines alternating currents are generally employed, with a maximum tension of 750 volts, as fixed by law; when continuous currents are used the maximum tension is 1,000 volts. The motor cars weigh from 9,900 to 16,500 lbs. and carry from 22 to 45 passengers. Handbrakes, working on 4 or 8 shoes, are usually applied to the wheels. For the tramways of Fribourg and Lausanne, where grades of 9.2 to 11.3% are met with, the heaviest grades on simple friction railways in Europe, very strong safety brakes are employed, in the form of spurs that may be forced into timbers running parallel to the rails. Speed on the Swiss tramways is fixed by law, at a limit of 7.5 miles per hour in cities and towns, and 15.5 miles in the open country.

◆

A NEW TIMBER DAM AND POWER PLANT will be constructed by the Twin City Rapid Transit Co., of Minneapolis, Minn., at a point about 3½ miles north of the city limits of Minneapolis, Minn. The dam will be 1,198 ft. long and will cross the Mississippi River, furnishing a head of water of 20 ft. Its total cost ready for the power house and machinery, is estimated at $308,079. The power house contemplated provides for nine flumes, each holding four 42-in. turbines on one shaft, or 36 turbines capable of developing under a 20-ft. head a nominal power of 10,145 HP. This power house and the machinery, including about $75,000 for flowage rights, will bring the total cost of the improvement up to $525,000. The bulk of the power—all but 3,000 HP. or 4,000 HP., which will be sold—will be used by the rapid transit company, which will thus be able to abandon all its steam plants. The preliminary estimates and plans for the timber dam have been made by Mr. E. T. Abbott, Civil Engineer, of Minneapolis, Minn., and a beginning on the construction will probably be made this winter.

◆

THE MOTOR USED ON THE ELECTRIC CABS in use in New York city are 4-pole, 2-HP. machines operating on 80 volts, and 23 amperes at a speed of 800 r. p. m. They are of the enclosed circular type with cast steel fields and laminated poles. The armatures have 41 slots, and both armature and field coils are machine wound. The fields are connected two in series, and these pairs in parallel, making four field wires and two armature wires which pass through the field frame and connect with the controller. At full load (23 amperes) the efficiency is 83%; at ¾-load 84%; at 1½-load 79%. At full-load the motor will operate for two hours with a maximum temperature rise of only 40° C.

◆

THE SWISS TELEGRAPH BUSINESS is a branch of the Post, Telegraph and Railway Department, and any post-office will receive or deliver prepaid telegrams. At the end of 1896 the telegraph lines represented a length of 4,865 miles, and there were 252 telephone stations, with 6,150 miles of wire and 25,090 subscribers. Snowfall is very troublesome, and 35% of the wires are now underground. In 1896 the official balance-sheet showed, for telegraphs, $562,780 received and $519,520 expended; for telephones, the statement was $866,700 received and $869,680 expended. On Jan. 1, 1896, the telephone rates were reduced, with an increase of 4,555 subscribers; but the annual income was decreased $56,870. The unfavorable weather of 1896 also affected the summer business in telegrams; in the extent of 3.83% in internal, 0.04% in international and 5% in through messages.

◆

MAGNETIC DEFLECTION OF IRON PLUMB-BOBS, in shaft work, is noted by Mr. O. Brathuhn in an article on underground surveying in the "Berg und Hüttenmannische Zeitung" for 1898. He notes that in plumbing a shaft 390 ft. deep with an iron plumb-bob, he found a considerable error. The explanation lay in a cross-cut from the shaft in which a large number of spare rails had been stored with one end of the pile very close to the plumbline. He says that by the induced magnetism of the rails the plumbline was drawn from its perpendicular position to such an extent that the bottom of two lines were 7.5 mm. further apart than the tops of the same lines, and the line connecting the plumblines at the points of suspension formed an angle of 6′ with that at the bottom of the shaft. The trouble was corrected by using brass plumb-bobs.

Typhoid Fever in the Army—The Comparative Corrosion of Iron and Steel—Laying out Turnouts and Crossings—Electro-Plating of Stones and Pebbles with Metal from Water Pipes.

THE EIGHT-TRACK DRAWBRIDGE which is to cross the Chicago drainage canal near Campbell Ave. is meeting with continued delay and opposition. A review of the history of this proposed great structure up to the final rejection of plans for a swing bridge was given in our issue of April 7. Since then new bids have been received and a contract awarded to the Scherzer Rolling Lift Bridge Co., but an injunction has now been granted to prevent this contract from being carried out. The chief engineer of the sanitary district estimated that the ultimate cost to the district, including a capitalization for payment to the railways of the cost of operation, maintenance, repairs and depreciation, would be about $915,000, as compared with $690,000 for a bridge of the type proposed by Mr. C. L. Strobel. This latter design, however, is entirely new and provides for a center pier 8 ft. wide, with two waterways 80 ft. wide, and the engineers of the railways interested estimate its ultimate cost at $1,069,393 instead of $690,000. The Scherzer bridge would give a clear waterway of 120 ft. (originally planned for 150 ft.), and would be in general similar to bridges now in successful operation in Chicago. In view of these facts and of a resolution adopted by the Trustees in favor of avoiding the use of center piers, the contract was awarded to the Scherzer design although two minority reports were presented in favor of the Strobel and Schinke designs. Suit was brought, however, to prevent the carrying out of this contract on the ground that the contract should have been awarded to Mr. Strobel as the lowest responsible bidder. The court has granted the injunction, but based its action mainly upon the methods adopted by the district in inviting bids. It was held (1) that the Trustees should have selected one of the designs in the first place, (2) that there must be a common basis for all the bids, and (3) that unless the design was selected in advance the terms and conditions were necessarily incomplete. On these grounds the court held that the award of the contract was invalid. The Trustees will appeal the case to the Supreme Court.

THE TRACK ELEVATION of the Chicago, Burlington & Quincy R. R. from Rockwell St. to W. 48th St., will be done next spring. In the mean time the foundations and abutments are being put in for the girder bridges of the 21 subways which will be required. The distance is 2.8 miles, with four tracks throughout. Mr. G. H. Bremner is the engineer in charge of the work. The Chicago, Milwaukee & St. Paul Ry. has some very extensive and complicated track elevation now in progress at junctions involving a large number of tracks and connecting Y's. On this road all the bridge abutments for subways are of monolithic concrete, and the plate girders are set in position by means of two cars with jib cranes, the cars being placed on each side of the subway and the girders being run out on cars on the trestling which carries the temporary tracks. Mr. W. L. Webb is the engineer in charge of track elevation.

THE HAVANA FLOATING DRY-DOCK, including its elaborate machinery, is said to have cost Spain about $4,000,000. It is capable of lifting a 10,000-ton vessel, and was towed from Newcastle-on-Tyne to Havana. At the latter point and during the tests of the dock unskilful manipulation of the machinery by the Spanish engineers resulted in the sinking of the dock; some valves failed to work, some rivets gave way and plates opened and the dock filled and sank on its side. The dock was raised, however, by an English engineer after considerable trouble owing to the mud in the harbor. The Spanish Government would doubtless dispose of this dock at a sacrifice under present conditions, and it is said that the harbor authorities of Kingston, Jamaica, are after it. Kingston now has a floating dock of 3,000 tons capacity; this Havana dock has actually lifted an 8,900-ton ship, and can raise a 10,000-ton ship. The Spanish dock charges are excessive, as they amount to 45 cts. per ton for the first 24 hours and 25 cts. per ton for each subsequent 24 hours or parts thereof.

◆

THE GROWTH OF THE U. S. NAVY is rapid at the present time, as 55 warships are now under contract and 20 are nearly completed. Of the 55 ships, 8 are first-class battleships, 38 are torpedo boats and destroyers, 4 are monitors and one is a heavy armored cruiser. Of the 20 nearly finished 17 have been launched and the other three will be afloat before the end of the year. Naval Constructor Hichborn, in a late report, says that the five battleships launched are respectively 68, 66, 55, 63 and 50% completed. The cruiser "Albany," bought from Brazil with the "New Orleans," is still under construction at the Armstrong yard in England; work on her was stopped during the war, but the builders promise to deliver her within six months. A number of the torpedo boats and destroyers contracted for are well on the way towards completion.

◆

A RIVAL NICARAGUA CANAL COMPANY is trying to obtain a concession from the Government of Nicaragua, according to recent press reports from Managua, the capital of Nicaragua. These state that Edwin F. Crogin, of Chicago, and Edwin Eyer and Frank J. Washburn, of New York, are negotiating with President Zeloya and his Ministers with reference to obtaining a new concession for an interoceanic canal. According to the same authority the Nicaraguan Government holds that the concession granted to the Maritime Canal Co., of Nicaragua, expires during the present month, the company having failed to begin active work on the canal within the limit of time prescribed in its charter. The company claims however, that the charter does not expire until October, 1899, and, further, that as Nicaragua has not furnished the police force which it agreed to provide to guard the company's stores, property, etc., the company is entitled to a further extension of time.

THE LOSS OF THE STEAMER "MOHEGAN" off the Lizard, England, on the evening of October 14, is one of the most serious marine disasters in recent years. The latest accounts state that 116 of the passengers and crew were lost, and only forty-five were saved. The vessel was bound from London to New York, and, as far as can at present be learned, when off the Lizard, between The Manacles and the Lowlands, ran onto the rocks. Lifeboats put off from the shore, and every possible effort was made to save those on board, but, owing to the extremely rough weather, only partial assistance could be rendered. The early reports stated that the engines broke down and that the vessel was blown ashore, but it now appears that she was out of her course. The "Mohegan" was a single screw steamer, 480 ft. long, 52 ft. beam and 36 ft. deep, with a carrying capacity of 8,500 tons and a displacement of 15,500 tons. She had stalls for 700 cattle, and was equipped to carry 125 first cabin passengers. She was built at Hull, and made her first trip in the summer of 1897, being at that time one of the freight steamers of the Wilson & Furness-Leyland Line. Later the Atlantic Transport Line bought the Wilson fleet, including the "Mohegan."

◆

A RAILWAY COLLISION in England, in which an express train ran into a freight train, which was switched across the main track, occurred on October 17, at Barnet, about eleven miles north of London. Nine persons were killed and thirteen were seriously injured, while a number of others received minor injuries.

◆

A WROUGHT IRON STAND-PIPE BURST at Waco, Tex., on Oct. 6. It is said that the pipe was full of water at the time, and that the break occurred midway in its height. According to "The Manual of American Water-Works" for 1897, the Bell Water Co., to which the structure belonged, had two pipes, one 20 × 80 and the other 20 × 88 ft.

THE EFFECT OF THE CHICAGO DRAINAGE CANAL upon the water supply ot St. Louis is again agitating the people of the latter city. It is said that the St. Louis Board of Health and a committee representing the Merchants' Exchange are discussing the possibilities of federal interference to prevent the use of the canal as designed; also that an attempt will be made to secure the co-operation of Illinois towns to prevent the use of the canal without proper dilution of the sewage with lake water.

PLANS FOR STORM SEWERS AT DENVER, estimated to cost $400,000, have been adopted, and contracts for the work will probably be let on Dec. 15. The largest sewer will be 81 ins. in diameter. The plan contemplates the drainage of 2,100 acres of land at an ultimate cost of $1,000,000. Mr. S. N. Wood is President of the Board of Public Works. Mr. Harvey C. Lowrie, M. Am. Soc. C. E., is the designing engineer.

◆

A JOINT OUTLET SEWER for South Orange, Milburn, Irvington, a portion of Newark, and a number of other New Jersey municipalities is being investigated by the places named. Mr. Alex. Potter, Assoc. M. Am. Soc. C. E., is making engineering studies for the scheme.

◆

THE MUNICIPAL ELECTRIC LIGHTING PLANT at Grand Rapids, Mich., will have the old-fashioned system of belted machinery instead of the more modern and more economical system of direct-connected machinery. This is contrary to the advice of the consulting engineers and due to the interference of some of the local authorities who have no technical knowledge whatever, and whose interference will result in increased expenditure on the part of the city. The plant as first designed by the engineers called for the direct-connected system, with engines running at 460 revolutions per minute. The claim was made by some of the bidders, however, that only the Willans engine could make that speed, and only the Western electric dynamos were built for the same speed. They therefore complained that there could be no competition. In spite of the fact that the engineers showed a great economy for the direct-connected system the local authorities rejected their advice and decided to advertise for new bids under different specifications, permitting of a very wide range of competition. While the former plan would have required a power house only 28 ft. wide the belted plant now decided upon will require a building 56 ft. wide. The cost of operation of the new municipal plant is estimated at $35 per lamp (or even less when the number of lamps is increased), while that of the old company plant was $97 per lamp. The old tower system of lighting will be retained, but the lamps will be of the Adams & Bagnall enclosed arc type. The contract has been awarded to the Chase Construction Co., of Detroit, Mich., for $90,000. This includes the pole line, 500 lamps, Russell engines, dynamos and Babcock & Wilcox boilers with the Hawley down-draft furnace. Nagle & Ball, of Chicago, are the consulting engineers.

◆

ASPHALT PAVING IN NEW YORK, about which there is just now considerable political controversy, is said to have cost nearly $1.00 per yard more, under Mayor Strong's administration, than similar pavement cost in other cities. The price paid in New York was generally about $3.10, and as low as $2.55 per yard. But the officials of the late Board of Public Works explain that with this price went a guarantee to keep the pavement in repair for 15 years without cost to the city. The city retained 30% of the contractors' pay for five years, and then paid this balance in ten yearly installments. If the company failed to make the repairs the city had them made, and charged the expense against the money retained. As a result the paving company could only figure on 70% of the contract price as ever coming to it, or $2.17 per yard. Practically all of the balance will be required to keep the pavement in repair for 15 years. To compare the $3.10, therefore, with work done in other cities with a shorter time-repair guarantee or no guarantee at all, and with light street traffic compared with New York, is evidently unfair. In New York other conditions also call for a relative higher price per yard. The grading of the street requires the removal of from 12 to 18 ins. in depth of soil, and to get rid of this dirt costs from 50 to 60 cts. for every square yard of asphalt laid. In other cities this cost may range from 8 to 15 cts. Long hauls, high rental of real estate and high prices for labor also tend to increase the cost of paving in New York city as compared with other cities.

◆

STREET CAR FENDERS are at last being introduced in Chicago after prolonged litigation between the railway companies and the city. The companies have fought several ordnances on legal technicalities, and have made the long-disproved claim that the stop planks set across in front of the wheels were more efficient than any fenders on the front of the car. The North Side cars are now being equipped with a fender composed of steel strips curving out in front of the dashboard and projecting over the track, but it is noted that in many cases the lower edge is set too high above the level of the paving.

◆

THE OPERATIONS OF THE ENGINEER CORPS, U. S. A., during the war with Spain, were reported upon to the War Investigation Commission by Gen. John M. Wilson, Chief of Engineers, U. S. A., in answer to specific questions. Gen. Wilson said that the expenditure for work on coast fortifications aggregated $4,821,500. Submarine mines to the number of 1,535 were planted in 28 different harbors, together with all their cables, anchors and electrical connections. Including additional mines and accessories, force of skilled electricians, fleet of tugs, detachments of engineers, etc., the expenditures on account of torpedo harbor defences amounted to about $1.661,000.

THE FAILURE OF THE SNAKE RAVINE DAM, TURLOCK IRRIGATION DISTRICT, CALIFORNIA.

By J. B. Lippincott.*

The Turlock Irrigation District, located in the San Joaquin Valley, in Stanislaus Co., Cal., is organized under the California law for the purpose of irrigating the semi-arid lands of the state. This law (known as the Wright Act) was passed in 1887, and has been the subject of such endless litigation that it is sometimes referred to as "the Wright Litigation Act," instead of the Wright Irrigation Act. It provides, in short, that a majority of freeholders living in any given neighborhood may define a "district" for purposes of irrigation, submitting their proposition to the County Board of Supervisors, who may then at their discretion call an election at which officers and bonds are to be voted for by all electors residing within the defined limits of the district. The bonds require a two-thirds vote to carry. These bonds, when passed, become a first lien on all lands. The officers, who are usually local farmers, or store-keepers, administer all finances and physical features of the district without any supervision save by injunction of the courts. They decide on the legality, quality and quantity of the water supply and the character of all works. Engineers and attorneys are employed by the district, but the directors pass the final judgment on all points. Landholders on the outer edges of the district may be excluded upon request, but no holder residing entirely within the lines can withdraw. The bonds frequently aggregate $20 to $30 per acre, and a failure of the enterprise means the ruin of all interests. In a few cases where the districts have exchanged bonds for existing plants the result has been satisfactory, but in over 90% of the districts, lack of judgment and endless litigation with large landholders has blighted all hopes. It would be as reasonable a proposition to give the ordinary granger a surgeon's knife and tell him to operate in a dissecting room as to be a combined banker and engineer over works that cost hundreds of thousands of dollars. If this work must be done in a communistic way, it should surely be under a very strong state financial and engineering supervision, which should ensure: (1) The rejection of enterprises without physical merit; and (2) upon endorsement by the state the full face value of the bonds. The central idea of common ownership of irrigation water by the consumers is a good one, but lack of proper detail has condemned the Wright Act as one of the blackest errors on our legal code. Defective engineering works and litigation directly reduces the market value of the district bonds, and, therefore, proportionately increases the actual cost of the work.

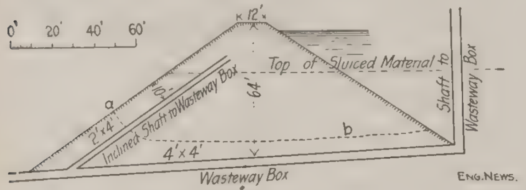

FIG. 1.—Improper Use of the Hydraulic Method of Dam Building—Turlock Irrigation District, California.

Mr. L. M. Holt, Secretary of the convention of irrigation districts, held in Sacramento, Jan. 6, 1893, stated publicly that out of 38 irrigation districts then in existence, 19 reported having voted bonds to the extent of $11,834,000. Out of this, bonds amounting to $2,622,000 had been sold for cash and $2,995,200 had been traded for water rights, making in all $5,617,200 of bonds disposed of, a little less than one-half the amount voted by the 19 districts. Thirteen other districts had voted bonds amounting to $4,942,000, none of these being sold. These 32 districts which had voted bonds contained 1,830,769 acres, and the bonds averaged $9.16 per acre. The 38 districts then in existence contained 2,149,069 acres. Out of this number 28 districts, containing 1,515,594 acres, had an assessed valuation of $39,982,849, the assessed valuation being thus $26.38 per acre.

Such a district is the Turlock, and from this prelude the two failures of the Snake ravine dam, described below, may be largely explained. The "District" contains 176,210 acres, and has voted $1,200,000 in bonds for the construction of its works. A contract was given for the delivery of the water by the contractor to the "District," and at his own cost, to make good all failure in the works.

The purpose of the dam across Snake ravine was to save the construction of 1,500 ft. of side hill canal and flume. The canal, with a capacity of 1,500 cu. ft. per sec., is designed to discharge into the basin above the dam, which basin would act as an enlarged section of conduit. At the western upper end of this reservoir the canal passes through a divide with a maximum cutting of 50 ft., and length of 800 ft. The material was an auriferous gravel in sizes from 1 in. to 2 ft. in diameter, imbedded in red clay with some sand. In original position it is extremely firm and impervious, standing when mined for years in walls nearly vertical, as high as 50 ft. A hydraulic mining canal of 24 sec. ft. capacity, 100 ft. above the grade of the irrigation canal and one-fourth mile distant, furnished existing conditions which were ideal for the construction of an earth dam by the hydraulic process.

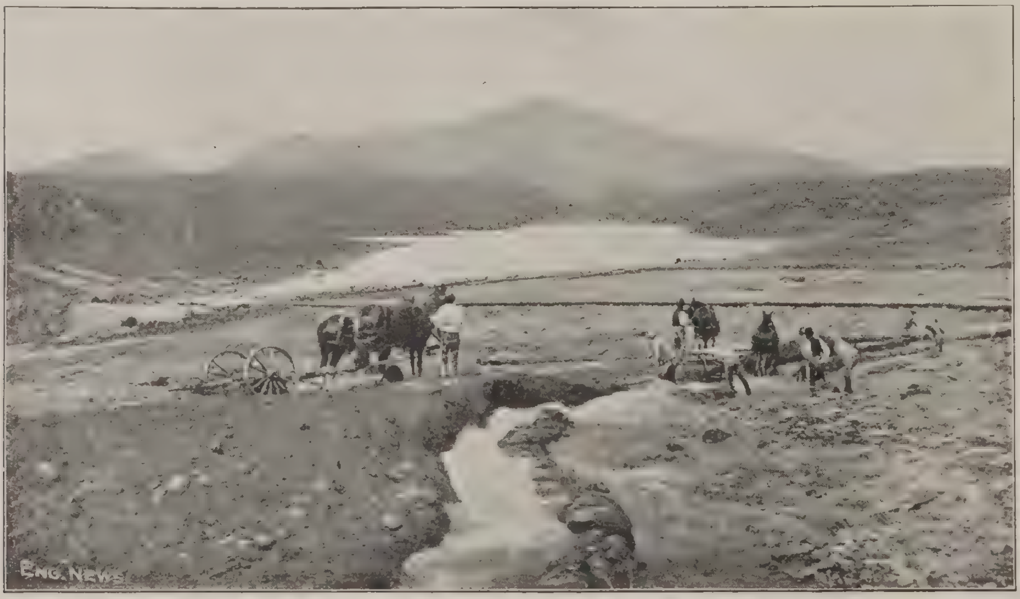

FIG. 2.—PROPER USE OF THE HYDRAULIC METHOD OF DAM BUILDING—LA MESA DAM, NEAR SAN DIEGO, CAL.

The plan was to make the dam from material from the big cut. The opening to be closed is 294 ft. long and 64 ft. maximum central depth. The top of the dam was 4 ft. above the maximum water line. The top width was 12 ft., and the slopes between 1½ to 1 and 2 to 1, which is lighter than is called for in good practice. The first dam was built in 1893, and went out when it had reached the 30-ft. level. The second dam went out when first tested, on June 14, 1898. The second dam was built upon the wreck of the first, and in the same manner.

Hydraulic mining in the ravine had deposited "tailings" at the dam site. These were never removed, or the bed-rock explored. A section of the dam is shown by Fig. 1.

The plan of the work was to build up the lower toe of the dam with scrapers and keep it all the time at an elevation of 2 ft. or more above the remaining portion of the dam, as shown by the lower dotted line, a b. Material was then washed down with a hydraulic jet at the big cut or from the adjoining side hills of the basin and sluiced to the dam site in the natural water courses.

The inclined shaft was built as the work progressed, its top opening being kept below the lower dike, as shown at a, and above the line a b. It was 2 × 4 ft. in the clear; the water carrying the earth in suspension would be stilled in the pond above a, deposit its load, and waste from its clarified surface through the inclined shaft. The purpose of the sand box, or vertical shaft, was an additional waste to draw down the water level in the reservoir when desired. The result of this procedure is obvious. The material from the bank instead of being carried in a homogenous mass, as would have been the case if conveyed in a flume or large pipe from the working face to the dam, segregated itself, boulders, gravel, sand and clay being progressively deposited from the cut to the dam. The basin was filled with many hundred yards of material that never reached the dam. The material that actually got in place in the dam was a very fine clay or silt which could not drain itself, and which remained slimy and slippery until the dam went out. The dam was stratified throughout, layers of this silt in some way being followed by layers of pure sand.

The first dam was constantly shaky and wet, vibrating when jarred. It slid out when 30 ft. high. The effort was made to "use more care" in the second structure, but, in a general way, the same method of work was followed. The waste box in the bottom of the dam was built 4 × 4 ft. in the clear, of 2-in. Oregon pine on two longitudinal 6 × 8-in. stringers as sills. There were no corner or central bracings. When the dam reached a height of 40 ft. it crushed in this box and prevented its further use as a wasteway. The dam was then finished by hauling the material deposited above the dam into position with carts. The dam leaked badly. With a few feet of water in the basin a stream of 1 cu. ft. per sec. passed under the dam, issuing from the broken waste box. This at first ran muddy and carried considerable sediment. Later this water became less in quantity and clearer. This was caused by sluicing in material from the side hill, above the dam, which closed the pores in the debris above and under the dam. There was more leakage through the material that was deposited by carts than through the stratified material that was sluiced into position.

It was optional with the contractor whether he should put in a flume across the ravine or build the dam. When the dam was decided upon it is said that the contractor rejected the request of the officers of the district, both as to its location and method of its construction, and, therefore, the loss falls entirely upon him.

The intake canal passes near the east end of the dam and a wooden box 4 × 4 ft. for a new wasteway was put in the west end of the dam 10 ft. below the top. The intake canal is located on a steep hillside. It soon leaked and sloughed off a piece of the side hill immediately next to the dam, which then began to leak around that end. The waste box, which was also leaking, was then opened on the west end and washed out a large hole from the side hill and dam on its lower side. The dam was leaking at its foundation also. Attacked on both flanks and center, the entire structure gave way. It was pushed en masse down the ravine at a velocity of from 6 to 10 ft. per sec., and thrown into the Tuolumne River. The total distance traveled was over 1,000 ft. It temporarily dammed the river to a depth of 20 ft. The Superintendent and two dogs were on the dam when it gave way. They all were carried entirely across the river and none of them hurt, though the man's shirt and pockets were filled with sand and mud on his trip. The ravine is now to be crossed by a flume.

---

*U. S. Geological Survey, Los Angeles, Cal.

Dams have been most successfully built by the hydraulic process elsewhere. The method is well described under "Reservoirs for Irrigation," XVIII., Geological Survey Report, by Jas. D. Schuyler, M. Am. Soc. C. E. Fig. 2 shows the construction of La Mesa dam, near San Diego, by the hydraulic process. This work has proved both economical and efficient and shows the proper method of handling the material. In this case a clay and gravel soil is being stripped from a hard pan and conveyed through an iron pipe to the dam site. The sluicing stream is so located as to erode rapidly, the clay and gravel and this material is also thrown into it by plowing and picking. The feature of this class of work is its economy, and when well done it should produce the very best class of earthwork. The method is being used extensively in the far Northwest in putting in large railroad fills at a cost of from 3 to 10 cts. per cu. yd., depending largely on the location and quantity of the water supply.

As an interesting demonstration of how not to do it, the history of the Snake ravine dam is unique.

PROGRESS ON THE NEW CROTON DAM.

(With full-page plate.)

After nearly six years of work on the part of the contractor for the new Croton dam, some portions of the masonry of the main structure are now up to a point slightly above elevation 50, about the original bed of the river. All of this part of the work has reached the zero level, or average mean tide at Sing Sing, 30 miles from New York. Although the masonry already built is 140 ft. in maximum height, the working levels are still spoken of as "the hole." In its greatest cross-section this immense dam will be 290.8 ft. high and 216 ft. wide at the base. These figures exceed the preliminary designs, owing to the fact that it was necessary to go deeper at one or two points than had been expected, the maximum depth reaching elevation — 80.7, or 130.7 ft. below the old river bed. A total of about 270,000 cu. yds. of masonry had been laid up to Aug. 1, 1898. All but about 100 ft. of the foundation for the heart-wall was in place when a representative of the editorial staff of this journal visited the dam on Aug. 23, and only some 250 ft. of the foundation for the spillway were still lacking at that time.

A typical section of the dam, showing the depths of the rock excavation at various points, is shown by Fig. 1. Views of the work at different stages of its progress since the beginning of 1896 are shown by Figs. 2 to 5, inclusive.

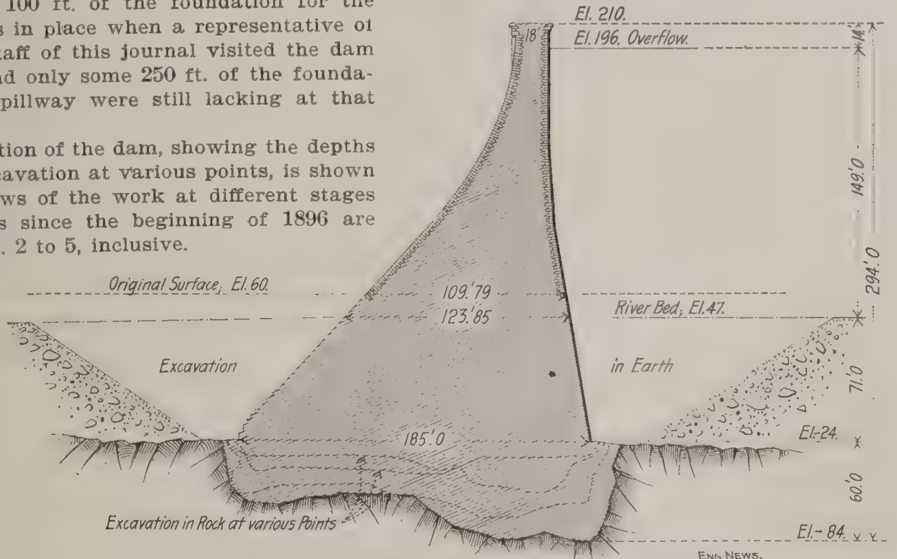

FIG. 1.—SECTION OF THE NEW CROTON DAM.

A full illustrated description of the new Croton dam was published in Engineering News for June 2, 1892, and the detailed bids for the structure were given in our issue of Sept. 5, 1892, under "Contract Prices." For the convenience of the readers of this article some of the information in these earlier issues will be repeated here. The new dam is located about 3.1 miles below the original Croton dam, and 3¼ miles above the point where the Croton River discharges into the Hudson. The dam site, in relation to the Croton drainage area, was shown in our issue of Nov. 22, 1890. The dam is divided into three parts: (1) A masonry structure about 700 ft. long and 18 ft. wide on top; (2) an earth embankment with masonry heart-wall joining the masonry at the south, some 500 ft. long; and (3), a masonry spillway about 1,050 ft. long, nearly at right angles with the main dam. The heart-wall and spillway wall, together with the main dam, form a continuous masonry wall across the valley.

The contractors for the dam complete are Coleman, Breuchaud & Coleman, of New York city. The preliminary estimates of quantities, together with the engineers' estimates of unit prices and the contractors' bid for the work, are reprinted from our issue of Sept. 8, 1892, as follows:

Quantities.			Eng'rs estimate.	Contract price.	
				Rate.	Amount.

(Am. cem., 2 to 1)..	470,000	" "	5.00	4.05	1,903,500
(Port. cem., 2 to 1).	30,000	" "	6.60	5.346	160,380
(Port. cem., 3 to 1).	50,000	" "	6.00	4.944	247,050
Riprap	5,000	" "	1.50	1.75	8,750
Broken stone	10,000	" "	1.50	1.50	15,000
Face work for rubble.	15,000	sq. ft...	.30	.40	6,000
Face dressing:					
Fine ham'r'd (6-cut)	22,000	" "	.75	.65	14,300
Rough pointed	12,000	" "	.40	.40	4,800
Highway fence	8,000	lin. ft..	.50	.50	4,000

The final estimates thus far, as compared with the preliminary estimates, indicate an increase in earth excavation and masonry, and decrease in embankment and earth excavation in vertical trenches.

The new dam will have a storage capacity of about 32,000,000,000 gallons, giving, with the other reservoirs completed, or under construction, a combined available storage capacity of about 72,000,000,000 gallons. The drainage area tributary to the new reservoir is about 360 sq. miles, and the run-off for the driest year from 1870 to 1895, inclusive, was about 15 ins. in depth, or 700,000 gallons per sq. mile. If none of this were lost it would afford an average minimum daily supply of about 250,000,000 gallons. With the new storage completed the average daily supply in a dry year will be 280,000,000 gallons.

The reservoir formed by the new dam will be about 18 miles long, overtopping the crest of the overfall of the old Croton dam to a depth of about 30 ft., and that portion of the old aqueduct between the old and the new dams to a depth of about 35 ft. above the crown of the arch. It is desired to send water back to the new gate-house at the old dam, through this submerged portion of the old aqueduct, in order to prevent the lower portion of the lake from becoming a dead end. This raises the question of the effect upon the old aqueduct embankment of lowering the lake so as to expose the embankment after it has been flooded. The subject is now being studied. There has been talk of reinforcing the old embankment and of laying pipes in this stretch of the aqueduct.

The principal change in the original plans for the new dam has been the making of the masonry portion some 115 ft. longer, and the consequent shortening of the earth embankment. This was due to a variety of reasons, one being the desirability of decreasing the height of the embankment, and another to limit the heart-wall to the stretch of hard pan reaching to bed rock. Where the hard pan has been found it has been a most excellent material in which to place the heart-wall. The masonry throughout the whole structure, it hardly seems necessary to say, is carried down to the solid rock.

In backfilling about the heart-wall every stick of timber is removed and the hard pan material replaced in 4-in. layers, wet and rammed. At first 6-in. layers were used, but great care is necessary to prevent the material from becoming jelly-like, and the 4-in. layers have been found to give the best results.

The immense trench to rock bottom for the foundations of the dam was excavated by means of steam shovels, the spoil being removed in cars on light railways. The stone for the masonry is a very heavy dark granite weighing 185 lbs. per cu. ft., quarried about 1½ miles above the dam. The sand for the cement mortar is obtained from the old river bed about a mile above the dam. Natural cement is being used for the rubble work composing the bulk of the masonry, and Portland cement may be used for the facing stone, the parts being 2 to 1 and 3 to 1, respectively. No faced stone has yet been laid on the main dam. The masonry is being carried up in benches about 15 ft. high, the approximate elevations on Aug. 23 being 0 in the center, 45 ft. at the north end, and 60 ft. at the south end. The faces are now being stepped by courses, but so as to bring the steps entirely outside the neat line of the cross-section.

In laying the masonry every block is lifted at least once. This gives an impression of the stone on the bed, and allows the latter to be dressed up as needed. Most of the masons have worked on the other dams, built in the drainage area by the Croton Aqueduct Commission. Many of them are Italians. In exceptional months the masons have averaged nine cu. yds. of masonry per day per man for entire months. Nearly all the rock is brought to the works on light railways located on each side of the dam, being shifted from the cars to the benches by derricks and also put in place by derricks. There are three cableways extending the length of the dam, one a Lidgerwood and the other two, Trenton. These are used principally for handling sand, cement and spawls, and for shifting the derricks, being especially handy for the latter work.

Work is carried on by night as well as by day, the night shifts working on back-filling. The back-filling against the main dam is kept well wetted. Thus far it has not been rolled or tamped, but it will be later on.

Most of the water encountered has been on the upper side of the dam. This is lifted over the masonry by means of centrifugal pumps, where it and the water from below is repumped to the new river channel. For the second pumping three 4,000,000-gallon Worthington pumps have been provided, but except after rains one of these is able to handle all the water upon emergency. A number of springs have been struck, one being a very large one. These have all been piped and eventually the pipes will be filled with grout.

The river has been diverted from its old channel by means of dams of earth and crib-work and a masonry wall. The new channel is 125 ft. wide, and during one freshet was filled to a depth of about 11 ft., the rate of flow being about 9 or 10 miles an hour.

A feature of the gate-houses at the new dam is iron guides for the stop planks, formed of channels, with exterior plates or webs to bind them into the masonry. It has been found that the heavy stop planks sometimes catch on the joints of the ordinary granite grooves.

Mr. Alphonse Fteley, Pres. Am. Soc. C. E., is Chief Engineer of the Croton Aqueduct Commission. Mr. Charles S. Gowen, M. Am. Soc. C. E., is the Division Engineer in charge of construction at the new dam, and Mr. B. R. Value is Assistant Engineer on the work. We are indebted to each of these gentlemen for courtesies and aid extended in the prepartion of this article.

A NEW RAIL SPLICE AND AN ANTI-CREEPER FOR STEAM RAILWAY TRACKS.

We illustrate herewith a new rail-joint which has recently been put into use on the Pennsylvania Railroad, and which seems to possess in an unusual degree the strength, stiffness and simplicity of construction which are now generally recognized to be the essential features of a successful rail-joint.

As every engineer who has given attention to the rail-joint problem knows, the perfect rail-joint must give to the two ends of the rail which it holds the same stiffness to resist transverse stress that is possessed by the rail itself. The common angle-bar joint cannot secure this, by reason of the limit of height by the distance between the head and flange of the rail; and most inventors of improved rail-joints have sought to give additional support to the rail in some manner. The joint shown herewith embodies one of the simplest and most effectual plans of strengthening the angle-bar that has ever been devised. It is also so designed to be simple and economical in manufacture, and to give the greatest strength with the least material employed. The two parts forming the splice have a combined section from 20 to 30% greater than that of the rail to be spliced, and the parts are rolled in practically the same form and in the same manner as the ordinary angle-bar, except that the flange of the bar is made about 3 ins. wider than usual. After it is rolled and cut into proper lengths, the plate is reheated and is then pressed by dies into the form shown in the illustration. The result is a largely increased bearing on the tie, and a deep and strong truss under the rail-joint, with gusset-plates connecting the depending flange and the horizontal, or bearing flanges. The value of this gusset-connection is especially marked, as it obviates all danger of the movement of the depending flange, either inward or outward, under applied loads; as has occurred in somewhat similar splice-plates where the lower flange was simply cut twice and turned down. This splice is simple, strong, economical and rigid, with single parts only for each splice-plate. There are no bolts or parts under the joint to be manipulated; a feature that will be appreciated by all trackmen.

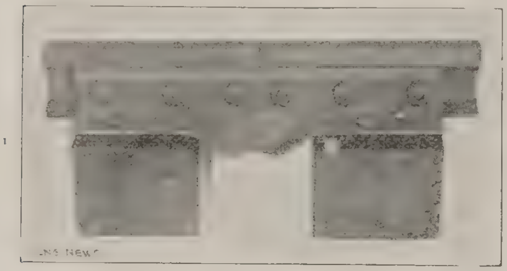

Fig. 1.—A New Rail Joint.
A. Bonzano, M. Am. Soc. C. E., Inventor.

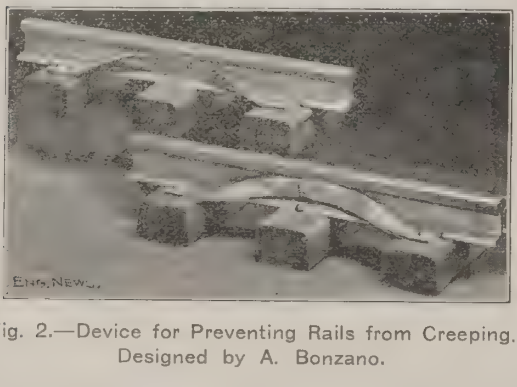

Fig. 2.—Device for Preventing Rails from Creeping.
Designed by A. Bonzano.

This rail-splice has now been in regular service for some months on three miles of the main line of the Pennsylvania R. R., west of Harrisburg, Pa.; and Mr. Joseph T. Richards, Engineer of Maintenance of Way, authorizes the statement that trains run so smoothly over this section that the rail-joints cannot be noted. Computations show that this joint has 1.08% of the stiffness of the rail itself; or, in other words, is somewhat stronger than the rail, and the rail is thus practically continuous. It is also shown that a track equipped with 70-lb. rail and this splice is equal in service to an 80-lb. rail fitted with the ordinary angle-bar splices. According to Mr. Richards the ordinary angle-bar joint is only from 28 to 32% as strong as the rail.

The creeping of rails under traffic presents another serious railway problem that has not yet been satisfactorily solved. But that some efficient method of preventing this creeping is imperatively demanded is made evident in battered rail-heads, wear and annoyance of jolting over open joints, and in the derailments caused by the vertical or horizontal deviation from track line resulting from the crowding together of rails under this creeping movement.

In the anti-creeper here described, the inventor proposes to firmly anchor each rail to the roadbed; where it is free to contract or expand within its own length, but cannot "creep," or concentrate at any one point the movement of a large number of rails. It is this latter feature that causes all the trouble. The device is so simple that it is remarkable that it has not been sooner applied. It is a metal bar, about 2¼ × ⅝-in., of sufficient length to be spiked, or secured by screw-bolts, to two cross-ties, preferably, with one tie intervening. The middle of this bar is bent at right angles to the ends, so as to fit the web of the rail, and it practically forms a bracket with either half acting as a strut or a tie according to the direction of the stress. The crossties embedded in the ballasted roadbed form a firm anchor, and the advantages claimed are that the distances between the rail-heads will be uniformly maintained; no bending or shearing of the splice-bolts is possible—and this alone would compensate for the cost of the bars; the rails cannot crowd together, and they will remain in position at frogs, switches and cross-overs, on draw-spans, trestles, etc., exactly as they were originally placed by the trackmen with much labor. The purpose of the anti-creeper is to save wear in track material, to decrease track labor, and to obviate as much as possible the danger from derailment from creeping rails.

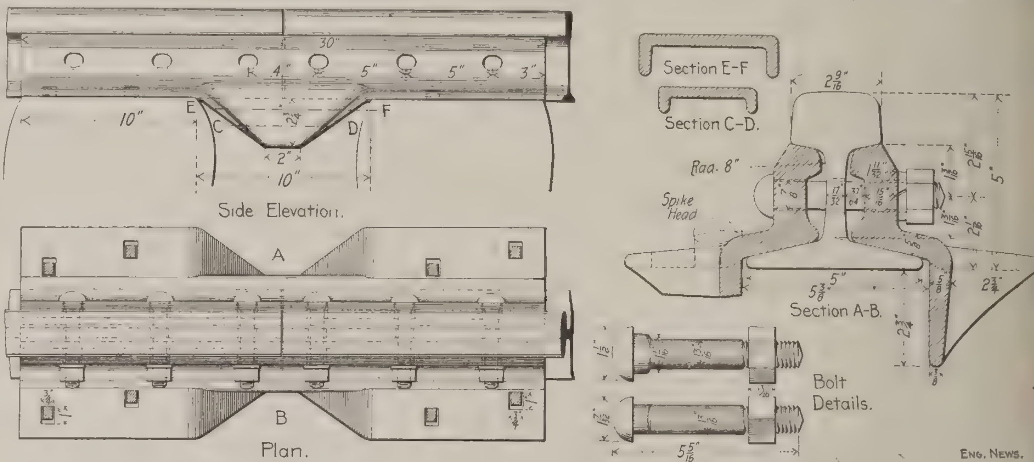

FIG. 3.—DETAILS OF BONZANO RAIL JOINT FOR 85-LB. RAIL, PENNA. R. R.

According to estimates submitted for applying this anti-creeper to five miles of track on the Pennsylvania Railroad, the cost for one rail is 50 cts. As there is practically no wear, the life estimate is placed at 20 years, and the annual cost is thus 2½ cts.; and as the scrap is worth 20 cts., the actual cost of the anti-creeper may be put at 1½ cts. each for one year. In other words, the claim is made that for 1¼ cts. per mile per day rails may be kept in their original and exact position, and the many troubles and expenses incident to creeping may be practically eliminated.

Both the rail-splice and the anti-creeper above described are the invention of a well-known civil engineer, Mr. Adolphus Bonzano, M. Am. Soc. C. E., 331 South 18th St., Philadelphia, Pa.

THE WORLD'S COAL TRADE.

From a statement recently issued by the British Board of Trade, the following figures are taken relating to the world's production and consumption of coal, from 1883 to 1896. In the latter year the most important coal producing countries gave the following outputs:

United Kingdom	195,361,000 tons.
United States	171,416,000 "
German Empire	85,690,000 "
France	28,750,000 "
Belgium	21,252,000 "
Russian Empire	9,229,000 "
Japan	5,000,000 "
British India	3,848,000 "
Canada	3,743,000 "
Australasia	5,345,000 "
Total	529,626,000 tons.

As to comparative cost per ton at the mine, the United States delivers the coal at the cheapest rate, the figure being about $1.14 per ton. The same cost for the United Kingdom is $1.40; Germany, $1.66; France, $2.08; Belgium, $1.82; Japan, $1.20; and the average cost in Australasia is $1.62 per ton. From these figures the "British Trade Review" expects that the United States, notwithstanding the distance to the seaboard and local demand, will be able to send huge quantities to foreign countries. In 1896 the excess amount of coal exported to other countries was as follows: From United Kingdom, 44,587,000 tons; from Germany, 6,122,000 tons; from Belgium, 4,018,000 tons; from United States, 2,337,000 tons; from Japan (1895), 1,805,000 tons; from New South Wales, 2,474,000 tons, and from Natal, 90,000 tons.

The consumption of coal per head of population is, of course, largest in the countries where steam traction and machinery are most used. But in France the average consumption seems very small for a country so far advanced in civilization; it is only .98 ton per head, as compared with 2.65 tons in Belgium, and 3.82 tons in the United Kingdom. The consumption is not noted for the United States; but, deducting the export and taking the population at as much as 75,000,000, the average would be 2.25 tons per head.

An important development of the coal trade is having a place in the far East. Including the output of Chili and the British export of coal to the east of Cape Horn and west of the Cape of Good Hope, the East is now consuming nearly 25,000,000 tons of coal annually. Indian coal production is rapidly increasing, and some of the Assam coal is said to be quite as good as the best English steam coal, and the cost of raising is about one-half of the English cost. The Japanese coal deposits are not very extensive, and their competition in the Eastern market need not be greatly feared by England; and the manufactures of that country are increasing so fast that coal is even now high in cost in that country. But there are great, undeveloped possibilities in China and Siberia. On the Trans-Siberian railway fifty groups of workable coal deposits are reported upon, and the output in Eastern Siberia, particularly from the Amour valley, is now about 2,000,000 tons annually. In China, a British syndicate claims a concession, in the Shansi district, for a coal field 250 miles long and 40 miles wide; and by its side are immense deposits of brown hematite and spathic iron ores and an abundance of limestone. The development of these deposits would enormously effect the evolution of industry in the far East, and have a marked effect upon economic and industrial conditions in Great Britain, says the "Review."

A DIRECT READING POWER GAGE FOR STEAM ENGINES.

The measurement of the power developed by a steam engine has always been a difficult operation, and is rarely a completely satisfactory one, involving, as it at present does, a series of operations, each one contributing a small error to a total which amounts sometimes to a considerable figure. Several ingenious integrating indicators have been devised to measure the total work done over any period of time. One of the most successful was described in Engineering News of July 28, 1898. Practically all of these instruments depend upon the elasticity of springs and the use of pistons, and there are several mechanical limitations which restrict the use of these devices. For instance, it is not mechanically practicable to operate continuously an indicator spring through its entire range of elasticity without permanent set or crystallization; neither is it practical to operate a piston within a cylinder with a constant coefficient of friction. In the device referred to in the title of this article, a radical departure has been made and an entirely new principle is employed for the meaurement of the pressure in the cylinder. For purposes of explanation it may be spoken of as a steam turbine driven by a steam jet whose pressure is the same as, or directly proportional to, the working pressure in the engine cylinder. This will be clearer if Fig. 1, a diagrammatic illustration, is examined. The cylinder represented may belong to any kind or make of engine, the details of construction or valve mechanism playing no part so long as there are the usual indicator taps, represented in the figure by A and B. From these, short curved pipes lead into the back of the instrument, which is placed beside the cylinder at a convenient height for observation.

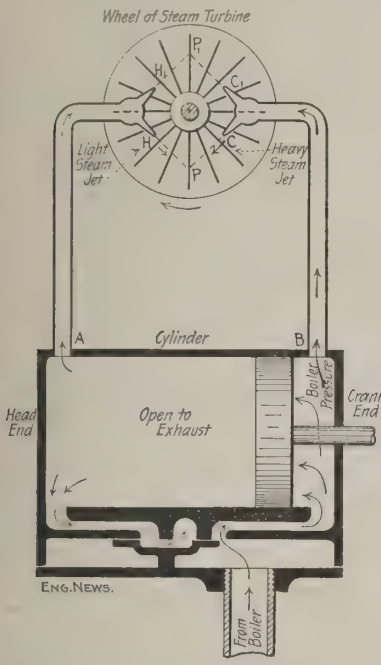

Fig. 1.—Diagram Illustrating Principle of Operation of the Atwood Power Gage.

Inside the instrument case the pipes just mentioned terminate in four nozzles, H H_1 and C C_1 shown in Figs. 1 and 2, and just back of the nozzles is a metal disk mounted upon a shaft and nicely balanced on ball bearings. This disk is provided with a series of thin radial blades set perpendicular to its surface. The nozzles H H_1 C C_1 are set at an angle, as will be seen in Fig. 1, and are inclined towards the turbine wheel, as shown in Fig. 2, so that the steam jets impinge at the two points P and P_1. In addition a simple valve or shutter arrangement cuts off the steam jets H C or H_1 C_1, as the case may be, just as the engine piston changes direction or better at the instant the steam pressures of the head and crank ends of the cylinder reverse. This jet-controlling mechanism is very simple, and is operated by a simple reducing motion.

Considering now the operation of this turbine wheel and referring to Fig. 1, it will be seen that the steam at boiler pressure is free to pass through the steam port into the crank end of the cylinder, and thence through B to the nozzle marked C (C_1 being at that instant closed by the shutter device). The steam jet issuing from C strikes the turbine wheel at P with a force which is directly proportional to the pressure in the working end of the cylinder. At the same time a jet is issuing from H, H_1 being closed, but here the pressure is that on the exhaust side. The result of these two opposing forces is a force tending to turn the turbine disk at a velocity which is at all times directly proportional to the effective pressure in the cylinder.

The disk is made of a weight sufficiently light to readily respond to the series of impulses and yet heavy enough to have sufficient inertia to integrate the impulses and maintain an approximately constant velocity, when the impulses are of equal value. In fact the turbine wheel plays exactly the same part as the flywheel of an engine, the speed of which, were there no governor upon the engine, would be a measure of the mean effective pressure. To prevent racing, and at the same time to put a constant load upon the turbine a fan consisting of several radial blades is mounted upon the turbine shaft (Fig. 2), but in a separate compartment. Directly in front of the load fan, but in no way connected to it, is another similar fan. Upon the shaft of this second fan, but in a third compartment, is mounted a dead beat or dampening device and a spiral retractile spring. The indicating needle or pointer is outside of this compartment, and swings around a dial, Fig. 3. The only connecting link between the turbine and the indicating portion is, therefore, the air in the enclosed compartment.

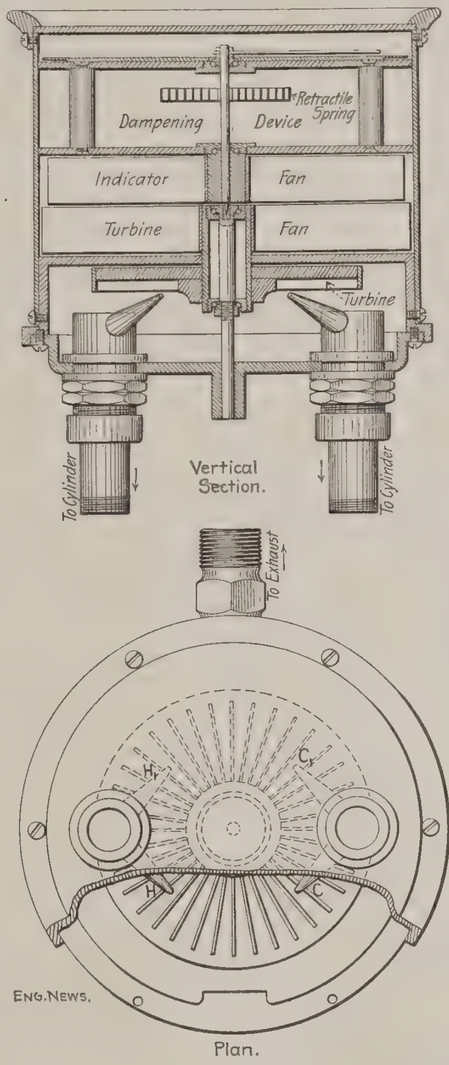

Fig. 2.—Section and Elevation of the Atwood Power Gage, Showing Arrangement of Parts.

In the operation of the instrument, the turbine revolves continuously in one direction, clockwise, with a speed ranging from a few revolutions up to 1,200 or 1,500 revolutions per minute, depending directly upon the effective pressure in the cylinder. In so doing it gives a rapid whirling motion to the air in the intermediate compartment, and this whirling air tends to turn the second fan against the resistance of the spring. Thus this fan is actually turned from its normal position a distance proportionate to the turbine speed. The dampening device prevents any sudden movement of the fan and needle.

In calibrating the instruments at the factory, two compressed air tanks are employed, one supplying each pair of nozzles. The air is compressed in these tanks by electric motor-driven compressors and a calibration can be made for any desired range of pressures. The scale on the dial can be graduated for indicated horse-power, or in the case of constant speed engines the scale may be marked for mean effective pressure on an inner scale, and the horse-power for various pressures marked on an outer scale. Other methods are possible and will suggest themselves.

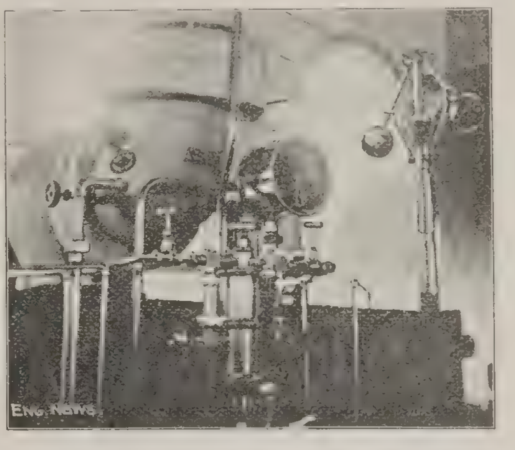

Fig. 3.—View of Engine with Atwood Power Gage Attached, Showing the Size of the Instrument.

In installing the instrument it is advisable to employ a 3-way cock at each end of the cylinder, and also in the pipe leading to the exhaust pipe. This will permit the testing of load distribution and the use of an ordinary indicator for valve adjustment should it be desired.

The possibilities and utility of the instrument are briefly as follows: It will enable an accurate and complete log of station operation to be kept; it forms a check upon the condition of the engine and will enable the efficiency of the plant to be easily determined and maintained; it forms a constant indication of valve setting, and will at any time show the distribution of work between the several cylinders or between the ends of the same cylinder. In the case of a condensing engine the operation of the condenser can be tested. Friction loads and the power required to run any one or several machines can also be readily determined, absolutely no skill being required, as the operator has only to open the valves and note the dial indication.

Several of these power gages have been in continuous operation on the engines of the Peoples' Elec. Light & Power Co., at Orange, N. J., for the past 18 months, during which time comparisons with indicator cards show a variation of less than 1%. Another instrument is at present in use on a high speed engine in the New York Telephone Building, 15 Dey St., New York city. The principal duty of this engine is to drive a generator furnishing current for several Sprague electric elevators, and a rough and ready check upon the power gage is afforded by comparing it with the switch-board ammeter. As the load is increased or decreased both needles swing out slowly in perfect unison.

This ingenious instrument is the invention of Mr. G. F. Atwood, of the Atwood Power & Speed Gage Co., 95 and 97 Liberty St., New York. We are indebted to him for the information and drawings from which our description and illustration have been prepared.

TELEGRAPH LINES IN SANTIAGO PROVINCE, Cuba, to the extent of 447 miles, have been ordered by the military authorities and are being put up under Capt. Jasper E. Brady, of the U. S. Signal Corps. These lines will connect Santiago with Manzanillo, Victoria de las Tunas, Holguin, Guantanamo and Baracoa. There is also a line from Guantanamo to Sagua Tanamo. As business increases the system will be extended. The line to Holguin and Victoria will connect with a line building eastward from Havana. American operators and American methods are employed, and any profits will be devoted to extending the lines, the same rates being charged for service as in the United States.

COUNCIL REPORT ON THE STREET RAILWAYS OF CHICAGO.

There has for a long time been strife between the street railway companies and the city authorities and the people of Chicago, over questions involving the terms of franchises, the relations of the companies to the city, and the character of service and accommodation furnished. In October, 1897, the City Council passed a resolution introduced by Mr. J. N. Harlan, directing the appointment of a special council committee to investigate the street railways, their franchises, financial operations, traffic conditions, and the wages paid to employees. The Mayor, Mr. Carter H. Harrison, was chairman of the committee. This report was presented in March, 1898, but its publication was delayed for some months, owing to a failure on the part of the city to provide an appropriation for printing. The report is lengthy and is not very well arranged, as might be expected, nor is it always quite logical, but it contains much matter of considerable interest, and it certainly shows the need of some change in the relations between the city and the street railway companies. The officers of the companies refused to furnish any information, and a certain bias against the companies is somewhat evident, but on the other hand it must be said that the city and the people of Chicago have many reasonable grounds of complaint against the street railways.

The first subject taken up for discussion is that of the franchises, and at the very outset a great difficulty was experienced, due to the fact that many of the lines are operated by lessee companies, instead of by the companies to which the franchises were granted, but that no copies of these leases were submitted to the Council for approval, or filed with the city, so that the Council might be informed as to their terms. Other difficulties arise from the fact that there is no ordinance requiring the companies to file statements as to their assets, or to furnish any other information, and that many of the franchises have been drawn up by the representatives of the companies instead of by those of the city. It is also noted that the public records contain no specific grants for some of the lines now in operation. In this respect the committee makes the following note, which contains a very important truth:

> The Metropolitan Railroad Co., of Washington, D. C., which has constructed and is operating an underground electric system probably unsurpassed anywhere in the world, makes an annual report to Congress, giving its assets, its receipts, an itemized statement of all its disbursements, and a list of all its stockholders, with the amounts of their holdings. This fact seems to indicate that openness and publicity of accounts and personnel are quite consistent with, if not distinctly conducive to, superior equipment and service.

As to the discussion of the franchises, the subject is so involved and so complicated by changes, legal quibbles, amendatory franchises, doubtful ordinances, ambiguous phraseology in the franchises, etc., that no direct line of argument can be followed out. The question of greatest importance, and the one which largely gave rise to the agitation which resulted in the appointment of this committee, was as to the time of expiration of the present franchises and the terms upon which extensions of these franchises should be granted. Most of the old franchises were for 25 years, but in 1865 the legislature passed the "ninety-nine-year act," extending the life of the three companies (operating on the North, West and South sides) and their several franchises from 25 to 99 years, or until Feb. 14, 1958. The "horse and dummy line act" of 1874, required the consent of the local authorities for the location or construction of any street railway, and provided that such consent should not be granted for a period of more than 20 years. In 1875, the city of Chicago adopted its new charter, which authorizes the city to permit, regulate and prohibit the locating, constructing or laying a track of any horse railway in any street, alley or public place, such permission not to be granted for a longer period than 20 years. These promises were undoubtedly made to prevent any future "ninety-nine year" grants, but could not affect grants already made.

In 1883, the period of the three main 25-year grants expired, and the question as to the legal effect of the ninety-nine year act came before the Council for decision. As the result of controversies over this question and that of car licenses, a compromise ordinance was passed July 30, 1883, granting the three companies an extension of time for their then existing lines until July 30, 1903, or postponing the settlement for 20 years. The committee arrives at the conclusion that these and all later grants are either terminable by the city at will on July 30, 1903, or will expire absolutely on that date, while the companies claim that the later grants do not expire until Feb. 4, 1958.

Grants for mechanical power are usually for a term of years, sometimes extending beyond the term of the original franchise, but it is not supposed that these could extend the franchises. In other cases, no duration is specified and the grants can be revoked, or would terminate with the original franchises.

The second part of the report deals with the history, operations, liabilities and profits of the three principal companies: The Chicago City Ry. Co., the North Chicago Street Ry. Co., and the West Chicago Street Ry. Co. The figures of the financial operations aim to show excessive profits by the payment of very large dividends and by the distribution to stockholders at par ($100) of stock which would sell on the market at $200 to $300. In other words, all the companies are charged with extensive watering of their stock, while they are further charged with misplacing money by means of contracts for installing mechanical traction, and building the Van Buren St. tunnel, etc., these contracts being let to construction companies composed of members of the street railway companies. The estimates of cost of all the work let under these contracts are claimed to have been very much too high. The cost of putting in the cable system on the main lines of the West Chicago Street Ry. Co. is given by that company as $8,000,000, although it gave the construction company $10,000,000 of its stock for the work. Independent estimates, however, have put the actual cost at only $5,000,000.

The committee considers that an income of 8% would be a liberal allowance, and presents tables showing the actual profits realized in excess of such an income. To ascertain these profits as realized up to any given date, the difference between the stockholders' investment and the present value of the entire stock was ascertained, and to this was added the sum of the annual excesses of dividends above 8%, these excesses being accumulated at 4% compound interest.

Another point taken up is the over-capitalization of the companies, which is derived by comparing the cost of duplication of the lines (as given by Prof. Bemis in the Report of the Illinois Bureau of Labor Statistics, 1896), with the capitalization, that is, the par value of stocks and bonds. From these figures deductions are drawn as to the payments which might have been made to the city, and the reductions in fares which might have been conceded by the companies if dividends in excess of 8% had been foregone, the reduction in fares being based on the assumption that it would not increase the number of passengers. The companies make certain annual payments to the city for car licenses, operating bridges, and public improvements, but in 1897 these payments amounted to only about $30,000 by each of the three main companies, as shown in the accompanying table, this being less than 1% of their gross receipts.

The general tenor of this part of the committee's report is that the companies are directly blamable for these conditions, but it should be borne in mind that if the city (through its representatives) has not looked out for its own interests, it is not reasonable to expect that the street railway companies will do so. The companies are not organised or operated on a philanthropic basis, but as money-making enterprises, and they cannot be expected to make payments to the city or concessions to the public which are not demanded by the terms of their franchises. It is true that it might be good policy on their part to make certain concessions, but that is a matter upon which the companies alone are the judges.

Another source of trouble which is discussed is the insufficiency of transfer privileges, by which many passengers have to pay two or more fares for comparatively short rides. This is due largely to the way in which the three sections of the city are apportioned among the three main companies, which give no transfers over each other's lines. In other cities, however, such interchange transfers are given, and have proved very satisfactory. The best system of transfers is said to be on the South Side, while on the North Side the transfers are limited. The latter case is said to be due to the fact that branches and feeder lines which should properly form a part of the main North Side system, are built and operated by separate companies which collect their own fares. These companies, however, are composed of representatives of the main company, which thus practically receives both fares.

Another curious fact in regard to transfers is that the first street railway grant was to the Chicago City Ry. Co., for a line running east and west on Madison St., from Western Ave. to State St., and north and south on State St., from Lake to 31st St. The ordinances for this and later lines extending from the South Side through the city to the West Side, required that the rate of fare for any distance should not exceed 5 cts. In 1863, however, the company sold its Madison St. line and all West Side lines to another company, and since then separate fares are required on the West Side and South Side lines, although the original requirement for a single fare has never been legally repealed, nor has the sale been approved by the city.

The three main street railway systems terminate in the business center of the city, and passengers going from one section of the city to another must change cars and pay at least two fares. The report states that a similar "radial" arrangement of routes formerly prevailed in Detroit, but that through or "diameter" routes have recently been adopted as a means of economy in operation and increased accommodation to the public. Under this arrangement the cars start from the city limits, on one side, pass through the business section and continue to the city limits on the opposite side. In Detroit, too, tickets and transfers are good on the cars of different companies. It seems very certain that in a city as large as Chicago, better facilities should be afforded in this respect, as well as in the number of cars on some of the principal routes. In some cases single cars only are run, even in the busiest hours when they are crowded to the great discomfort and even danger of the passengers. The danger is especially great with the open cars having foot boards. On other lines of the same system trail cars are put on during these hours.

Another point which may be considered in this connection, but which is not referred to in the report, is the frequent use of open cars in cold, wet and wintry weather. In view of the very changeable and uncertain climate of Chicago, an ordinance should be adopted and enforced, requiring the companies to run a certain proportion of closed cars throughout the year, as is done in some eastern cities. The companies usually have two sets of equipment, and keep one in use and the other on storage tracks until the weather makes it absolutely necessary to change the sets.

As already noted, the companies cannot be expected to take the initiative in these improvements, although it might be good policy and even economy for them to do so. The city, however, has the remedy in its own hands, but in Chicago the ordinances for such purposes are usually so drawn that the companies successfully fight them in the courts. Even when such ordinances are allowed to stand, only spasmodic efforts are made to enforce them, and consequently the companies pay no attention to them unless disposed to do so. The use of fenders is a case in point. For a long time the city has tried to get the companies to equip their cars with fenders, but ordinance after ordinance has been turned down by the courts. One of these required "all cars" to be equipped, but the companies argued that this would include trail cars, which could not and need not be so equipped. The companies claimed that the fenders would be an absolute danger, and that the stop planks across the wheels were sufficient safeguards, in spite of the fact that investigations have shown their claim to be unsupportable. Fenders are now, however, beginning to be applied to the cars on some lines.

An ordinance was passed last year requiring the motor cars and grip cars to be equipped with vestibules or shelters for the men, and there were threats of vigorous enforcement. No attention was paid to the ordinance, however, and no practical results ensued, but throughout the severe winter the men worked exposed to the weather as usual, except on some few lines which ordinarily use vestibule cars.

To return to the committee report. The next subject taken up is that relating to wages of employees and conditions of employment, on which points very little official information was obtained. The gripmen and conductors on the cable lines appear to be ranked above the motormen and conductors on electric lines, the former receiving from 25 to 28 and 30 cts. per hour for a 10-hour day, while the latter receive 21 cts. per hour and work from 10 to 11 hours. If the cable lines should adopt the trolley system, as has been suggested, the lower rates of wages would prevail. It is commonly understood to be the policy of the companies to discourage and prevent any trade organization on the part of their men, and they are said to require these men to sign contracts not to join any labor organizations, though no copies of such contracts are given to the men or made public.

One rather important matter mentioned is the existence of many sections of tracks and junction curves which are disused. These are especially numerous in the business center of the city, and there are also two or three lines which are operated in a desultory way, merely to hold the right of way, and are of no use to the public. These tracks constitute a serious obstacle in the streets, especially in the case of curves at street intersections. While none of the ordinances for street railway grants contain specific provisions requiring the companies to operate the lines or entailing the forfeiture of the lines if not operated, yet it is held that the acceptance of the grants implies an obligation to operate the lines. The committee is of opinion that the city has the right to remove these tracks and to regard the lines as forfeited.

No reference is made in the report to the condition of the tracks and pavements, nor to the requirements as to paving, repairing and cleaning the streets, or removing snow therefrom. In all these respects the companies are very negligent, and they are frequently the source of trouble between the companies and the city. This class of investigation, however, was not included in the instructions to the committee, but from an interesting digest of laws and city ordinances affecting the rights of the street railways, which is appended to the report, we take the following:

(1883). Companies to repair and maintain 8 ft. and 16 ft. of streets then occupied.

(1887). When companies remove snow from their tracks, they must within reasonable time clear this from the cross walks and level it down along the roadway.

(1893). It shall be unlawful for the companies to sweep the snow from the center of the streets and allow it to remain, preventing access to the stores and dwellings along the route.

In conclusion we give a table, compiled from the voluminous figures and tables in the report, giving some of the most important and interesting items bearing upon the discussion of the relations of the street railways to the city. The figures given are brought down to Dec. 31, 1897:

Statistics of Operation of Chicago Street Railways.

MINERAL PRODUCTS OF THE UNITED STATES IN 1897.

Mr. David T. Day, Chief of the Division of Mineral Resources, U. S. Geological Survey, has issued a tabular statement of the mineral products of the United States for each year from 1888 to 1897, inclusive. An abstract of the chief items follows; though this abstract is generally confined to the year 1897, with some comparisons with previous years:

The pig-iron output for 1897 was 9,652,680 tons, valued at $95,122,299. This is the largest output in tons in the decade under consideration; but the 9,202,703 tons of 1890 were valued at $151,200,410, indicating a marked decline in price per ton since that date. The gold and silver output last year was 2,774,935 ozs. of gold, valued at $57,363,000, and 53,860,000 ozs. of silver, valued at $69,637,172; generally speaking, there has been a decline in the silver production and a gain of nearly 40% in that of gold in the past decade. The copper output for 1897 exceeds that of any previous year, and has risen from 231,270,622 lbs. in 1888, valued at $33,833,954, to 491,638,000 lbs. in 1897, valued at $54,080,180. The lead produced in 1897 amounted to 208,192 tons, worth $14,885,728; this is also larger than for any other year in the decade, and has steadily increased from 151,919 tons in 1888, valued at $13,399,256, again showing a fall in price per pound. Of other metallic products in 1897, zinc shows 99,980 short tons, worth $8,498,300; quick silver, 26,648 flasks, worth $993,445; aluminum, 4,000,000 lbs., worth $1,500,000; this latter is an increase from 1,300,000 lbs. in 1896, 920,000 lbs. in 1895, and 19,000 lbs. in 1888. There were reported for last year 23,707 lbs. of nickel; no tin, and 150 lbs. of crude platinum.

The non-metallic products also generally show marked gains in 1897 over other years in the decade 1888-1897. Bituminous coal amounted to 147,789,902 short tons, worth $119,740,052, and the increase is practically steady from 102,039,838 short tons in 1888, valued at $101,860.529. Pennsylvania anthracite, however, fell, in 1897, to 46,814,074 long tons, worth $79,129,126, from a maximum output in 1895, for the decade, of 51,785,122 long tons, worth $82,019,272. The petroleum output last year was 60,568,081 barrels, worth $40,929,611, as compared with 60,960,361 barrels in 1896, valued at $58,518,709. Of cement, 10,989,463 barrels, worth $8,178,283, were made in 1897; this is greater than for any year in the decade. Other important non-metallic products were as follows, for 1897: Mineral waters, 23,255,911 gallons, worth $4,599,106; phosphate rock, 1,039,345 long tons, worth $2,673,202; 15,973,202 barrels salt, worth $4,920,020; 4,247,688 long tons limestone, for iron flux, worth $2,124,000; and 16,000,000 lbs. borax, worth $1,080,000.

The total values of the mineral products of the United States for 1897 sum up as follows: Nonmetallic, $329,113,845; metallic, $302,198,502; unspecified, $1,000,000; grand total, $632,312,347. This is the maximum total for the decade 1888-1897; that for 1888 being $540,781,936, or $91,530,411 less in amount than for last year.

* * *

THE NEW PUBLIC ELECTRIC LIGHTING CONTRACT for Boston contains some novel features. It is for a period of ten years, from Feb. 20, 1899, and thereafter until a new agreement is made or either party notifies the other in writing of its decision to terminate the contract. The contract, however, is subject to the yearly appropriations of the city council. The prices are on a sliding scale, ranging from 35 cts. per lamp per night, or $127.75 per year, for 2,365 lamps, to 30 cts., or $109.50, each, for 5,000 lamps. The price must be readjusted by arbitration at the end of five years, and may be so readjusted at the end of 2½ and 7½ years, if the Mayor so elects, as to keep the net earnings down to 6% on the capitalization devoted to public business, or at a correspondingly lower rate in case any of the bonds bear less than 6% interest. The distribution of the expenses and earnings between public and private lighting is to be based on the relative electrical outputs, measured separately in kilowatt hours, for each class of business. A maximum depreciation of 7%, exclusive of land, is to be allowed in calculating the net earnings. The city may also refer to its arbitrators any invention or improvement which it claims will reduce the cost of electric lighting. If the arbitrators report that the claims of the city are valid, the price for public lighting is to be decreased accordingly, whether the company adopts the improvement or not. The company is to substitute, at its own expense, wooden poles, with ornamental iron goose-neck lamp supports, for the iron posts now owned by the city. It is also to provide closed arc lamps, like those described in U. S. Patent No. 603,630, dated May 10, 1898, for the open lamps now in use. The new lamps are to require an electrical energy of not less than 500 watts on the average and not less than 480 in any case. The present lamps have a nominal candle power of 2,000. This contract is a modification and continuation of the five-year contract made in 1894. Its new features are largely due, we judge, to Mr. Josiah Quincy, Mayor of Boston, who recently gave it his approval.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; 6 *months,* $2.50; 2 *months,* $1.00. *To all other countries in the Postal Union: Regular Edition, One Year,* $7.60 (31 *shillings*); *Thin Paper Edition, One Year,* $6.31 (26 *shillings*). *SINGLE COPIES of any number in current year,* 15 *cents.*

In ordering changes of mailing addresses, state BOTH old and new addresses; notice of change should reach us by Tuesday to be effective for the issue of the current week. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number 328 *means that subscription is paid to the* 32*d week (that is the issue of Aug.* 11) *of the year* 1898; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line. Want noticees special rates, see page* 18. *Rates for standing advertisements sent on request. Changes in standing advertisements must be received by Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

Street cleaning and garbage collection in Chicago are being now more than usually neglected, the money appropriated and the time of the men employed having been apparently largely diverted to political campaign purposes. Chicago is notorious for its ill-paved and dirty streets, and in fact it has hardly a street in good condition, with the exception of the boulevards (which are cared for by the Park Commissions and not by the city authorities), and some suburban roads. Many of the important business thoroughfares have great holes and pools of mud, which it would be impossible to clean in any ordinary way, even if the attempt were made. Such repair work as is done is largely of a very poor quality, and in some cases the property-owners have preferred to do the work by private contract, under permission from the city. All municipal work is under political rule, in spite of efforts to introduce the civil service system. Only recently, a man who had the work of street cleaning in one of the wards, but who had not a regular contract (being paid by the day), was replaced by another man without any notice, because he had interfered in some way with the aims of a local politician. The new man, having no proper machinery, made a failure of the work. To one who has seen the streets of Detroit, Milwaukee, Denver, San Francisco, or even Kansas City, the Chicago streets appear to be deplorably bad and filthy. After the litigation over the garbage collection contracts, which has been recorded in our columns, the city took up the work, and the authorities talked loudly about the great improvements that were to be made. At the present time, however, the garbage boxes are overflowing with the accumulation of weeks, and dirt, refuse and waste paper are thick in the alleys. In some of the residence districts the garbage wagons come along at irregular intervals of two to four weeks. Recently, the complaints have been so numerous that the authorities have taken steps to have this matter attended to, for fear of their political opponents making capital out of it during the coming campaign, and they have also promised to clean the streets on the route of the jubilee parade. The Council has made an appropriation of $50,000 for the work, but this has been declared illegal, as the city, under the terms of its charter, exhausted its power in this direction last spring, when it made an appropriation for the same purpose, and which has long since been expended. Even if the appropriation should hold, the local papers express the opinion that it would not result in $50,000 worth of street cleaning. After a few weeks, the present condition of affairs will doubtless prevail again. Many of the bridges, and viaducts also, are in very bad condition, owing to failure to provide money for painting or repair. The city of Chicago is loud in proclaiming preeminence among western cities, but it is more noted for a certain bad eminence as an example of defective municipal government under political administration on the "spoils" system.

◆

For a long time, builders and users of steam engines have felt the need of some better method of measuring and recording the power developed by a steam engine than the ordinary piston indicator. The desirability of this has been more than ever felt since electrical machinery came into general use, and its advantages in the way of accurate indicating and recording instruments became familiar to mechanical engineers. The electrical engineer, although the industry with which he is concerned is not a score of years old, has at his disposal instruments which show him at a glance the amount of power which his machines are giving out or absorbing. The steam engineer who desires to know the power his engine is developing must perform the tedious work of taking an indicator card, measuring and computing it, and when his task is done he knows only the power developed at a given instant, which in an engine with a variable load may vary widely from the average work that the engine is doing.

The task of doing for the steam engine what the wattmeter does for the electric motor, has been attacked within recent years by a number of inventors. The devices they have produced, however, have generally been based upon the ordinary steam cylinder indicator invented by James Watt, and first employed by him in experimenting with his engines. Taking this as a foundation, other inventors have devised various types of continuous recording instruments which it may be interesting to briefly review.

In the simplest of these the oscillating drum of the ordinary indicator is replaced by an arrangement which feeds a continuous ribbon of paper. An example of this class was described by its inventor, Prof. Thomas Gray, at the meeting of the American Society of Mechanical Engineers, in May, 1897 (Eng. News, June 3, 1897). The record of this instrument is a continuous zigzag line or wavy line, the amplitude of the waves giving the indicated pressure and their length, the length of stroke.

A step in advance of the instrument just described is to make an instrument in which a mechanical integration of the continuous diagram is effected. One of the best of this class of instruments is that devised by Mr. W. O. Amsler, of Pittsburg, and described in the "Sibley Journal of Engineering," for October, 1896, and later by Mr. A. A. Cary.* In this instrument the inventor still adheres to the piston and spring, although the spring is not in direct contact with the steam. With this instrument steam is admitted to both sides of the piston, which moves up and down under the combined influence of the steam from the engine cylinder and the indicator spring. In so doing it shifts the center of a spherical roller which is in contact with a small cylinder whose axis is parallel with the piston motion. This spherical roller is being continually oscillated about its axis by a reducing motion similar to that used with the ordinary indicator. With atmospheric pressure in the engine cylinder the axis of the spherical roller is perpendicular to the rolling cylinder, and no motion results. Increase the pressure and the axis of the spherical roller tips, throwing the point of contact out of line with its axis and immediately the cylinder begins to turn. In turning (which it will do to an amount proportional to the inclination of the axis of the spherical roller and the rate of rotation of the latter which depends upon the position of the engine piston), it drives a small dial at one end of the cylinder, which always turns in one direction. It will be seen that the instrument can be so calibrated as to continuously indicate the power developed.

Another example of this class of instrument was described in Engineering News, July 28, 1898. It is the invention of Messrs. W. G. and C. W. G. Little, Bexley, Kent, England, and as in the other cases depends upon the small steam cylinder, piston and spring. The paper drum is replaced by a plain metallic drum upon which rolls a small integrating wheel, the inclination of whose plane of rotation is varied by the indicator piston. In other words, this integrating wheel replaces the pencil motion of the ordinary indicator.

There is also a modification of this form designed by Prof. C. S. Brown, and described by Prof. Thomas Gray, in the Transactions Am. Soc. M. E. (Vol. XVIII., p. 1,035), in which the drum, instead of oscillating, is given a reciprocating motion back and forth along the line of its axis by a reducing motion. The wheel or roller presses against its surface, and as its plane is shifted by the movement of the piston, just as in the Little instrument, the cylinder is turned. The force with which the cylinder revolves is considerable, and is used to drive a light train of gears turning needles over properly-calibrated dials.

◆

This steam engine power gage is a wide departure from the other instruments above described. The ordinary steam engine indicator preserves the cylinder and piston which are the essential parts of the engine itself. The new power indicator discards these and adopts in their place the steam turbine. Briefly stated, the power measuring part of the device consists of a small steam turbine operated by two jets of steam, one from the working end of the cylinder and one from the exhaust, arranged to oppose each other so that the actual turning force at any instant is proportional to the effective cylinder pressure, and the greater the pressure the greater the speed of the turbine. This turbine, which has sufficient weight and inertia to maintain its speed between the impulses which occur, owing to the reversal of piston direction and the changing of pressures from one end of the cylinder to the other.

It may be asked whether the speed of the turbine is directly proportional to the pressure of the steam issuing from the cylinder. If the turbine were entirely free to revolve, this probably would not be the case, since the velocity of the steam issuing from a nozzle increases very slowly with increase of pressure after about 10 lbs. gage pressure is reached. However, as the turbine is given a load which causes it to revolve much more slowly than the steam, its speed will be proportioned not to the velocity of the steam, but to the energy of the issuing steam jet, and this is approximately proportional to the steam pressure.

We think our readers who follow the detailed description of the power gage in another column will be satisfied that the instrument is designed upon correct principles. It may seem to them, however, that it would be impossible for an instrument of this sort to be accurate in its indications. The only proof of this, of course, is actual test; and we are informed that the tests thus far made have shown gratifying results.

The practical value of an instrument which will indicate upon a dial at every moment the horsepower which an engine is developing is too obvious to require proof. It will doubtless be an easy step from such an instrument to an automatic recording instrument which will tell a graphic story at a glance to the eye of the Manager or Superintendent.

◆

Gen. Henry L. Abbot, Corps of Engineers, U. S. A., and member of the technical commission on the Panama Canal, asks us to correct several errors in the original manuscript of his article printed in this journal Oct. 6. The errors are important and for this reason we call attention to them in this place. Under the heading of the "Regulation of the Chagres River," in the second paragraph, the sentence, commencing "the largest within the memory of the inhabitants," should read, "is at Gamboa, 2,040 cu. m. per second," in

stead of 1,630 cu. m. In the next paragraph, the sentence, "reservoirs to contains 1 million cu. m., above Alhajuela and 1.5 million cu. m. above Bohio," should be corrected to 100 million cu. m. above Alhajuela, and 150 millions cu. m. above Bohio." In the sixth paragraph, the sentence "calling for a layer of water 9 m. deep, to contain 1 million cu. m.," should read "100 million cu. m." In the eighth paragraph, the sentence "a capacity of 1.5 million cu. m.," should read "150 million cu. m."

LOSSES OF HEAT IN A STEAM PLANT.

The science of thermodynamics is taught, and we presume well taught as a rule, in all our schools of mechanical engineering, and its elements at least are more or less familiar to all engineers engaged in steam engineering work. And yet we venture to say that there are few among either students or practitioners who will not obtain, if they study the accompanying diagram, a clearer idea of the heat losses and heat interchanges that take place in a working steam plant than they have ever had before.

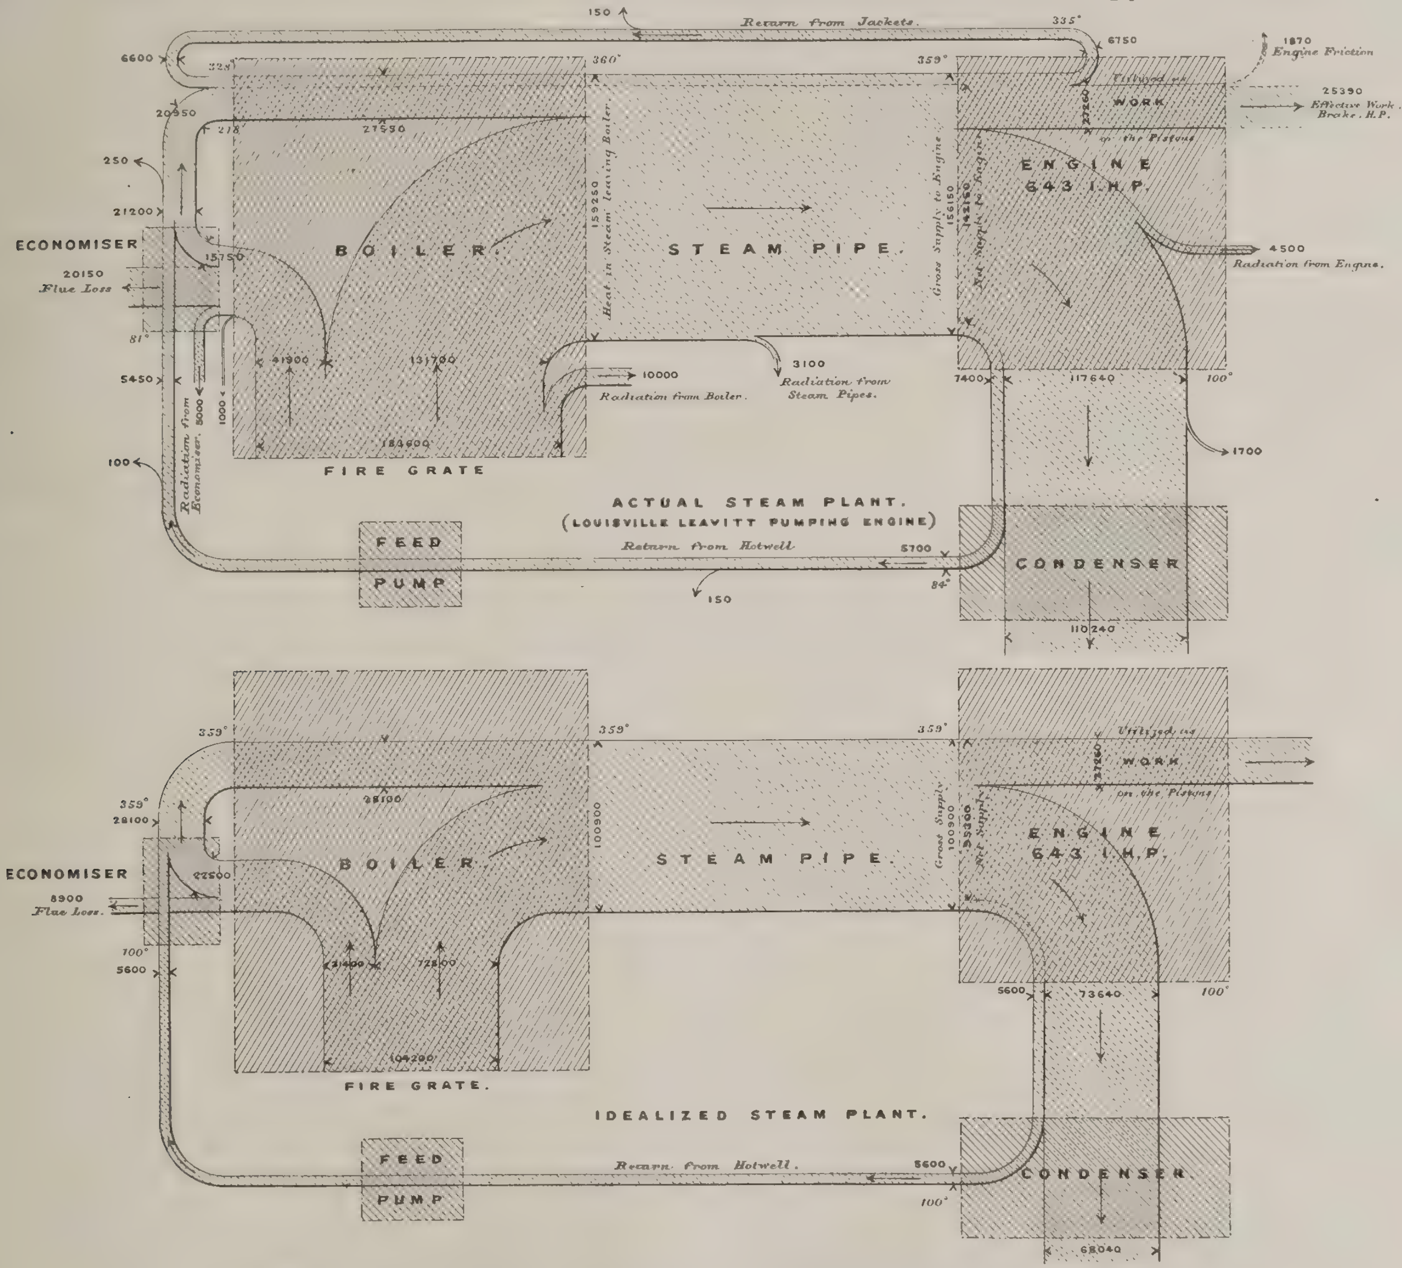

FIG. 1.—DIAGRAMS ILLUSTRATING THE LOSSES AND TRANSFERS OF HEAT IN STEAM POWER PLANTS.

It is a fact too often forgotten by teachers—and let us add, by those who write for and edit technical journals, as well—that it is the fact presented in the simplest and most forcible form that sticks in the mind. For example, the literature of steam engineering contains much with reference to the losses that take place during the expansion of steam in an engine cylinder. They have been explained and presented in diagrams and equations galore, yet an engineer of thorough education and wide acquaintance with the literature of steam engineering tells us that this never became a vivid, concrete reality to his mind until he ran across the statement that the difference in the temperature of steam in an ordinary engine when it entered the boiler, and when the exhaust port was opened was greater that the difference between the hottest day of summer and the coldest day of winter.

It is the trouble with much of our teaching and much of our learning, too, that we fail on the one hand to present facts, and on the other hand to grasp them in a way that shall make them vital realities to the mind. It is one of the objections to advanced mathematical work for engineering students, that it diverts the mind from realities to abstract things. The student absorbed in algebraic manipulations too often forgets what his symbols represent, and thereby falls into errors of reasoning which make his whole work of no value.

Turning again to the diagram shown herewith, it seems to us that it presents more vividly and clearly to the mind the heat interchanges of a steam power plant than anything which we have ever seen in technical literature. The broad river of heat generated by the coal burned on the grate is shown flowing to and through every part of the apparatus, losing by radiation at every step, and finally emerging at the chimney in a flow of heated air and gases, at the condenser in the circulating water discharged and at the engine shaft as useful work.

We have reproduced this diagram from the report recently issued by a committee of the Institution of Civil Engineers upon the "Thermal Efficiency of Steam Engines," made up by Professors Kennedy, Macfarlane, Gray, Ewing and Beare, Capt. H. R. Sankey and Messrs. Capper, Davey, Donkin, Longridge and Maw. The diagram shown herewith was made by Capt. Sankey, to accompany an introduction to the report, and to make clear exactly what is meant by the "thermal efficiency" of a steam engine.

The boiler, the engine, the condenser and the air pump; the feed-pump and economizer, are each shown on the diagram by rectangles (of arbitrary size). The flow of heat is shown as a stream, the width of which is proportional to the amount of heat entering and leaving each part of the plant per unit of time. The losses are shown by the many waste branches of the stream. Capt. Sankey continues the description of the diagram as follows:

> The upper diagram represents, in the main, the trial of the Louisville Leavitt pumping engine as described in the Transactions of the American Society of Mechanical Engineers, Vol. XVI.,* and the data are sufficiently full to enable the flow of heat to be stated at all points with fair accuracy. The numerals represent British thermal units flowing per minute; the streams are drawn to such a scale that each inch of width represents a flow of 100,000 B. T. U. per minute. Temperatures are also given.
>
> Starting at the fire-grate, it is shown that 183,600 B. T. U. are produced per minute by the combustion of the coal, and that 131,700 of these go direct into the water of the boiler, 10,000 are lost by boiler radiation and leakage, and the remainder, viz., 41,900, pass away with the flue gases. On the way to the economizer, 1,000 B. T. U. are lost by radiation, but in the economizer itself 15,750 B. T. U. are diverted into the feed water, 5,000 B. T. U. are dissipated by radiation, and finally 20,150 B. T. U. pass out of the economizer and into the chimney, and are lost to the steam plant. The heat entering the economizer with the feed-water is 5,450 B. T. U., which is added to the 15,750 B. T. U. diverted from the flue gases, thus giving a flow of 21,200 B. T. U. in the feed out of the economizer. Radiation, however, reduces this flow to 20,950 B. T. U. per minute at the entry to the boiler, where a further

---

*Eng. News, Dec. 13, 1894.

addition is made of 6,600 B. T. U. returned by the jacket water.

The steam produced by the boiler is thus seen to derive its heat from three streams, as shown on the diagram; the steam finally leaves the boiler with 159,250 B. T. U. per minute. Before this heat gets to the engine, however, 3,100 B. T. U. are lost by radiation and leakage from the steam pipes, so that the flow of heat is reduced to 156,150 B. T. U. per minute, which is the gross supply of heat to the engine; the net supply is less, because there are certain returns of heat to the boiler to be deducted. In the first place credit has to be given to the engine for the heat which could be imparted by means of the exhaust steam to the feed-water, inasmuch as the exhaust is theoretically, and very nearly practically, capable of raising the temperature of the feed to the exhaust temperature. On this basis, 7,400 B. T. U. should be credited to the engine, although the actual return to the boiler, or rather to the economizer, is only 5,450 B. T. U. The difference is due to excess of circulating water, which lowers the hot-well temperature, and also to radiation in the feed arrangements, which are a necessary portion of the steam plant, independent of the engine proper, and which are not applied to correct any fault of the engine. The loss of 1,950 B. T. U. should therefore be debited to the feed and condensing arrangements, and not to the engine. It will be seen that the 7,400 B. T. U. credited to the engine is equal to the water-heat of the feed at the temperature of the exhaust. In the present case a special credit has to be given to the engine, because 6,750 B. T. U. leave the engine in the jacket water to return to the boiler; but 150 are lost by radiation on the way, so that the net return is 6,600 B. T. U. Only the net return to the boiler should be credited to the engine, because the jackets are applied to correct a fault of the engine, namely, cylinder condensation; hence any loss to the steam plant that may be entailed by the use of jackets (i. e., the radiation in question) should be reckoned as a loss due to the engine, although it takes place outside the engine. In the case under consideration the jacket water was returned direct to the boiler; but if, as is frequently the case, the jacket water is drained into the hot-well, the heat in it cannot be credited to the engine, for the reasons given above.

The net supply to the engine can therefore be obtained as follows:

	B. T. U.	B. T. U.
Gross supply	....	156,150
Less returnable by feed...............	7,400	....
" returned by jackets	6,600	....
		14,000
Net supply per minute.................		142,150

It will be seen that only 27,260 B. T. U. are utilized as work upon the pistons. The ratio of the heat so utilized to the net heat supplied is called in this report the "Thermal Efficiency of the Engine." In the numerical case under consideration the thermal efficiency is $\frac{27,260}{142,150} =$ 0.15.

The engine under discussion indicates 643 HP.; the heat supplied "per minute per I. HP." is therefore $\frac{142,150}{643}$ = 221 B. T. U., and it is this figure which, as recommended in the report, should be used to express the thermal economical value of a steam engine. This recommendation is made with a view of replacing the present usual method of stating the performance in lbs. of feed-water per I. HP. per hour, although the latter statement is useful for other purposes.

It will be seen that 1,870 B. T. U. are deducted from the 27,260 utilized as work on the pistons, as engine friction, so that the effective or brake power of the engine corresponds to 25,390 B. T. U. per minute; in other words, the brake HP. of the engine is 599, so that the "B. T. U. per minute per I. HP." are $\frac{142,150}{599} = 237$, another figure which the committee recommends should be quoted whenever it is possible to ascertain the brake efficiency.

Let it now be supposed that the actual steam engine is replaced by an ideal steam engine, forming part of an idealized steam plant working according to the "Rankine cycle," using for this cycle the name recommended by the committee. It must be assumed that the I. HP. of the "ideal" engine is the same as that of the "actual" engine, namely, 643 HP., and that the admission and exhaust temperature are the same, namely, 359° F. and 100° F. respectively. The flow of heat in the ideal steam plant is represented by the lower diagram, and it will be observed that all the losses have disappeared, except the flue loss and the heat carried away by the condensing water. There are no jackets, but there is an economizer, because, although the boiler is perfect, 31,400 B. T. U. are sent into the flue, since the gases cannot be cooled down below the temperature of the water in the boiler, and a portion of this heat can be saved by heating the feed to the steam temperature. The heat returnable by the feed is, of course, less than in the case of the actual engine, owing to the reduced weight of steam passing through the engine. The heat supplied to the ideal engine is therefore:

	B. T. U.
Gross supply .... , ...	100,900
Less returned by feed	5,600
Net heat supplied per minute................	93,300

The I. HP. of the ideal steam engine being the same as that of the actual engine, the same number of B. T. U. per minute are utilized as work upon the piston, namely, 27,260. The thermal efficiency of this ideal steam engine is therefore $\frac{27,260}{95,300} = 0.285$, and the B. T. U. per minute per I. HP. are $\frac{95,300}{643} = 148$, as against 221 for the actual engine. The actual engine, therefore, requires 73 B. T. U. per minute per I. HP. more than the ideal engine; these heat-units are lost on account of imperfections in the actual engine, and can be looked upon as a measure of these imperfections. The ideal steam engine thus becomes the "standard of comparison," as recommended and defined by the committee.

The number of B. T. U. per minute per I. HP. required by the ideal engine depends on the temperature of the steam at admission, and its temperature at exhaust, and also on whether the steam is saturated or superheated. Fig. 2 has been drawn to enable this number of B. T. U.'s to be read off directly in all cases likely to occur in practice.

If the number of B. T. U. per minute per I. HP. required by the ideal engine be divided by the number needed by the actual engine, there is obtained what has been called the "efficiency ratio" by the comimittee. In the numerical case under consideration this ratio is $\frac{148}{221} = 0.67$.

The report of the committee, to which the above forms an introduction, is too long for us to reprint. Their recommendations, however, are summarized as follows:

1. That "thermal efficiency" as applied to any heat engine should mean the ratio between the heat utilized as work on the piston by that engine and the heat supplied to it.

2. That the heat utilized as work be obtained by measuring the indicator diagrams in the usual way.

3. That in the case of a steam engine, the heat supplied be calculated as the total heat of the steam entering the engine less the water-heat of the same weight of water at the temperature of the engine exhaust, both quantities being reckoned from 32° F.

4. That the temperature and pressure limits, both for saturated and superheated steam, be as follows:

Upper limit: the temperature and pressure close to, but on the boiler side of, the engine stop-valve, except for the purpose of calculating the standard of comparison in cases when the stop-valve is purposely used for reducing the pressure. In such cases the temperature of the steam at the reduced pressure shall be substituted. In the case of saturated steam the temperature corresponding to the pressure can be taken.

Lower limit: the temperature in the exhaust-pipe close to, but outside, the engine. The temperature corresponding to the pressure of the exhaust steam can be taken.

5. That a standard steam engine of comparison be adopted, and that it be the ideal steam engine working on the Rankine cycle between the same temperature and pressure limits as the actual engine to be compared.

6. That the ratio between the thermal efficiency of an actual engine and the thermal efficiency of the corresponding standard steam engine of comparison be called the "efficiency ratio."

7. That it is desirable to state the thermal economy of a steam engine in terms of the thermal units required per minute per I HP., and that, when possible, the thermal units required per minute per brake HP. be also stated.

8. That, for scientific purposes, there be also stated the thermal units required per minute per HP. by the standard engine of comparison, which can readily be obtained from a diagram similar to that given in Fig. 2, and from which the efficiency ratio can be deduced.

Your committee would also suggest that in papers submitted to the institution bearing on steam-engine economy, authors be invited to conform to the above recommendations.

The only matters in the above recommendations which may need further explanation relate to what the committee defines as the "standard steam engine of comparison," and which is designated on the diagram as an ideal steam engine. The description given of this engine in the report is as follows:

After careful consideration, your committee recommend an ideal steam engine working as part of the Rankine cycle as the standard steam engine of comparison, both for saturated and for superheated steam engines.

The definition of the Rankine cycle is as follows: It is assumed that all the component parts of the steam plant are perfect, and that there are no losses due to initial condensation, leakage, radiation, or conduction, and that there is no clearance in the cylinder. The feed-water required is taken into the boiler at the exhaust temperature, and its temperature is gradually raised until that corresponding to saturated steam is reached. Steam is then formed at constant pressure until dry saturated steam is produced, after which, if the steam is to be superheated, heat is added at constant pressure and at increasing temperature, until the required temperature of superheat is reached. The steam is introduced into the cylinder at constant pressure, displacing the piston, and performing external work equal to the absolute pressure multiplied by the volume swept through by the piston up to the point of cut-off. Beyond that point expansion takes place adiabatically, doing work until the pressure in the cylinder is equal to the back pressure against which the engine is working. The steam is then completely exhausted from the cylinder at constant pressure corresponding with the lower limit of temperature, work being done on the steam by the engine during exhaust, equal to the absolute back pressure multiplied by the total volume swept through by the piston. The steam is thus removed from the cylinder and the cycle is complete.

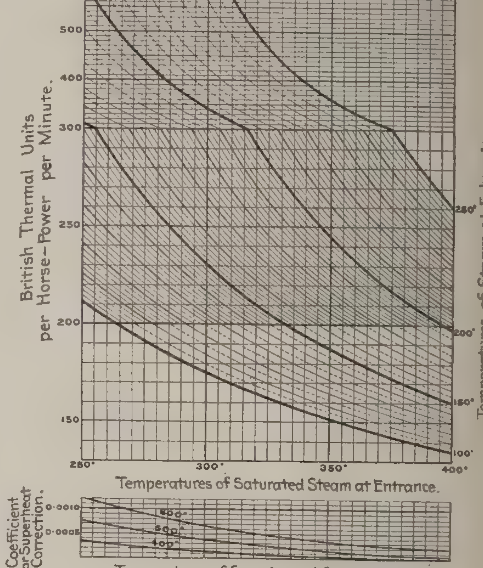

Fig. 2.—Curves Showing British Thermal Units Expended per Minute per. I. HP. by the Standard Engine of Comparison, viz., the ideal Steam-Engine Forming Part of the Rankine Cycle. (Temperatures in Degrees Fahr.)

(It will be noticed that the upper and lower portions of the diagram are to different scales; this is in order that the lower and more important part may be read more easily, and accounts for the cusps in the curves.)

The formulas for finding the heat units per minute per HP. for an ideal steam engine working on the Rankine cycle above described, are so long and complex that a diagram has been prepared from which this quantity may be found at a glance. It may be remarked that in the plotting of the diagrams for superheated steam the specific heat of superheated steam at constant pressure has been taken at 0.48. The practical use of these diagrams may be made clear by an example. Suppose it be desired to determine the B. T. U. per minute per HP. required for a "standard steam engine of comparison," taking saturated steam at 350° and discharging it at 212°. Follow up the vertical line from the figure 350 at the bottom of the diagram until it intersects the curve starting from 212° on the right-hand side. From the point of intersection follow a horizontal line to the left, and the required quantity is found to be 265 B. T. U.

Again suppose that it be required to obtain the B. T. U. per minute per HP., for the "standard steam engine of comparison," working with superheated steam at 135 lbs. pressure and 500° F. temperature, and with an exhaust temperature of 212°. Find the B. T. U. as before, using for the higher temperature the temperature corresponding to the pressure in saturated steam, then subtract from the B. T. U. per minute thus found a number to be found as follows: On the small lower diagram follow up from 350 to the curve marked 500°, and then from the point of intersection to the left on a horizontal line, by which process the correction coefficient is found to be 0.00015. Multiply this coefficient by 212, the exhaust temperature, and the product by 265, the number of B. T. U. found from the under diagram. Subtract the final product, 8.5, from the 265 B. T. U. already found. The remainder, 256.5 B. T. U. is the quantity required.

With the above explanation we believe our readers will have no difficulty in making practical use of the method of recording the efficiency obtained in steam engine trials recommended by the Institution committee. The advantages of the heat unit system as a basis of comparison have already been made familiar to American engineers to a considerable extent by the adoption of the system by the American Society of Mechanical Engineers in its standard code for duty trials of pumping engines. To state the economy of an engine merely in terms of the weight of coal or of steam which it uses per horse-power in a given time, is something like stating the width of a piece of land in paces.

In conclusion, we will again call attention to the diagram showing the various heat losses in a real and an ideal steam plant, which forms, we are inclined to believe, one of the most valuable parts of the committee's report.

While the facts it displays may be elementary to many of our readers, the general plan of the diagram may be studied with much profit by all engineers who have to do with the records and testing of steam or electric power plants. The idea of representing the energy in a power plant as a flowing stream and the various losses and dispositions of the energy as diverging branches therefrom is one which is worthy of general adoption. Facts displayed in such a graphical manner may be impressed on the minds of Boards of Directors, or other superior officers, when columns of figures and tables would be ignored. The most successful engineers are those who can deal with men as well as with materials; and the ability to present the facts of a situation forcefully and graphically is often worth as much to an engineer as all his knowledge of mathematics or materials.

LETTERS TO THE EDITOR.

Typhoid Fever in the Army.

Sir: I am directed by the Surgeon-General to acknowledge receipt of an article on "Typhoid Fever in the Army" in Engineering News, Sept. 22, 1898. The article appears to be clear and comprehensive and based upon competent knowledge of the subject. Cases of typhoid fever, diagnosed as such, were, however, not transported through the country to distribute their diarrhoeal discharges without disinfection along the tracks. Such cases were only transported by the Medical Department of the Army in hospital trains, fully equipped with all modern hospital appliances, where disinfection was as thoroughly carried out as in any civil hospital in the country. It may be true that certain undiagnosed cases sent home on sick leave proved ultimately to be typhoid infection, but such cases represented only an extremely small proportion of the typhoid cases. They were allowed to proceed on their journey simply because the symptoms manifested did not warrant the diagnosis of any grave affection. Their return was perhaps due to mistaken diagnosis based on incomplete data, but certainly was not a sin of omission or commission to be attributed to the Medical Department of the Army.

The publication of such a fair-minded and dignified article as the one above mentioned cannot fail to have a decided influence in shaping public opinion at a time when newspaper sensationalism appears to have run riot.

Very respectfully, Edward L. Munson,
Captain and Assistant Surgeon, U. S. Army,
Washington, D. C., Oct. 12, 1898.

The Comparative Corrosion of Iron and Steel.

Sir: Your answer to R. S. W., of Milwaukee, Wis., in Engineering News of Oct. 6, is, I believe, partially incorrect. My opinion is that hard steel, which you say corrodes more slowly than iron, corrodes more than twice as fast as iron. This opinion has been confirmed in nearly every talk I have had with some of the best posted men on the subject, and I believe this is the reason why the best informed builders are now using iron instead of steel for roofing and sheet metal work. If I remember correctly Mr. M. P. Wood, in his essay on "Rustless Coating for Iron and Steel," says steel corrodes about five times fast as iron. It is certainly much easier to make paint stay on iron than on steel. As this is an interesting and important matter I for one would like to hear from any others who can speak with authority on this subject.

Very truly, C. H. H.
Cleveland, O., Oct. 15, 1898.

(We join our correspondent in asking those who have experience to discuss this topic. The literature upon the comparative liability to corrosion of iron and steel is exceedingly meager and unsatisfactory. Mr. Francis T. Bowles, Naval Constructor, U. S. N., states that "good unpainted iron or steel plates" will lose on one surface in 100 years from .30 to .50-in. thickness, if immersed in sea-water; .02 to .03-in. if in pure, fresh water, and .25 to .30-in. if exposed to the atmosphere. But, unfortunately, he makes no distinction between the iron and the steel. The action of sulphurous gases upon iron and steel, the presence of sewage in the water in which iron and steel are immersed, and the general prevailing conditions will doubtless much modify the rate of corrosion in each, and these conditions should be carefully noted in observations of this kind.—Ed.)

Laying Out Turnouts and Crossings.

Sir: I wish to heartily concur in the remarks of Mr. E. D. Wileman on the subject of frogs and crossings in your issue of July 28, which has just come to my notice. He is quite right in saying that it is impossible to make a satisfactory plan of a crossing by measuring an old one in the track, or a new one either. The only way is to measure the angle of intersection of tracks, calculate angles and dimensions, and check them from a large-scale drawing.

The whole subject of turnouts and crossings has been completely befogged by a multitude of useless and cumbersome formulas. Every young engineer approaches his first turnout with fear and trembling, having imbibed the idea from the books that the subject is exceedingly difficult, whereas it is very simple, involving only problems in the use of simple circular curves, and requiring only such formulas as should be at the finger-tips of every transitman of two months' experience.

A common mistake in laying out turnouts is to begin with the location of the head-block instead of the frog point. If the latter be chosen first, and the frog angle be turned from the main line or from a tangent to the main line at that point, the turnout can be run as easily as any other curve. A table of leads and turnout curves for straight track should be constructed by considering the frog from heel to toe as one tangent, and the main line rail for stub switches, or the switch rail for split switches as another, and calculating the circular curve required to join them. Then calculate the offset between the main line and turnout curve at a point half way between the frog point and the head-block for stub switches, or heel of switch rail for split switches. This offset will be the same for the same frog, whether the turnout be on either side of tangent, taper, simple or compound circular curve, and should be used in staking the lead, as it saves the trouble of determining the degree of the turnout curve in the three last named cases.

Frogs of the same number but different lengths will of course have slightly different turnout curves, as will also stub and split switches with the same frog.

Respectfully, J. P. Newell, O. R. & N. Co.
Portland, Ore., Oct. 10, 1898.

Electro-Plating of Stones and Pebbles With Metal From Water Pipes.

Sir—In the article on "Electrolysis of Water Pipes at Dayton, Ohio," in your issue of Oct. 6, I note the following quoted from the report of Mr. Harold P. Brown:

> Furthermore, the stones or pebbles near the pipes seem to be electro-plated with the metal of the pipe. This condition I have not seen at any other place, and, as far as I know, it has not been observed before.

In this connection I would refer to a letter of mine, dated March 15, 1894, and published in your issue of March 22, 1894 (Vol. 31, p. 242). With this letter I sent you samples of earth in which the redeposited metal from the pipes was plainly visible. At that time, and frequently since then, we have observed here that stones or pebbles near the pipes were especially apt to be electroplated with the metal of the pipe, whether lead or iron; and where there were moist streaks or faults in a clay soil, I have found samples of the redeposited metal extending as far as the sides of the excavation, sometimes 6 ft. from the pipes. I have been very much interested in the portions of the Dayton report which you published, more especially since our experience here agrees in many particulars with the results of the careful observations made by the experts employed there.

Yours truly, Dabney H. Maury, Jr.,
Engineer and Supt. Peoria Water-Works Co.
Peoria, Ill., Oct. 13, 1898.

(As a matter of interest in this connection we take the following additional remarks respecting the electro-plating of pebbles, etc., at Dayton, from the report of Mr. E. E. Brownell, one of the electrical experts employed by the city.—Ed.)

> Wherever any electrolytic action has attacked the cast-iron mains, there remains upon or adjacent to the mains a black substance, that is due to the nascent oxygen being liberated from the decomposed water, oxidizing the iron in the pipes, and this iron is then carried or held in solution by a solvent, which is formed by the reaction of a current of electricity upon the constituents of the soil; from this solvent the iron, lead or whatever metal it has attacked, is taken or given up to be deposited or electro-plated upon the soil and stones to the distance of several inches.

◆

Sir—In your issue of Oct. 6 is an abstract of reports upon the damage to water pipes at Dayton, Ohio, by electrolytic corrosion. In this there are several statements which clearly appear to be founded on misadvertence or misinterpretation of facts.

For instance, it has been fully proved by experiments made here in 1893 and 1894 that such electrolytic corrosion is a direct electrolytic action and not one in which free oxygen comes into play. Similar conclusions may be derived from the results of Mr. Farnham's experiments of about the same date. It would be a very fortunate thing if the view of the cause of electrolytic damage set forth in your abstract were correct; since, in this case, an electric pressure of some considerable magnitude would be requisite to set up the action, and careful bonding for the purpose of reducing the difference of pressure between pipes and track return would bring this below the critical value required to liberate oxygen under the existing conditions, and the danger of damage would be entirely avoided. Unfortunately, the action does not take place in this way, but was shown in the experiments referred to above to be a direct electrolytic action, which may be set up by a mere directive force. Hence results the carrying away of iron from the pipes and its deposition elsewhere. This is plainly explained in the paper read on July 11, 1894, before the Western Society of Engineers, and published in the Journal of the Association of Engineering Societies (monthly number for September, 1894). I have frequently observed an accumulation of iron or lead salts in the earth near electrolytically damaged pipes, and the phenomenon is well known amongst those who have had experience in making examinations for the purpose of prescribing alleviative measures.

Respectfully yours, D. C. Jackson.
Department of Electrical Engineering University of Wisconsin, Oct. 13, 1898.

STANDARD SPECIFICATIONS FOR STEAM BOILERS.

At the recent annual meeting of the American Boiler Manufacturers' Association, at St. Louis, the report of a committee appointed at the convention of a year ago to prepare a set of specifications for steam boilers was presented, and after extended discussion was adopted with slight changes. The report as finally adopted is as follows:

Materials.—The materials for first-class boiler work should be the standard materials as adopted at Philadelphia, by final vote recorded on page 77 of Proceedings of 1897, and as given in concise form on pages 207 and 208, Proceedings of 1897. Other materials not therein specified are given in the body of these specifications in connection with provisions for the design and workmanship of the parts to which they apply.

Riveting.—Holes should be perfectly true and fair, made so by use of clean cutting punches or drills; sharp edges and burrs to be removed by slight counter sinking and burr reaming before and after the sheets are joined together. Under side of original head of rivet must be flat, square and smooth to insure perfect contact with the plate. For rivets from ⅝ to 13-16-in. diameter allow 1½ diameters for length of stock to form the head; for large rivets allow less length. For button set on snap rivets 5% more stock may be allowed to form the driven head. Light regulation riveting hammers to be used until rivet is well upset in the hole; after that the snap and heavy mauls. For machine riveting more stock may be left for the driven head, to make it equal to the original head; this to be fixed by experiment. The amount of pressure on the die should be obout 80 tons for 1⅛ or 1¼ in. rivets; 65 tons for 1 in., 57 tons for 15-16-in., 35 tons for ¾-in. rivets.

Rivets should be tested both hot and cold by driving down on an anvil with the head in a die, by nicking and bending, and by bending back on themselves, all without developing cracks or flaws. The heads of rivets to be of equal strength with the shanks. This is fulfilled by giving the head at the periphery of the shank a height equal to one-third the diameter of the shank. A slight fillet at this point is advisable. The rivets should have a diameter about double the thickness of the thinner plate; the pitch should be about three times the rivet hole; the distance between staggered rows of rivets half the pitch; the lap for single riveting about equal to the pitch; the lap for double riveting about one and one-third times the pitch. and one-half pitch more for each addtional row of rivets.

All these are approximations; the exact dimensions to be determined by making the resistance to shear of the total rivet strength of the net or standing metal.

A factor of safety of 4½ shall be used where the tensile strength of the plate and the shearing strength of the rivets have been determined by actual tests. Where this has not been done a factor of safety of 5 shall be taken, and at most 55,000 lbs. tensible strength per square inch for steel plate and 40,000 lbs. shear strength per square inch for rivets be allowed. Rivet holes may be punched with good sharp punches and well fitting dies in American Boiler Manufacturers' Association steel up to ¾-in. in thickness. Above that thickness either punching and reaming with a fluted reamer, or drilling is advisable. The judicious use of the drift pin with light hammers in pulling the plates into place and rounding up the holes is not objectionable; but enlarging or gouging holes to a fit by driving in a drift pin with heavy hammers or mauls is condemned as a barbarous practice. When drawn into an approximate fit the holes must be trued up by means of reamers.

Calking—The old style, known as split calking, is unfit for boiler work. Excellent work can be done, both by hand calking or calking with pneumatic hammer and the Conery or round tool. Excessive calking throws undue strains on the rivet heads and must be avoided. The square nosed tool should be used only in corners where the round nosed cannot reach, and in taking up small local leaks, and extreme care is necessary to avoid nicking the lower plate. The fit should be made in the laying of the plates, the calking only to correct the natural and unavoidable roughness of the surfaces of contact. Calking edges should be prepared by bevel planing, bevel shearing or bevel chipping.

Flat Surfaces.—The rules for flat surfaces have been experimentally determined, and should be amended from time to time in the light of tests of full sized structures built up of the best modern materials and with the best modern tools and workmanship. The mathematical formulae for a plate supported on all sides have never been worked out to full satisfaction. The exact factor of safety under any empirical rules cannot, therefore, be determined. The rules of the United States Board of Supervising Inspectors approximate a factor of safety of five. And as they have given satisfactory results during past years, with materials of less excellence than American Boiler Manufacturers' Association stock, they are recommended as safe rules—viz.:

State of thickness of plate in sixteenths of an inch, thus for ½-inch plate, 8-16 or 8; then:

Assume a constant (C) for the following varying methods of construction:

C = 112 for plates 7-16 inch thick and under, with screw stays, riveted ends.

C = 120 for plates over 7-16 inch thick, with screw stays, riveted ends.

C = 140 for all plates when in addition to the screw threads in the plates a nut is used both inside and outside of each plate.

Whenever salt, acids or alkali are contained in the feed water all plates must have nuts inside and outside, in addition to the screw threads in the plate. The safe working pressure per square inch is

$$P = \frac{C \times t^2}{p^2} \text{ (where p = the pitch in inches)}$$

by formula. Or it can be expressed in the rule: Multiply the constant C by the square of the thickness of plate expressed in sixteenths of an inch, and divide by the square of the pitch expressed in inches. The quotient is the safe working pressure:

The supervisor's rules allow a still higher constant, C equals 200, based on large washers riveted as reinforce plates on the outside of the plates. But this introduces the element of doubt as to weakening by rivet holes (which has caused abandonment of this method of reinforcing manholes), and it is therefore wiser to discard it.

Bumped or Dished Heads.—Whenever a head is uniformly dished or bumped as a segment of a sphere, any radial section of same is under the same conditions of equilibrium as the circle seam of a cylinder, and as a circle seam has double the strength of a side seam (subject to percentage reduction due to riveting), it follows that the thickness of a convex or dished head should be the same as that of the cylindrical shell whose diameter is equal to the radius of curvature of the dished head. As this rule applies to a solid plate any reduction by rivet holes, man holes, etc., must be allowed for by proportionate increase in thickness.

Flanging, Bending and Forming.—The exact heat for flanging, bending and forming cannot be fixed, but must be left largely to the judgment of the flanger, since it depends on various qualities of the steel or iron, but under no circumstances should any blow be struck, or bending attempted, after that portion of the plate undergoing manipulation no longer shows red in the dark. As the danger point is what is known as blue heat, this rule must be understood to apply to parts of the plate at least 4 ins. distant from the point where the actual bending takes place or the blow is struck.

Rolling.—All rolling should be done cold, and gradually by regular increments from the straight plate to the exact circle required, and care must be taken that the whole length of the plate is rolled to a true circle. If the lap for the rivet seam is left straight instead of being brought to this true circle there is always a danger point on the line of demarcation.

Boiler Tubes.—Boiler tubes should be made of charcoal, iron or mild steel, specially made for that purpose, and should be lap-welded or drawn. They should be round, straight, free from scales, blisters and mechanical defects, and each tube subjected to an internal hydrostatic pressure of 500 lbs. per sq. in., and so stenciled. The manufacturer's name should also be plainly stenciled on each tube. The metal thickness should be as follows, but may be increased when demanded by specially high pressure or extreme lengths:

No. 13 B. W. G.	1 in., 1¼ ins., 1½ ins., 1¾ ins.
No. 12 B. W. G.	2 ins., 2¼ ins., 2½ ins.
No. 11 B. W. G.	2¾ ins., 3 ins., 3¼ ins., 3½ ins.,
B. W. G. No. 10.	3¾ ins., 4 ins.
B. W. G. No. 9	4½ ins., 5 ins.

Tests.—A section cut form one tube taken at random from a lot of 150 or less must stand hammering down vertically without cracking or splitting when down solid.

Size.	Length of test section.	Size.	Length of test section.
For 1-in. tubes.	¾-in.	For 2¾-in. tubes.	1¼ ins.
" 1¼-in. "		" 3-in. "	
" 1½-in. "	1 in.	" 3¼-in. "	
" 1¾-in. "		" 3½-in. "	1½ ins.
" 2-in. "		" 3¾-in. "	
" 2¼-in. "		" 4-in. "	
" 2½-in. "		" 4½-in. "	
		" 5-in. "	1¾ ins.

All tubes should stand expanding flange over on tube plate and bending without flaw, crack or opening of the weld.

Tube Holes.—If punched, should not be full size, but allow not less than ⅛-in. on the diameter for reaming. Tube sheet should be annealed after punching, and before reaming. All holes should be slightly countersunk on both sides to prevent cutting tube by expanding and beading.

If copper ferrules are used the hole should be a neat fit for the ferrule. If ferrules are not used the hole should be 1-64 to 1-16-in. larger, according to size of tube.

Tube Setting.—Ends of tubes should be annealed in the tube mill before setting. The tube should be allowed to extend through the sheet 1-16-in. for every inch of diameter, which is ample for beading, then expanded until it is tight in the hole and no more. Excessive expanding should be guarded against. On the end exposed to direct flame, flange tube partly over the sheet, allowing part of the right angle flange or bead to be completed by beading tool. The beading tool should not come in contact with the tube sheet, but work entirely on the tube. After beading, tube should be slightly expanded to counteract the loosening effect of the beading process.

Copper Ferrules.—Copper ferrules should be used in fire-tube boilers on the ends subject to direct heat. They protect the flue holes; protect the flues from crystallization on account of expanding, and make better and surer joints on account of softer metal being compressed between the two harder ones. The tubes are more readily removed on account of tube holes being larger, and when scaled, scale and sediment is removed with them, while when body of tube fits the hole it scrapes all scale and sediment off and leaves it on the inside of the boiler. Ferrules should be from 18 to 14 wire gage, according to size of tube.

Removing Old Tubes.—This depends largely on circumstances. There is always one end of the boiler where the tube is more readily removed than on the other. Some times it is convenient to drop them down and take them through a man or hand hole, then again raise them to a dry pipe hole, or take them through the hole they have been occupying. In any event, first remove the beading with a flat chisel. Be very careful not to injure the flue sheet. Then cape in past inside of flue sheet with a chisel or round back diamond point. Have sharp corners removed from tool to avoid cutting or scoring edge of flue hole. Then cave end of tube inward. The tube is then ready for removing from boiler, as circumstances may suggest. Where the tubes have not been beaded over they can be readily loosened for removing by using a crimping tool made with two fingers of unequal length, between which the metal of the tube fits easily. The longer finger inside the tube forms a fulcrum; the shorter one outside crimps the metal inward.

Riveted and Lap-Welded Flues.—There are so many variations in details of construction involved in the question of the strength of such flues that a mathematical determination of their strength, which must necessarily depend on certain assumptions, is not practical. On the other hand, experimental work in testing flues of this character is necessarily very expensive and would have to cover so large an amount of ground that no private firm or corporation could undertake it, and the determination should be left to the government testing works. Your committee, therefore, deems it best for the present, and until other experimental data are available, to adopt in full sections 8 to 13, inclusive, of Rule 11 of the Board of Supervising Inspectors of Steam Vessels.

Corrugated Furnace Flues and Steam Chimneys.—The same remarks as made regarding flues apply to corrugated furnace flues and steam chimneys, and your committee, therefore, recommends the adoption, for the present, subject to amendment on the basis of further experimental data, the provisions of sections 14 and 15 of Rule 11 of the Board of Supervising Inspectors of Steam Vessels.

Stay Bolts.—Should be made of iron or mild steel specially manufactured for the purpose. If made of iron, the material should have a tensile strength of not less than 46,000 lbs., and not less than 26,000 lbs. elastic limit. Elongation not less than 22% in 8 ins. for bolts of less than 1 sq. in. net area, nor less than 20% in 8 ins. for bolts of 1 sq. in. and more in net area. If made of steel the material should have a tensile strength of not less than 55,000 lbs., and not less than 33,000 lbs. elastic limit. Elongation not less than 25% in 8 ins. for bolts of less than 1 sq. in. net area, nor less than 22% in 8 ins. for bolts of 1 sq. in. and more in net area. Stay bolts should be subjected to the following tests:

1. A bar to be selected at random from a lot of 1,000 lbs. or a fraction thereof. After being threaded with a sharp die, V-thread with rounded edges, it should bend cold 180° around a bar of the same diameter without showing any crack or flaw.

2. Another piece similarly threaded to be screwed into well-fitting nuts formed of pieces of plates to be stayed and riveted over so as to form an exact duplicate of the bolt in the finished structure. It is then to be pulled in a testing machine, and the ultimate stress carefully noted. If it fails by pulling apart, the tensile stress per square inch figured on the original net section is to be used in figuring the safe load. If it fails by shearing, the shear stress per square inch of the mean section in shear is to be thus used. This mean section in shear is found by multiplying half the thickness of the plate or nut by the mean between circumference at base and at crown of thread. The safe load to be determined by applying a factor of safety of 5 to the ultimate stress per square inch thus found.

Stay bolts should be carefully threaded with sharp, clean dies. They should be cut on a threading machine equipped with a lead screw, so that there will be no variation in the pitch of the stay bolt threads. Holes should be tapped with tap extending through both sheets and to a neat, smooth fit, just large enough so that the bolt can be put in by hand lever or wrench with a steady pull. Great care should be taken to make full, clean V-threads, rounded edges, making a close,neat fit, so that very little riveting will be required; 1-5 of diameter is proper height for projecting and riveting. Riveting is detrimental to threads in sheet and on stay bolts. In the case of hollow stay bolts a long, slender drift pin should be driven into the bore before and kept there during riveting, and afterward driven home firmly to slightly expand the bolt and counteract the tendency to loosen the thread due to the riveting, and finally removed by loosening it by slight taps of the hammer all around, or by driving out by a bar from the other end. When nuts are used on screw stays the height of thickness of such nut shall not be less than 60% of the diameter of the bolt. The largest pitch permissible for screw stays is 10 ins.

Braces and Stays.—The material in braces and stays should be fully equal to stay bolt stock. A bar not less than 10 ins. long shall be taken from each lot of 1,000 lbs. or fraction thereof and tested to destruction; the tensile strength thus found, subject to a factor of safety of 5, shall limit the tensile stress per square inch permitted on the brace in direct pull. Where such tests are not made the material shall be subject to careful inspection, and if it appears satisfactory, 6,500 lbs. per sq. in. for wrought iron and 8,000 lbs. per sq. in. for steel shall be the highest loads permitted. Welding should be avoided where possible, and where welds have to be used they are to be considered as having only 80% of the strength of the solid bar. Rivets by which braces are attached to the boiler when the pull on them is other than at right angles, should be subjected to only half the stress permitted rivets in the seams.

Manholes.—The older methods of reinforcing manholes have been found by practical tests to be defective. A ring or plate riveted on inside or outside never becomes a part of the original plate, and there are many instances where the main plate was fractured under test, while the reinforce plate or ring was as good as new. This shows that it is not possible to make the reinforce plate relieve the main plate of the portion of the load intended. This becomes worse when the metal of the reinforce plate is different in quality from that of the main plate. Besides this the rivet holes necessary for joining plate and ring together introduce a new element of weakness and uncertainty. Cast-iron reinforce flanges are of no value whatever, and are unqualifiedly condemned. The best method of forming a manhole is to cut the hole considerably smaller than required, and then flange it in with a straight flange on a radius of not less than three times the thickness of the metal. In place of attempting to rivet on a piece of plate to make up for that cut away, it is better to make the original plate that much thicker. Or the flange may be reinforced by shrinking on a reinforce ring around it, and this should always be done where the plate is ½-in. or less in thickness.

Domes.—Domes should be avoided when possible. No method of reinforcing the shell where the hole is cut for the dome gives absolute security. But where domes cannot be avoided the cylindrical portion of the dome should be flanged down to the shell of the boiler and the shell either flanged up inside of the dome or reinforced by a collar flanged at the joint, and these flanges should be double riveted.

Drums.—Drums may be put on with collar flanges of A. B. M. A. steel, not less than ⅜-in. thick, double riveted to the shell and the drum and single riveted to the neck or leg, or the flanges may be found on the legs.

Saddles or Nozzles.—Should be of flanged steel plate or of soft cast steel. The latter, however, has the disadvantage that it is frequently porous, and has not the same ductility as the shell plate, and cannot be held to be as good as flanged A. B. M. A. plate. Cast iron must not be used for any opening in which it will be in tension.

Hanging.—The boiler should be supported wherever practicable at the points where there is the greatest excess of strength. Excessive local stresses from the weight of the boiler and contents should be avoided, and therefore short lugs are objectionable. Any straps or lugs from which the boiler is suspended should be made very long on the shell, so as to insure them against distortion of any kind, and the rivets for securing them to the structure should be so proportioned as to take only one-half of the stress which is permitted for rivets in the seams. The boiler should be set in such a manner that the furnace may be rebuilt without in any way disturbing the proper suspension of the boiler. All boilers should be so set that there will be a little less water at the gage cocks than at the opposite end of the boiler.

Hydrostatic Pressure.—The old methods of testing by excessive hydrostatic pressure are condemned as barbarous, and tending to weaken the structure and disturb the proper fit of the parts. The hydrostatic test should never be used to take the place of a proper and thorough examination of the quality of materials, proportions and workmanship of the boiler. The hydrostatic test should never exceed a pressure of one-third above the regular working pressure, and under no circumstances should this excess be more than 100 lbs. per sq. in. The water used for hydrostatic test should never be less than 125° F. in temperature.

We present these specifications in this form in order that a full discussion of them may be had. We think we have done our duty, as we understand it—i. e., simply to bring into a tangible form, and as short as possible, the vast amount of information which has been contributed by all members during the discussions at our nine previous conventions. Where conflicting opinions exist we have attempted rather to harmonize them or to arrive at a just and fair compromise between them, than to assume an attitude of partisanship. We are far from believing that this is the best specification that could possibly be written to-day, but we know that it represents the average opinion of those of our members who have been most earnest in the work of this association and most desirous of establishing uniformity in excellence.

After it has been fully discussed, amended and adopted, we propose to recast it in a more concise form, leaving out matters of explanation and reciting only the rules which should govern good boiler work. It will, in our opinion, then be best to incorporate under the head of "Materials" the standard specification heretofore adopted, so that when finally completed it can be issued to the members at the joint work of the two committees.

Even then we shall consider it only as representing for the present time the average standard of good American boiler practice, and to bespeak for our work the advantage of additional amendments so that it may keep pace with all improvements tested and finally adopted in the best American boiler shops. Committee: E. D. Meier, Henry J. Hartley, George N. Riley, James Tappan, D. Connelly.

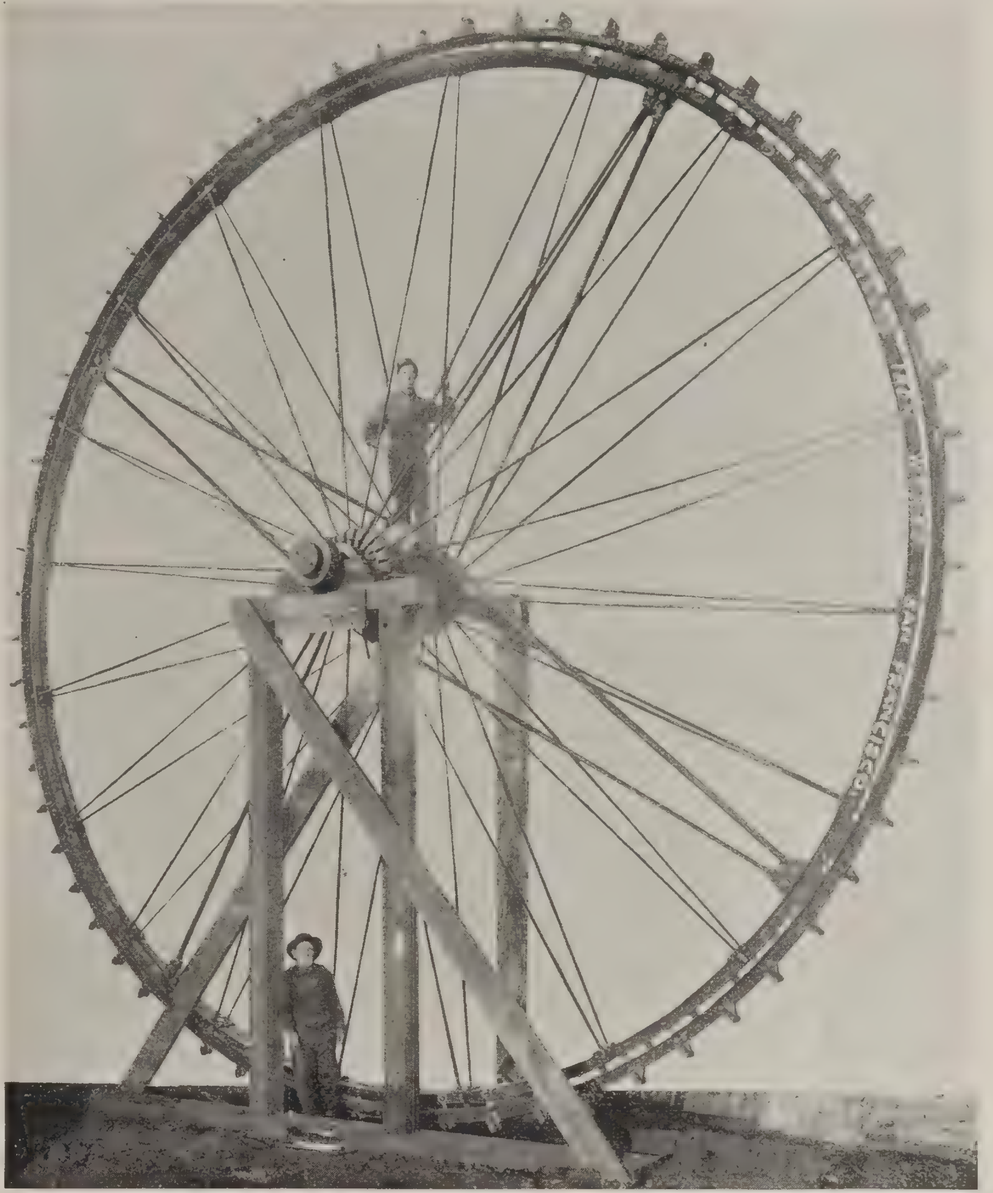
IMPULSE WATER-WHEELS OF LARGE DIAMETER.

In our issue of Dec. 10, 1895, we illustrated an impulse water-wheel for driving an air compressor at the North Star Mine, Grass Valley, Cal. The wheel was 18 ft. 6 ins. diameter, and was designed by Mr. E. S. Cobb, of San Francisco. Mr. Cobb has patented this design of wheel, and the accompanying cut shows one of still larger size (30 ft. diameter) made from his designs by the Risdon Iron & Locomotive Works, of San Francisco. It will be seen that the spokes of the wheel are all in tension, and that tangent as well as radial spokes are used. The wheel weighs about 15,000 lbs. It is entirely of steel, with the exception of the hub, and was built in four sections for convenience of shipment. It runs at the rate of 65 revolutions per minute, operating under a head of 775 ft. water pressure, and develops 330-HP. when driven by one nozzle, or 1,000-HP. with three nozzles, all of 1¾ ins. diameter. The power is used to drive a duplex, single-acting, compound air-compressor.

The buckets on the wheel are of a pattern covered by a patent issued to the Risdon Works, March 1, 1898. They are finished on the inside and polished to a smooth surface.



30-FT. DIAMETER IMPULSE WATER-WHEEL FOR A HEAD OF 775 FT.

Designed and Patented by E. S. Cobb, San Francisco, Cal.; Built by the Risdon Iron & Locomotive Works, San Francisco.

THE MACHINERY OF STEAM VESSELS ON THE GREAT LAKES.

A summary of the machinery of 1,300 steam vessels engaged in traffic on the Great Lakes has been prepared under the direction of Mr. Walter Miller, of Cleveland, Ohio. The substance of the information obtained is contained in a paper read by Mr. John H. Coffin before the Engineers' Club, of Cleveland. Referring to the survey of the 1,300 vessels in which work he assisted, Mr. Coffin said:

> There are 1,150 screw propellers and a trifle over 50 paddle, or side wheel, propellers; the balance being schooners or tow barges, which are equipped with boilers and steam pumps, or hoisting or steering machinery. Of those fitted with screw propellers, 960 have solid cast wheels, 6 of them being of bronze, 8 of steel and 946 of cast iron; 185 have sectional wheels, one of them being bronze, 6 steel and 178 cast iron. Of the entire number, 1,060 of these propeller wheels are fitted on the tail shafts with straight bore and key, while only 74 are fitted on a taper end with feather and nut, the latter arrangement being more modern practice and considered by most engineers to-day to be the preferable way of fitting propellers on the shafts. Of the paddle wheels, 23 are fitted with feathered floats and 29 have solid floats.
>
> The lack of uniformity of proportion of parts of these machines is surprising. There seems to have been no hard and fast rules for the construction of engines on the lakes, and each builder has followed his own ideas. In the item of crank-shafts, about 400 are of the solid forged type, 17 of these being of steel and 383 of wrought iron; 780 are built-up shafts, of which 23 are of interchangeable sections, 13 of them being of steel and the balance of wrought iron. Of the total number, 354 are light in section, according to Lloyd's rules for determining the size of crank-shafts. 106 cases were also found where the intermediate shafts are light of section, and 387 cases where the propeller shafts are light by these same rules; and 48 cases where the shaft couplings are reinforced, either or account of breakages or because of developed weakness. There are 296 cases where the thrust bearings are insufficient to properly relieve the crank-shaft from fore and aft strains. A perhaps more serious defect, from the insurer's standpoint, exists in the light cross-head connections, there being 446 cases where cross-head keys are too light and 54 cases where the nuts fastening piston rods in cross-heads are small. A point which seems to have been very sparingly covered by authorities on engine design, and yet which seems one of vital importance, is the bolting of cylinders to columns, of columns to bed-plates, and of bed-plates to seatings in marine engines. The strain to which each of these parts is subjected being a direct strain, the necessary strength of these parts is easily found by computation based on the steam pressure and the size of the cylinders. In these parts 340 cases were found where the cylinders are too lightly fastened to the columns, 68 cases where the columns are insufficiently secured to bed plates, and 64 cases where the bed plates are not sufficiently bolted to their seatings.
>
> The marine fire-box boiler is the most common type, though it has lost its prestige, the Scotch boiler having rapidly displaced it; 731 boilers of this type are in use to-day. The marine water-tube boiler is of more recent date, only one having been built earlier than 1880. There are none of this type now on the lakes built between 1880 and 1890, but there are 35 vessels, built since 1890, equipped with this type of boiler, and there are several vessels now under construction which are to be equipped with this type of boiler. It is also interesting to note the gradual increase in pressures in boilers built during these several periods, as shown in the accompanying table.
>
> 295 boilers were found having patches inside and 264 having patches on the outside; 82 boilers are poorly fastened to the hulls of the vessels; 139 boilers are without stop-valves between them and the throttle-valves; there are 191 cases where the slip joints in the main steam pipes are not protected with safety guard bolts; there are 134 cases, where there are no cocks between the feed check valves and the boilers; and there are 165 cases where the feed check valves are only common pipe checks.

PROGRESS ON THE WATER PURIFICATION PLANT AT ALBANY, N. Y.

(With full-page plate.)

One of the most interesting pieces of engineering construction now in progress is the water purification plant at Albany, N. Y. The plans for this work were shown in our issue of Feb. 10, 1898, just before bids were received for its construction. The contract was let to T. Henry Dumary, and the Wilson & Baillie Manufacturing Co., of Brooklyn, N. Y., and the work is now at a very interesting stage. The purification plant includes a low-lift pumping-station, drawing water from the Hudson River, a 16,000,000-gallon sedimentation basin, eight covered filter beds, each 0.7 acre in area, with a combined daily capacity of 15,000,000 gallons, and a 600,000-gallon covered pure water basin. The bottom of the sedimentation basin is composed of 16 ins. of puddle, covered with 6 ins. of concrete; the slopes have first a covering of 16 ins. of puddle, then 2 ft. of broken stone, on which is 10 ins. of stone paving. The floors and roofs of the filter beds and clear water basin are of concrete; the walls of the filter compartments are lined with brick and the piers of the compartment are of the same material.

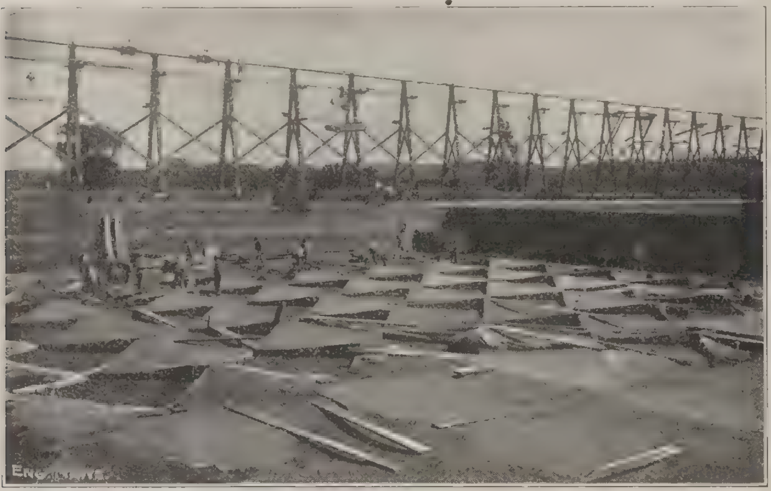

FIG. 5.—CONSTRUCTING THE INVERTED ARCHES FOR THE FLOOR OF THE FILTER BEDS.

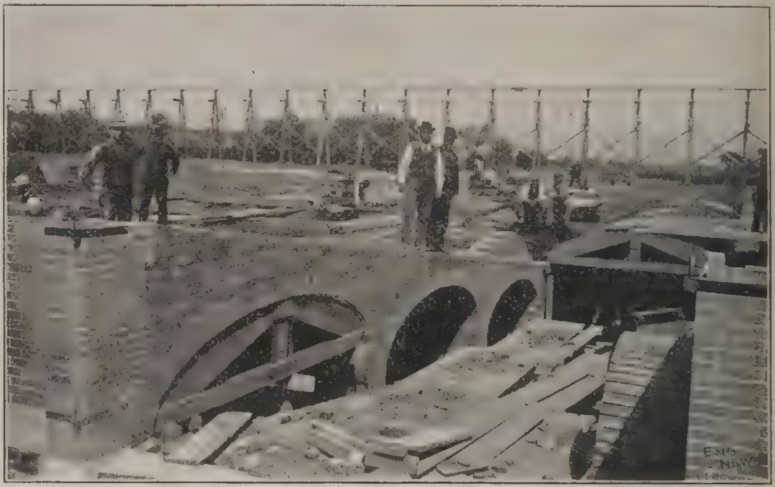

FIG. 6.—INCLINED ENTRANCE TO FILTER BEDS.

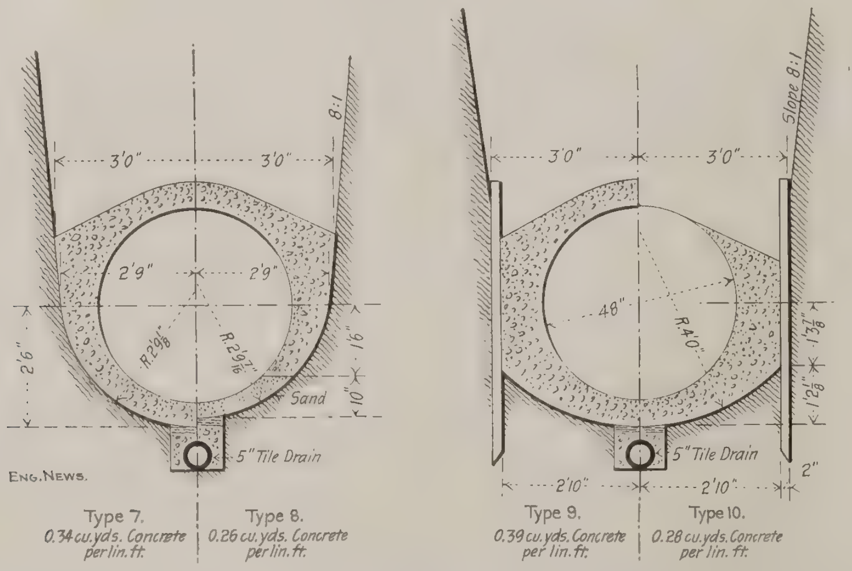

FIG. 7.—TYPICAL SECTIONS OF CONCRETE BACKING FOR 48-IN. STEEL PIPE.

In moving the large quantities of concrete, brick, stone, pipe and other material required for the plant, the contractors are using a "Sherman Aerial Hoisting, Carrying and Distributing Apparatus." This apparatus, as used on a much smaller scale, was illustrated and described in Engineering News of May 18, 1893. It was invented by Mr. W. D. Sherman. The present plant consists of four cableways, each of 730 ft. span, attached to cars running on trestles about 1,000 ft. in length, extending the length of each of the longer sides of the site of the plant. This apparatus hoists the material, moves it in a horizontal plane, both longitudinally and transversely, and lowers it at any desired point in an area 900 × 700 ft. A general view of one end of the plant is shown by Fig. 1, on the inset sheet. There is an engine for each cableway, as shown in the view, Fig. 2. The attendant of each engine controls the operations of the corresponding cableways from his station, in accordance with signals given him. Figs. 3 and 4 show the hoisting and transferring apparatus in more detail, as well as other parts of the contractor's plant. The trestles and cableways are also shown in the backgrounds of Figs. 5 and 6, in the text, and by the section, Fig. 10.

The purification works are very well located for receiving material, having the river on one side, canals on two other sides, and the railway not far distant.

The sand and gravel used for concrete is dredged from the river about two miles above the work, brought down in barges and dumped in the river, alongside a dock. From the river bottom it is again dredged up and is deposited in a pile on the dock, as shown in Fig. 1. From this pile the sand and gravel are automatically loaded on conveyors, by which they are hoisted and dumped into the screen, shown in Fig. 3. Here it is washed and separated into sand, gravel and tailings, the latter being gravel above the regulation size. The tailings are passed through a crusher and added to the gravel.

The concrete is composed of approximately 1 part of cement, 3 parts sand, and 5 parts gravel, but the proportions are changed slightly as occasion demands. The cement is paid for separately, so the city may vary the richness of the concrete at pleasure. All the cement is tested in a Fairbanks machine, a sample being taken for each ten barrels, from which twelve briquettes are made. Atlas cement is used, and it is expected that about 30,000 bbls. will be required.

The sand and gravel are elevated to an upper hopper, where cement is added, and all goes to a cubical mixer, where it is turned five times dry and five times wet. There are two mixers, each with a capacity of about 1½ yds. per charge, or 200 yds. per day. From the mixers the concrete goes onto skips of ⅔-yd. capacity. The concrete mixing plants are shown in the views, Figs. 3 and 4, the cubical mixers being enclosed so they are not visible.

The cross-tracks shown in Fig. 4 are used to convey the concrete and other material along the line of the trestle to the cableways, thus saving some of the time required for moving the cableways to position for picking up material.

The steam for power is furnished by a battery of four boilers. There are ten or eleven engines in use.

The filtered water is to be delivered to the present main pumping plant, further down the river, through a 48-in. riveted steel conduit, 8,000 ft. long, encased in concrete. The pipe is made from 5-16-in. plates and has in and out joints. For a distance of 5,000 ft. the conduit is located in the bed of the Erie Canal, and for a distance of 2,200 ft. its bottom is at an average depth of 22 ft. and a maximum depth of 25 ft. below the surface of the ground. To overcome the tendency of the canal section to float, and to withstand the external pressure on the other section, the whole length of the conduit is encased in concrete. The cross-sections of concrete used for the greater part of this casing are shown by Fig. 7, types 7 and 9. A portion of the conduit 168 ft. long, beneath railway tracks, was built in a tunnel about 6 ft. wide and 7 ft. high. The concrete filling about the pipe in the tunnel was conveyed by means of a small car, running on the top of the pipe. A sketch of the car is shown by Fig. 8. Fig. 9 is a section of the tunnel, the dotted lines indicating the position of the car. The car was designed by Mr. Hilt, of Hilt, Johnson, Fitzgerald & Mulderry, contractors for the steel conduit. Nearly all the work on the conduit was done in winter. The excavation contained considerable running sand. The pipe, in excavation, was suspended in slings until the concrete was placed beneath it. It was found that concrete made with broken stone did not pack well beneath the pipe, but with gravel instead of stone, and a curved rammer, no trouble was experienced.

When a representative of the editorial staff of this journal visited the work on Oct. 5 the puddling and concreting of the floor of the sedimentation basin were about half done and stone for the slope paving was being received; four of the eight filter beds were well on towards completion, and the foundation walls for the clear water basin were in. It is expected that the four filter beds now so far advanced and the clear water basin will be put in use before Jan. 1, but that work on the other beds and the sedimentation chamber will be suspended as soon as cold weather sets in.

Mr. Allen Hazen, Assoc. M. Am. Soc. C. E., is

Chief Engineer for the plant, and Mr. Wm. B. Fuller, M. Am. Soc. C. E., is Resident Engineer. We are indebted to these gentlemen, and to the contractors, for the information here given.

◆

THE COAST SIGNAL SERVICE DURING THE WAR.

In a remarkably short time after the outbreak of the war with Spain there was established a thorough system of communication along the whole coast line of the United States, between the inner line of naval defence and the outer army line of coast defence. The establishment of this system in so short a time called forth the unstinted praise of the European military authorities, and the report of Captain John R. Bartlett, U. S. N., Chief of the Navy Intelligence Bureau, indicates how these results were secured.

End Elevation.

FIG. 8.—CAR USED IN DEPOSITING CONCRETE AROUND THE 48-IN. STEEL PIPE IN TUNNEL.

Captain Caspar F. Goodrich, U. S. N., then President of the Naval War College, began work upon the plans on March 15, 1898, and in less than one month he announced that he was ready to put them into operation. He was not permitted to incur the expense, however, until the Spanish fleet was well on its way to Cuba and attacks by Spanish vessels upon the Atlantic seaboard seemed probable. On April 22, permission having been granted, he sent the following telegram to the commanders of the naval militia, from Massachusetts to Louisiana:—

> Establish and man coast signal stations already determined by me. Lowest bids, greatest economy, most speed necessary. Let crews sign temporary agreement pending receipt of enlistment forms. No heliographs needed. Send further communication to Superintendent, New York.

On April 23 Captain Goodrich was ordered to sea on the "St. Louis," and Captain Kane took his place, until May 9, when Captain John R. Bartlett, then Chief Intelligence Officer, was placed in charge, and to him belongs the credit of building up the system. Within twenty-four hours after the receipt of the above telegram the men had reported at their stations, and in a week they were fully established and equipped with apparatus ordered in accordance with the instructions of Captain Goodrich.

The preliminary organization covered eight districts and 36 signal stations, officered and manned from the State Naval Militia, with 18 officers and 210 men in all. The station equipment consisted of the international code flags and books, "wigwag" flags, "shapes" (cones and drums), powerful telescopes and binoculars, torches and an improvised Ardois system of red and white lights. At each station quarters were built for the crew, and a 90-foot mast, with a 40-foot yard, was erected; in some cases signal towers were built. There was also a telegraph or telephone outfit, or both, which connected with the Life Saving Service lines along the beach. The station crew included one chief quartermaster, three second-class quartermasters and one landsman. These men were divided into watches and armed with Springfield rifles; there was a daily and weekly routine of exercise and drill, and notes of this were entered into the log. Once in every two weeks each station was inspected by an officer, who reported to headquarters.

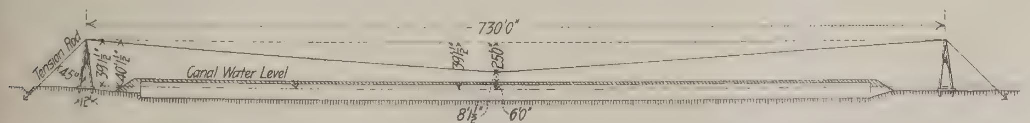

FIG. 10.—SECTION OF HOISTING AND DISTRIBUTING APPARATUS.

The services of these 210 men were efficiently supplemented by the watchful crews of the life-saving stations, including 1,443 men, and the 850 light-keepers along the coast. Including 33 observers of the Weather Bureau there was thus an aggregate of 2,536 men on the lookout for the approach of suspicious vessels. Tests of wires were made at the beginning of each watch, and a daily telegram was sent from each station to the district headquarters. By arrangement with the telegraph companies the Coast Signal Service had the right of way over the wires by simply notifying the company in advance. Arrangements were also made at each district headquarters to send notice of the presence of an enemy to the auxiliary naval force and the principal forts and batteries in the district.

Captain Bartlett says that from the practical operation of the Coast Signal Service for three months he is confident that it would have well served the use for which it was established—to observe and report the approach of an enemy's vessel or fleet. It was frequently of use in keeping the Navy Department advised of the movements of its own vessels, and was particularly serviceable in the case of the battleship "Oregon." It also kept the several navy yards advised in advance of the approach of vessels, and enabled them to make preparations for their reception. The most valuable result, however, was the determination of points where signal stations are necessary, in time of war, to supplement the systems of Life-Saving, Lighthouse and Weather establishments. Captain Bartlett recommends a permanent service of this nature, as being in fact an integral part of a naval coast-defence system. Each life-saving station should be made a coast signal station, and the crews should be drilled in the "wigwag" code and naval night signals. The same should be done for lighthouses and certain of the stations of the Weather Bureau. Permanent Coast Signal Stations should be established at designated important points, and equipped with three-armed semaphores and an acetylene gas "Ardois" system for night work.

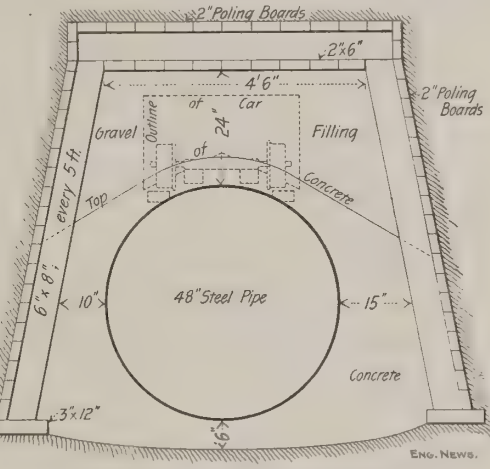

Fig. 9.—Section of Tunnel Showing Position of Car.

THE WESTERN UNION TELEGRAPH CO. reports for the year ending June 30, 1898, total gross earnings of $23,915,732, an increase over 1897 of $1,276,873, and net earnings of $6,090,151, an increase of $357,848. During the year the company sent 62,173,749 messages, against 58,151,684 in 1897. This total has only been twice exceeded—in 1893 with 66,591,858 messages, and in 1892 with 62,387,278 messages. The present mileage of wire is given at 874,420, against 841,002 miles in 1897; there are 22,210 telegraph offices, an increase of 441. The average toll per message is 30.1 cts., against 30.5 cts. in 1897 and 30.9 cts. in 1896. The cost per message is rising, however; this was 24 cts. in 1896, 24.3 cts. in 1897, and was 24.7 cts. last year. In this case the decrease in average tolls and increase in sending cost is ascribed to the large number of Government and press messages sent during the war with Spain.

◆

GERMAN ADVANCED TECHNICAL EDUCATION in Saxony is commented upon by U. S. Consul Monaghan, of Chemnitz. He says that with a population of 3,783,014 Saxony has 1,953 of these schools attended by 75,358 boys and 1,699 girls. There are besides these 39 higher industrial schools, with 10,660 scholars; 112 industrial technical schools, with 10,119 scholars; 44 commercial schools, with 4,781 scholars; 11 agricultural schools, with 691 scholars, and 18 technical schools for girls, with 2,445 scholars. Compulsory education is established for graduates of common schools, and the hours of attendance are early in the morning or a certain number of afternoons in each week. Boys make a special study of the trades in which they are occupied.

◆

THE PEOPLE'S TELEPHONE CO., of New York, has been incorporated and the following officers have been elected: Darwin R. James, President; E. S. A. de Luna, Vice-President; Silas B. Dutcher, Treasurer; Frank S. Gardner, Secretary. This new corporation originated with some influential members of the New York Board of Trade who have been working to reduce telephone rates for some years past. The company promises to give its subscribers unlimited service in Manhattan for $100 per year, as compared with $240, the present charge, with free use of public pay stations for 100 calls per year for each subscriber. The message service will be cut from $90 for 600 messages to $40 for 400 messages; for a larger number of messages the rate will go as low as 4 cts. per message. The residence rate for service on private wires will be $30, and $1 per month on group lines. In Brooklyn the unlimited service for business places will be $75 per year instead of $150 as now charged. The new corporation says that its appliances and system are tested in over 2,000 independent exchanges now in operation in the United States, and all its instruments will contain the newest devices in receiver, transmitter and switchboard, with metallic circuits throughout the system.

◆

THE MANHATTAN STEAMSHIP CO., which now maintains a weekly service to Rockland, Camden, Belfast, Bucksport and Bangor, Me., and to Eastport and St. John, has secured four large lake steamers for this Atlantic service. Counting the fleet lately acquired by the Atlantic Transportation Co. for a similar service, 55 lake vessels, of from 1,400 to 2,500 tons capacity, have been purchased from the lake fleets to trade between Atlantic ports. The causes of this movement is the scarcity of available steamers on the Atlantic and the trade rivalry in barge traffic. The Atlantic Transportation Co. says that it was forced to secure lake vessels by the antagonism of other coal lightering companies, which advanced rates when this company needed more vessels than it owned in the conduct of its own business. The effect of the new method of coal transportation will eventually be to break up the single trip chartering business for coal and enable coal shippers to know exactly what rate they will be called upon to pay for transportation. They can thus quote prices "alongside" instead of "f. o. b.," as at present.

◆

A NEW YORK COMMERCE COMMISSION, appointed by Governor Black, is now investigating the existing dock system in this city. This commission is made up as follows: Ex-Mayor C. A. Schieren, of Brooklyn; Andrew H. Green, Alex. Smith, Hugh Kelly and C. C. Shayne. At the first meeting on Oct. 18, Mr. George S. Greene, Jr., for many years Chief Engineer of the old Dock Board, said that it was the policy of the Dock Department to gradually acquire the entire water front and to improve or lease it. This department had an income of $2,000,000 per year, and in a couple of years this will be increased by from $300,000 to $500,000. Of this sum only about one-fourth is paid by steamship companies for use of the city water front. As a general thing rentals of private dock property are higher than the rentals charged by the city. The lessees of private docks are nearly all domestic companies not engaged in foreign trade. Mr. Greene did not believe in free docks, as offered in other cities; these free docks were usually owned by railway companies who thus sought to attract trade for their railway lines and in this way really obtain a rental. The advantages of Staten Island for commercial purposes were urged by Erastus Wiman; and Mr. Charles Stoughton advocated a deep waterway in the Harlem River, to cost $1,750,000.

◆

THE SUBSIDIES TO THE FRENCH LINE of steamers, the Compagnie Generale Transatlantique, were originally granted in 1857. The government was to pay annually to the company the sum of $1,794,900, of which sum $579,000 was applied solely to the steamers running between Havre and New York. This was an average subsidy of $10.77 per nautical league on the New York line; with a minimum speed exacted of 11½ knots and 26 trips per annum. In 1873 the amount of the New York subsidy was increased to $703,292; but the trips were increased to 40 per year, or $8.50 per nautical league. In 1886 this franchise was renewed for 15 years; but sailings were made weekly and a minimum speed of 15 knots was exacted. To encourage the building of larger and faster steamers a bounty of $2.32 per gross ton was allowed for every tenth of a knot of speed in excess of 15. This speed bounty, however, was not to exceed $231,600, and this amount has been paid since 1892. The subsidy was also raised to $1,057.640 per annum, and with speed bounty added this is equivalent to $11.66 for every nautical league steamed. The Steamship Company is now building three new mail steamers which are to have a minimum speed of 22 knots under forced draft. The fleet of the Compagnie Generale Transatlantique numbers 63 ships of a gross tonnage of 166,797, developing 169,850 I. HP. The assets of the company amount to $28,273,314, in steamers, real estate, supplies, outstanding accounts and cash. The capital stock is 80,000 shares of 500 francs each, on which they paid in 1897 15 francs dividend, or about 3%; there are also $18,231,448 in 3% bonds, with some minor securities. The legal reserve and insurance fund is $1,944,197; the net earnings for 1897 amounted to $238,769.36. The total receipts of all kinds in 1897, including bounties and subsidies, was $8.879,538, and the total expenses were $7,647,784, leaving an excess of receipts of $1,231.754. The gross receipts decreased $487,442 in 1897, but the expenses were also decreased by $359,769. During 1897 the ships of the company made 681,342 marine leagues; and the Havre-New York line made an average speed of 16.72 knots, as compared with an average of 13.13 knots for the line to the Antilles. The foregoing statement is condensed from a more detailed one made by U. S. Consul A. M. Thackara, of Havre, and contained in the "Consular Reports" for October, 1898.

◆

A WIRE-MEASURING WHEEL, for finding the length of wire used in obtaining the depth of a shaft, has been devised by Mr. O. Brathuhn, and is described in the "Berg und Hüttenmannische Zeitung," 1898, p. 155. The brass wheel used had a diameter of 35 ins. and was 0.3-in. thick, with a rounded groove in the rim for the wire. The circumference of the wheel was divided into 100 divisions; and by the aid of a pointer and vernier a 1-10,000th part could be read. To the axle of the wheel was attached a counter registering complete revolutions; and a small spirit-level on the cast bed-plate of the wheel enabled the plane of the wheel to be kept vertical. In this plane was a ratchet winch for lowering or raising the wire passing over the wheel. Before measuring, the wire was weighted and hung over the wheel into the shaft for several hours, until it was fully stretched. By means of a level at the shaft-bottom a fixed point on the bottom of the wire was then marked by tying on a piece of thread; and another level at the top was adjusted to sight the wire. With the counter at zero the position of the pointer is read and the wire is carefully hauled up. When the top level strikes the thread-mark the wheel is clamped and the number of revolutions noted. The difference between the first and final reading, multiplied by the value of one revolution, is the required depth. The apparatus is sufficiently accurate and costs about $75.

BOOK REVIEWS.

INSPECTION OF THE MATERIALS AND WORKMANSHIP EMPLOYED IN CONSTRUCTION. A reference book for the use of inspectors, superintendents and others engaged in constructing public and private works. Containing a collection of memoranda pertaining to the duty of inspectors, quality and defects of materials; requisites for good construction; methods of slighting work, etc. By Austin T. Byrne, C. E., author of "Highway Construction." New York: John Wiley & Sons. Cloth, 7 × 4¼ ins.; pp. 540. $3.00.

This is a new and useful handbook compiled from recent but very widely scattered materials, and Mr. Byrne has performed an excellent work in here bringing together in compact and accessible form a large amount of information necessary for the successful performance of the varied duties connected with the inspection of materials and workmanship. Structural materials are first very clearly described and classified; with the requisites of good materials, tests for fitness and methods of detecting qualities that make them unfit for use in public works. This list includes stone, brick, cement, timber, metals and miscellaneous materials. Fastenings of all kinds come next, covering nails, screws, pins, bolts and nuts, rivets and rivet inspection. Under the general head of construction we have earthwork in all its forms, foundations, masonry and stone-cutting, mortars, carpentry, iron and steel work, plumbing, roofing, plastering, glazing and painting. Water supply, sewerage and paving are discussed under separate chapter heads. Without entering into detail, it is sufficient to say that under each of these many heads the author briefly, but clearly, indicates to the inspector the quality of material and workmanship required in general good practice, and he also points out the methods by which certain kinds of work are scamped. An excellent feature of the work is the introduction of nearly every chapter by a definition of the use and a description of the tools employed in that special class of work; and this feature is supplemented by an appendix covering the definitions of terms used in general construction. As this book is essentially a handbook for inspectors, the chapters on water-supply, sewerage and paving, deal only with the qualities of the materials employed and the methods of placing them in the work; but throughout the whole book hints and suggestions abound that are quite as useful to the practicing engineer. In fact, it is difficult to find a book of similar bulk that contains more generally useful engineering information upon detail matters occurring in practice. It is supplemented by a number of tables of common use, such as weights and measures, specific gravity and weight of materials, mensuration tables, trigonometrical functions, etc. From the long list of authorities consulted, given in the end of the handbook, it is evident that Mr. Byrne has put patient and intelligent work into its compilation; and this and the contents of the book itself warrant him in the assertion that it is up to date and embodies the latest available practice in construction and inspection.

THE INDICATOR HANDBOOK.—A Practical Manual for Engineers. By Charles N. Pickworth. Part I. The Indicator, Its Construction and Application. Manchester: Emmott & Co, Ltd.; New York: D. Van Nostrand Co. Cloth, 12mo.; pp. 130. $1.50.

This is an English book, but much of its contents are from American sources, such as the descriptions of instruments made in this country and abstracts of discussions of errors due to long pipe connections, inaccurate reducing motion, etc., which have appeared in our technical press. The book is one of the best that we have seen on the subject. It contains good descriptions of all the standard forms of indicators, including the most recent improvements, and of a great variety of indicator rigs. There is a good chapter on errors of indicators, and another on errors of reducing motions. The book might be improved by expanding the brief account of the method of testing springs, showing the use of a steam gage tester for checking the readings of a gage when it is used for testing indicators. The illustrations have the muddy appearance which is common in English text books.

THE JOURNAL OF THE IRON AND STEEL INSTITUTE. Vol. 53, No. 1, 1898. Edited by Bennett H. Brough, Secretary. London: E. & F. N. Spon, New York: Spon & Chamberlain. 8vo.; cloth; pp. 606.

This volume contains the proceedings of the London meeting of the Institute, in May, 1898, an extended obituary notice of Sir Henry Bessemer, which includes a reprint of his famous paper read at the Cheltenham meeting of the British Association for the Advancement of Science, Aug. 13, 1856, "On the Manufacture of Iron and Steel Without Fuel," and the usual Notes on the Progress of the Home and Foreign Iron and Steel Industries.

The titles of the papers read at the London meeting are: "On the Use of Blast-furnace Gas for Motive Power," by A. Greiner; "On Coking in By-product Ovens," by J. H. Darby; "On the Relative Merits of Limestone and Lime in Blast-furnace Practice," by C. Cochrane; "On Steel Permanent Way," by R. Price-Williams; "On the Iron Ore Deposits of the Ural," by H. Bauerman; "On the Crystalline Structure of Iron and Steel," by J. E. Stead; "On Allotropic Iron and Carbon," by E. H. Saniter; "On Brittleness in Soft Steel," by C. H. Risdale; "On the Solution Theory of Iron and Steel," by Bacon H. Juptner.

THERMODYNAMICS OF THE STEAM ENGINE AND OTHER HEAT ENGINES. By Cecil H. Peabody, Professor of Marine Engineering and Naval Architecture, Massachusetts Institute of Technology. Fourth edition. Rewritten and reset. New York. John Wiley & Sons. London: Chapman & Hall, Ltd. 8vo.; cloth, pp. 522; $5.

The first edition of this work was published in 1889. It is one of the best American treatises on thermodynamics and is largely used as a text book in engineering schools and as a reference book by engineers. The present edition contains much matter not in the earlier editions, and much of the text of the earlier editions has been changed in revision. More space than before is given to the subject of gas engines. The first seven chapters, covering about one-third of the work, are devoted to mathematical treatment of the principles of thermodynamics, including gases and vapors. The remainder of the book treats of flow of fluids, injectors, hot-air and gas engines, the steam engine, compressed air and refrigerating machines. Over 200 pages are devoted to the subject of the steam engine, and much of the matter given under this head is of a practical nature, outside of what is usually included in works on thermodynamics, such as economy of actual engines, cylinder condensation, testing of engines and friction of engines. The value of a book on thermodynamics, to the practicing engineer, is enhanced by the amount of matter contained in it which is not thermodynamics, and this work is well supplied with such matter. The information concerning economy of engines is brought down to the latest dates. We notice particularly a discussion of the Diesel oil motor, the latest of the petroleum engines. We would suggest that the theoretical part of the book might be improved for use as a reference book by adding a page or two giving in brief form the meaning of all the symbols used in the formulae.

THE COFFER-DAM PROCESS FOR PIERS.—Practical Examples from Actual Work. By Charles Evan Fowler, M. Am. Soc. E., Bridge Engineer. John Wiley & Sons, New York. Cloth, 6 × 9 ins.; pp. 159; illustrated; $2.50.

This is the first time we have seen this subject separately treated, and Mr. Fowler imparts much useful information in the actual examples of work done here described and well illustrated. Commencing with the history of early bridge foundations, he describes many varieties of coffer-dams and caissons as found in comparatively late engineering practice. In each case the methods followed and results obtained are briefly but clearly given. The several chapters cover timber and sheet pile construction, metal construction, the pumping and dredging plant, and separate chapters upon the character of the foundation soil, the use of concrete and the general location and design of piers. An interesting table notes 44 coffer-dams, used on generally important works, and gives the conditions of current, head of water, character of bottom and general dimensions and thickness of puddle. As Mr. Fowler says in his introduction, he takes the great part of his examples from current engineering literature but he does a good work in thus bringing them together in one book.

TUNNELING SHIELDS. (Emploi du Bouclier dans la Construction des Souterrains.)—By Raynald Legouez, Ingenieur des Ponts et Chausses. Paris: Beaudry & Co. Cloth; 8vo.; pp. 440; illustrations, 337. Price, 20 francs ($4).

This book is the first to bring together details of the various forms of shields used in tunnel excavation and of the works executed by means of these shields, although most of the shields and works have been described in the technical papers. The first design and use of the shield is attributed to Isambard Brunel ("a French engineer who emigrated to England"). To English engineers is given the credit for simplifying the design (even beyond reasonable limits), while to French engineers is given the credit for the use of oval shields and of substituting masonry for metallic lining behind the shields. American engineers are said to have followed on the English lines.

The first 14 chapters deal with individual shields and the works executed by them, commencing with Brunel's Thames Tunnel of 1825, and including the Mersey tunnel, the London and Glasgow underground railways; the Hudson, St. Clair and East River (gas) tunnels in the United States, and the Clinchy sewer tunnels near Paris. Many of these are dealt with in considerable detail, both as to the plant used and the progress of the work, while other tunnels are also mentioned. The next chapter discusses the design and construction of the shields, the dimensions, air pressure employed, safety appliances, etc. The tunnel lining is then taken up, and it is stated that Brunel in England and Beach in America (Broadway underground railway) employed a brick lining. In the Clichy tunnel, the shield was followed by a steel centering, upon which was built the brick lining, but for the extension of that tunnel under the city of Paris the shield itself formed the centering. The iron lining has the advantages of requiring a minimum of excavation outside the inner line of the finished tunnel, but it is very costly and involves an enormous weight of material. A lighter iron lining with an inner lining of masonry is not approved. The various operations connected with the progress of the work are described, and tables of cost are given.

The book is well printed and fully illustrated with line and half-tone engravings, but in many of the latter the figures are too small to be read conveniently, which is a defect very common to French engravings of this kind. For English and American works, dimensions and weights are given in metrical and duodecimal measures. The table of contents occupies about eight pages, but there is no index, which is a great defect in a book of this character, as we have several times pointed out.

REPORT OF THE CHIEF OF THE WEATHER BUREAU. U. S. Department of Agriculture. 1896-97.—Washington, D. C., 1897. Cloth; 11½ × 9 ins.; pp. 431; maps and other illustrations.

This report of Mr. Willis L. Moore, Chief of Bureau, under the head of administration, states that the cost of running the bureau, in 1896-97, was $883,772, as compared with $993,520 expended on the weather service in 1883. But the work now performed is largely in excess of that done in 1883. In the fiscal year reported upon, 4,315,000 weather maps were issued; 51,694 daily forecasts and warnings were forwarded by mail, telegraph and telephone; about 8,000 places reported climate and crop conditions; about 3,000 voluntary observers now make daily readings of U. S. Standard thermometers and rain-gages, and 253 stations on the Great Lakes displayed storm signals. The bulk of the report is devoted to the records of results for the year in tabular form, with explanatory text and maps graphically showing the year's record. The rainfall of the United States is very fully treated in a separate article by Mr. A. G. Henry, Chief of Division; and Mr. Park Morrill, Forecast Official, contributes a lengthy illustrated paper upon the floods of the Mississippi River and its main tributaries.

Relative Corrosion of Iron and Steel—Conditions in Havana.

A HEAVY FREIGHT TRAIN was hauled from De Witt, near Syracuse, to West Albany, on the New York Central & Hudson River R. R., last week. The train consisted of 81 loaded grain cars, and its total weight was 3,478 tons. The total amount of grain was about 80,000 bushels. The distance hauled was 140 miles, which was made in 12 hours and 55 minutes. The train was hauled by locomotive No. 786, a Mogul, with 123,000 lbs. on the drivers, 20 × 28 cylinders and 57-in. driving wheels.

◆

A VERY HEAVY PASSENGER TRAFFIC was carried by the Chicago surface and elevated railways on the day of the Peace Jubilee parade, Oct. 19. The railways had made special rates for the week, and the city was crowded with visitors who came to see the President and the parade. As no surface cars were allowed within the limits of the parade from 9 a. m. to 3 p. m., all the traffic centered on the elevated loop. The trains ran at intervals of five to ten seconds, and took nearly 40 minutes to make the circuit, instead of the usual time of 14 minutes. The cars were packed to the gates, and policemen had to be stationed at the entrance to the stations, to keep the people from overcrowding the stairways and platforms. The street and elevated railways carried about 1½ million passengers, from which it is estimated that 700,000 people were carried to the scene of the parade and back again. The traffic was apportioned as follows:

West Chicago Street Ry.	450,000
Chicago City Ry.	440,000
North Chicago Street Ry	250,000
Other surface lines	30,000
Metropolitan Elevated Ry.	162,165
South Side Elevated Ry.	129,415
Lake St. Elevated Ry.	77,184
Total number of passengers	1,538,764

◆

CHEAP RAILWAY TRAVELING is to be made a specialty in Switzerland by means of tickets good for two weeks to twelve months, during which periods the holders can travel as much as they like on the entire railway system. The tickets are not transferable, and no baggage is carried free. They are available on the lake steamers, a second-class ticket being good for first-class accommodations on these steamers. The rates are as follows:

	Class		
	First.	Second.	Third.
15 days	$11.58	$8.11	$5.79
30 days	19.30	13.51	9.65
3 months	46.32	32.81	23.16
6 months	73.34	52.11	36.67
12 months	115.80	81.06	57.90

◆

GROOVED RAILS are proposed for Chicago's street railways, according to an ordinance recently introduced in the Council. In view of the condition of the streets. however, and the city's neglect to clean or repair them, the grooved rails would effect little or no improvement and would be of little benefit to the public. When the city undertakes to maintain its streets in good condition then it will be reasonable to consider the improvement of the railway tracks.

◆

CONTRACTS for the equipment of the Third Avenue (New York) conduit lines have been awarded. Electrical apparatus to the extent of $4,500,000, it is understood, will go to the Westinghouse Electric & Mfg. Co., Pittsburg, Pa. The underground construction, estimated at $1,500,000, will be done by the National Conduit & Cable Co.; 15,000 tons of 110-lb. rails fall to the lot of the Johnson Co., and the castings, such as yokes, handholes, etc., to the Pennsylvania Steel Co.

◆

THE EXTENSION OF CUBAN RAILWAYS, so as to provide a trunk line running the length of the island, is to be recommended by the Secretary of War, according to Washington items. He will also recommend that this work be undertaken by the government as a military necessity, and that Congress appropriate the funds necessary.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred on the Rock Island R. R., near Fort Worth, Tex., on Oct. 22. From newspaper reports it apppears that a freight train broke in two at the top of a steep grade and before the rear portion could be stopped it collided with the front section, wrecking several cars in one of which were 10 men stealing a ride. It is said that five were instantly killed and three mortally injured.

◆

A LOCOMOTIVE BOILER BLEW UP near Budsboro, Pa., on Oct. 17, killing four men. The engine which was drawing a freight train on the Wilmington & Northern R. R. had just taken water at Joanna and the explosion was a severe one, totally destroying the locomotive.

◆

AN EXPRESS TRAIN RAN 20 MILES with a dead engineer at the throttle on the Erie R. R. on Oct. 24. The train was drawn by a double-cab engine, and soon after leaving Binghamton it was noticed that the usual crossing signals were not given and that the train was running at an unusual speed. When the whistle was not blown for Susquehanna, 23 miles from Binghamton, the fireman went forward to the engineer's cab and found the engineer dead with his skull crushed. It is thought that he must have been struck by a swinging water crane just east of Binghamton.

◆

THE BURSTING OF SEVERAL BOILER TUBES on the torpedo-boat "Davis," which was undergoing an official trial at Astoria, Ore., on Oct. 20, scalded three men to death and injured four others so severely that they died later. It is understood that some derangement of the automatic water gage permitted the water to get low in the boiler. Although there were 40 men on board only those in the boiler room were killed. The "Davis" was one of two torpedo-boats recently built by Wolff & Zwicker, of Portland, Ore., for the United States Government.

◆

RECENT FLOODS IN JAPAN are reported to have caused great loss of life and to have done an immense amount of damage. A report received on Oct. 20, via Vancouver, B. C., states that in the valley of the Feng River 250 towns are under water and 2,000 persons were drowned; also that 1,000 persons suffered a like fate along the Ishikari River.

◆

THE NEW YORK CIVIL SERVICE COMMISSION gives notice that open competitive examinations will be held at its office on the dates given for the following positions: Nov. 14, Examiner to the Municipal Civil Service Commission; Nov. 15, Supervising Engineer. In the latter case candidates must have knowledge as to the construction, management and repairs of marine and stationary engines, and hold licenses for both; they must also have knowledge of the installation of steam heating, ventilation, boilers, plumbing and drainage. The candidate for Examiner will be examined in arithmetic, grammar and composition, general intelligence, special qualifications and experience.

◆

THE AWARDS OF PLANS FOR THE UNIVERSITY of California have been announced as the result of the preliminary competition. Out of about 100 sets of plans the following have been chosen to enter the final competition: Barboud Bauhain, Paris; E. Benard, Paris; F. Blunschli, Zurich; D. Dexpradelles and Stephen Codman, Boston; Rudolph Dick, Vienna; J. H. Freedlander, New York; Howard & Eichmuller, Paris; Howard & Cauldwell, New York; Howells, Stokes & Hornbostel, New York; Lord, Hewlett & Hull, New York; Whitney Warren, New York. Successful competitors in the preliminary competition will have six months in which to perfect their plans for the final competition, and a sum of at least $20,000 will be devoted to premiums for the best plans. These premiums will be awarded to at least five of the competitors.

◆

A NATIONAL PHYSICAL LABORATORY is proposed in England, and the committee appointed by the Treasury, in August of last year, has submitted its report. The committee, consisting of Lord Rayleigh (chairman), Sir Courtenay Boyle, Sir Andrew Noble, Sir John Wolfe Barry, W. C. Roberts-Austen, Robert Chalmers, Prof. A. W. Rucker, Alexander Siemens and Prof. T. E. Thorpe, was directed to consider and report upon the desirability of establishing a national physical laboratory for the testing and verification of instruments for physical investigation; for the construction and preservation of standards of measurements, and for the systematic determination of physical constants and numerical data useful for scientific and industrial purposes, and to report whether the work of such an institution, if established, could be associated with any testing or standardizing work already performed wholly or partly at the public cost.

This committee investigated the subject very thoroughly, visiting the various government physical laboratories of the Continent. As a result, the committee proposes that the Kew Observatory be enlarged by the addition of new buildings where the desired work can be conducted. It is further suggested that the institution be controlled by a governing board appointed by the Royal Society and by the principal commercial organizations.

THE PARIS EXPOSITION MANAGEMENT has granted 26,000 sq. ft. additional space for American exhibitors, making the present total 203,000 sq. ft.

◆

THE EXTENSION OF THE PARCEL-POST SYSTEM in the United States is favored by the managers of the Philadelphia Commercial Museum. They contend that such an extension of privilege is necessary in the export trade to enable manufacturers to send samples to possible foreign buyers. Their competitors in England, Germany, France and Belgium can do this, and doubtless secure in this way considerable business. Objection is made that manufacturers would get into the habit of sending samples abroad and thus divert the trade from customary channels and build up a system of direct business which will not be satisfactory to either manufacturer or buyer, owing to a disarrangement of credits. The second objection is that the extension of the parcel-post might encourage the direct importation of European goods of small bulk, to the detriment of accredited importing agents, or of American manufacturers in similar lines. The Museum Managers think that as to the first objection, if the line of goods is of sufficient importance to warrant pushing in foreign markets, the manufacturer would arrange his own agencies. As to the second objection, they believe the danger is overestimated. It is always objectionable to deal out of established channels; and it is possible to make this parcel traffic subject to such tariff regulations as would prevent any great derangement of trade. Representative manufacturing firms believe that the extension of privilege in sending samples abroad would more than outweigh any damage from possible European competition.

◆

EXPORTS OF AMERICAN IRON TO GERMANY are exercising German trade papers. In 1895 Germany took raw iron and steel and manufactured goods and machinery to the value of about 4,500,000 marks; in 1897 these imports into Germany exceeded three times this amount. In 1895 the import of American machinery amounted to 2,761 tons, valued at 1,600,000 marks; in 1896, 5,213 tons, worth 3,000,000 marks; in 1897, 9,593 tons, worth 5,500,000 marks, and Germany has taken in the first seven months of 1898 12,570 tons of machinery from the United States.

◆

AMERICAN WATER PIPE IN GLASGOW is troubling Scotch makers of cast-iron pipe. The order for 1,000 tons of pipe has been given to R. D. Wood & Co., of Philadelphia, in the face of determined opposition. In the first letting the American firm offered to do the work for about $24,825, against $28,205 as the next lowest Scotch bid. The fact that the American pipe was 12 ft. long, instead of the 9 ft. usual in England, was made the grounds for a new letting. R. D. Wood & Co. reduced its bid about $366 and the Scotch firm reduced its offer $3,410; but the American bid was still the lowest, and it was then proposed to give the order to the home firm because it had a testing machine which could be used. Some members of the City Council objected to this unfairness, and an amendment was adopted giving the Scotch firm the small pipe. This offer was refused by the firm at the price named, and the American corporation received the whole contract. "Engineering" says that the Scotch makers have probably not heard the last of American pipe.

◆

THE KLONDIKE GOLD REGION has produced over $8,000,000 of gold this season, of which the Seattle assay office has taken about $4,400,000 and the San Francisco mint about $3,800,000. It is estimated that dust amounting to $500,000 was sent to Denver, Helena and Philadelphia.

◆

A NEW AND SHORTER CHANNEL FOR YUKON-bound vessels has been found by Mr. John F. Pratt, in charge of the U. S. Coast and Geodetic Expedition, working in these waters. The new channel saves 400 or 500 miles of distance, and will carry 8 ft. of water over the bar at low water, instead of 2 ft., as at the old Aphoon entrance. Vessels of moderate draft can now pass directly into the mouth of the Yukon and proceed over 400 miles up the river before transferring passengers and loads to smaller vessels.

THE LARGEST LOCOMOTIVE EVER BUILT.

The Union R. R. Co., of Pittsburg, Pa., has recently received from the Pittsburg Locomotive & Car Works some consolidation locomotives which, so far as we can find, are the heaviest and most powerful locomotives ever constructed. The weight on the drivers (208,000 lbs.) is greater than any locomotive of which we can find a record. The Mexican Central double-boiler locomotives designed by Mr. F. W. Johnstone, have 200,000 lbs. on two separate driving-wheel bases, and have the same total weight (230,000 lbs.) as the Union R. R. locomotive. The tank locomotives which run through the St. Clair tunnel, have 195,000 lbs. on ten driving wheels, and no truck wheels. The 12-wheel locomotives of the Great Northern Ry. (illustrated and described in our issue of April 17, 1898), have a total weight of 212,750 lbs., of which only 172,000 lbs. is on the driving wheels. The cylinders of this new locomotive are 23 × 32 ins., as compared with 21 × 34 ins. for the Great Northern locomotive, and its total boiler heating surface is 3,322 sq. ft., as compared with 3,280 sq. ft. for the Great Northern.

It will be seen, therefore, that this new locomotive not only has greater weight on its drivers than any other locomotive thus far built; but it exceeds also in cylinder power and in the steam producing capacity of its boiler, the huge machines of the Great Northern, which when they were built were generally agreed to be, on the whole, the most powerful locomotives ever constructed.

It is therefore entitled, until some new leviathan claims the precedence, to the distinction of being the largest locomotive in the world.

Our readers will of course be interested to know the class of work which these huge machines are to do. The Union R. R. Co., on which they are run, forms a part of the system operated in connection with the various works of the Carnegie Steel Co., and very heavy trains of iron ore, coke and mill and furnace products have to be moved over it. About four miles of this line has a grade of 70 ft. per mile, and one stretch of about 2,000 ft. from the yard at the Edgar Thomson works up across the main line of the Pennsylvania R. R., and reaching to the foot of the 70-ft. hill, has a grade of 2.4%. The road is laid with 80-lb. steel rails, and now extends from Munhall to North Bessemer, Pa., about 12 miles.

The accompanying half-tone view is reproduced from a photograph of one of these locomotives, and its great size is well shown by comparison with the small tank locomotive beside it. The principal characteristics of its design are, perhaps, best expressed in the remarks of Mr. D. A. Wightman, General Manager of the Pittsburg Locomotive Works, to whose courtesy we are indebted for the photograph from which our illustration is prepared, that the engine is "big all over." In other words, its great weight has been obtained by making all details of generous size and putting on metal liberally where it will do its part in taking strains, and there has been no loading with cast iron merely for the sake of adding weight.

Great pains has been taken to take care of the enormous strains which are thrown on the cylinder castings at the front end. The cylinder castings are of the half-saddle type, with unusual thickness and great longitudinal depth. The frames are 4½ ins. wide cut from rolled steel slabs made by the Carnegie Steel Co., and weigh when finished, 17,160 lbs. per pair. At the front end a steel plate 1⅜ ins. thick, and of the same width as the bottom of the saddle extends across from frame to frame, and is securely bolted to the lower frames. The cylinders are fastened to this plate, as well as to the frame. Heavy bolts pass through the top frame bars in front of and behind the saddle and form additional transverse ties. The longitudinal strains usually transmitted to the cylinders through the frames are largely absorbed by the use of a casting extended from the bumper beam well up to the saddle, and securely bolted to the top and bottom front frames. This casting also acts as a guide for the bolster pin of the truck. This method of relieving cylinders of longitudinal stress was introduced by the Pittsburg Locomotive Works nearly two years ago, and has proven, in practical use on a large number of locomotives, to be of great value in reducing the breakage of saddle castings.

The locomotives are now in daily use, steaming well, are not extravagant in the use of fuel and water, and appear to have ample grate surface for the work required of them.

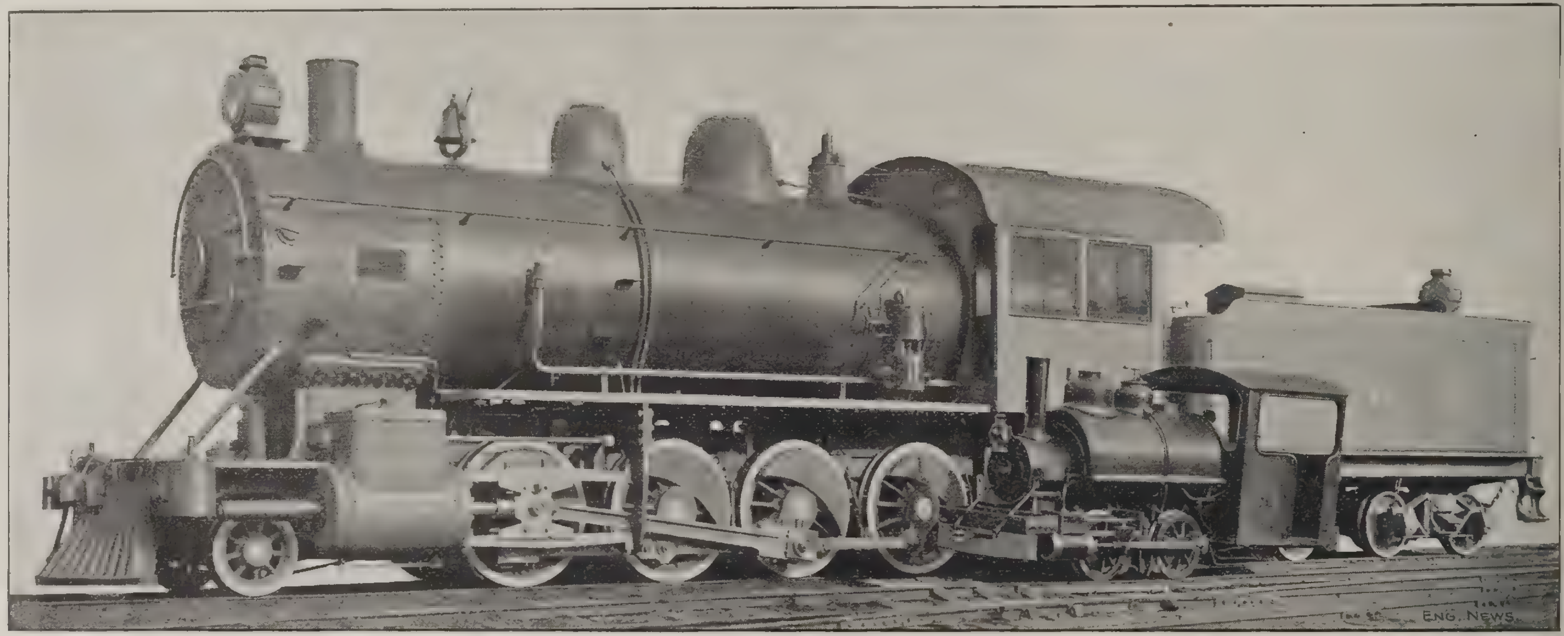
We give below in our standard form the principal dimensions of this locomotive. We would call especial attention to the fact that the load on each driving wheel reaches 26,000 lbs., which is a larger wheel load than has ever been adopted in any locomotive, so far as we are aware. The single driver passenger locomotive of the Philadelphia & Reading R. R. has 24,000 lbs. on each driver. It will also be noticed that the total driving wheel load of 104 tons is concentrated on a wheel base of 15 ft. 7 ins., giving an average load per foot of nearly 7 tons. The mere fact that such a locomotive as this is built and running is one which designers of railway bridge floors will do well to bear in mind in considering provision for future traffic requirements.

On another page of this issue we have noted the recent feat on the New York Central R. R. of hauling a train carrying 80,000 bushels of grain a distance of 140 miles with a single mogul locomotive, having a weight of 123,000 lbs. on its drivers. Let us see what train load this huge machine of the Union R. R. Co. could haul if working under the same conditions as the New York Central locomotive. If we take the hauling power as proportionate to the weight on the drivers, we have:

123,000 : 208,000 : : 80,000 : 135,000.

That is to say, this machine on such a track as the New York Central, from Syracuse to Albany, could haul a paying load of 135,000 bushels of grain, or a net weight of 3,375 tons, an amount equal to the cargo of a fair-sized Lake steamer.

We do not mean to say, of course, that the hauling of such huge trains would be practicable or economical with present rolling stock and railways. We do believe, however, that such powerful machines as this point the way toward future possibilities, if not probabilities, in the economical movement of bulk freights by rail; and the advocates of ship canals and barge canals for internal transportation will do well to bear the fact in mind.



THE LARGEST LOCOMOTIVE IN THE WORLD.
Built for the Union R. R. Co,, Pittsburg, Pa., by the Pittsburg Locomotive & Car Works.
Geo. E. McCague, General Manager Union R. R. Co,; D. A. Wightman, General Manager Pittsburg Locomotive Works.

Dimensions of Consolidation Locomotive for the Union Ry., Pittsburg, Pa.; Built by the Pittsburg Locomotive & Car Works.

Running Gear:
  Driving wheels (8), diameter ....54 ins.
  Truck wheels (2), diameter ....30 "
  Tender wheels (8), diameter ....33 "
  Driving wheel centers ....Steeled cast iron, and cast steel for main drivers.
  Journals, driving axles ....9 × 12 ins.
Wheelbase: Driving ....15 ft. 7 ins.
  Total engine ....24 ft.
  Engine and tender ....54 ft. 9½ ins.
Length over all: Engine ....39 ft. 8¾ ins.
  Engine and tender ....65 " 3½ "
Weight in Working Order:
  On driving wheels, 208,000 lbs.; truck wheels 22,000 lbs.
  Engine, total ....230,000 "
  Tender, loaded ....104,000 "
  Water in tank (full) ....37,500 "
  Coal on tender (full) ....10 tons.
  Total engine and tender, ...334,000 lbs.
Cylinders:
  Diameter and stroke ....23 × 32 ins.
  Diameter of piston rod, ...4½"
  Connecting rod, length between centers ....9 ft. 10½"
Valve Gear:
  Ports, steam ...20 × 1⅝ ins.; ports, exhaust...20 × 3¼ ins.
  Bridges, width, ...1½ "
  Slide valves, style,..Balanced; maximum travel....6 "
  " " inside lap..0 ins.; Outside lap..........1 in.
  " " lead (full forward gear)..............1-16-in.
Boiler—Type ....Straight barrel, sloping back end.
  Diam. barrel, inside smallest ring ....80 ins.
  Dome, diameter ....32 "
  Thickness, bar'l plates, ⅞-in.; smokebox tube sheets, ⅝-in.
  Horz. seams..Butt joint, double welded, sextuple riveted.
  Circumferential seams ....Double riveted.
  Height from rail to center line ....9 ft. 3⅜ ins.
  Length of smokebox ....68⅝ "
  Form of spark arresting device....Netting, 2 × 2-in. mesh.
  Injectors ....Two No. 11.
  Working steam pressure. ....200 lbs.
Firebox ....Above frames.
  Length, inside........10 ft.; width, inside....3 ft. 4¼ ins.
  Depth at front.....76¾ ins.; depth at back....69 7-16 "
  Thickness, sides and back ....⅜-in.
  Thickness, crown plate, 7-16-in.; tube plate..........½-in.
  Crown stays, diameter ....1⅛ ins.
  Grate bars ....Cast iron; rocking.
  Is firebrick arch used?..........Yes; supported on studs
  Water spaces, width all around ....4 ins.
Tubes.—Knobbled charcoal iron; No. 355
  Diameter, outside..2¼ ins.; length over tube plates, 15 ft.

Heating Surface and Grate Area.	
Heating surface, tubes (exterior area)	3,116.5 sq. ft.
“ “ firebox	205.5 “
“ “ total	3,322.0 “
Grate area	33.5 “
Ratio of total heating surface to grate area	99 to 1
Miscellaneous.—Exhaust nozzle. .Single; diameter	5¾ ins.
Exhaust nozzle below center line of boiler	5⅝ “
Smokestack, diameter at top, 18 ins.; diam. at base,	17 “
“ height above smokebox	2 ft. 9 “
“ height of top above rail	15 “ 6 “
Total tractive force. . . . .(builder's figures)	53,892 lbs.
Total adhesive tractive power at ¼ weight on driving wheels	52,000 “

Note.—The locomotive is equipped with pneumatic track sander; Westinghouse American brakes; sight-feed lubricator; metallic packing on piston-rod and valve stems; two 3-in. open-pop safety valves and one 3-in. muffler. The tender frame is of steel channels, and the tender has rigid bolster trucks with elliptic springs.

◆

THE NEW 50-FT. FURNITURE CARS OF THE CHICAGO ROCK ISLAND & PACIFIC RY.

(With two-page plate.)

A furniture car is nothing but a box car of exceptional size, intended particularly for light bulky freight, such as furniture or carriages, but it has come to be a very troublesome part of the equipment of a railway as far as the transportation department is concerned, owing to the fact that it is very frequently used in regular freight service. When a shipper has once sent a "carload" in a furniture car, he is apt to object when future shipments have to be made in the ordinary cars of less capacity. For this reason the furniture car is one of the important features in the large-car question, which was discussed at some length in our issue of March 12, 1896. We do not intend now to take up this question again, but the above remarks will serve as an introduction to a description of some enormous cars, which are exceptionally large even for furniture cars, and which are certainly among the largest freight cars ever built. In fact, there are probably many roads, especially in the eastern states, which could not handle the cars on account of the limitations of their tunnels.

These cars are 54 ft. 6½ ins. long over the couplers, 52 ft. 3 ins. long over the deadwoods, 9 ft. 10 ins. wide over the roof, and 14 ft. 1¾ ins. high from the rails to the running board. They are somewhat peculiar in appearance, as may be seen from Fig. 1, the huge box being set as low as possible, so that the bottoms of the sills project 2 ins. below the tops of the wheel treads. To allow of this, the outer intermediate sills are not extended over the trucks.

From the general plans given in Fig. 2, it will be seen that the underframe consists of two end sills and eight longitudinal sills, the frame being trussed by four 1½-in. truss rods. The rods have 1¾-in. upset threaded ends, and are set up by hollow turnbuckles. All the rods pass through the end sills, and the two inner rods also extend through the deadwoods. The transoms, to which the truss rod struts are attached, are 5 × 9 ins., 7 ft. 11¼ ins. c. to c. The outer intermediate sills do not extend from end to end of the car, but are fitted to cross pieces 4 ft. 5⅛ ins. back from the body bolsters, thus leaving a space for the wheels and allowing the frame to be dropped below the tops of the wheels, as above noted. The end sills are 13¼ ins. deep and taper in width from 9 ins. at the middle to 4¾ ins. at the ends. Upon the sills is laid the flooring of transverse planks 1¾ × 6 ins., tongued and grooved.

The side frames have posts 6½ × 2 ins. and braces 8 × 2 ins., fitted to malleable iron castings, and ¾-in. vertical rods extend through the plates and sills, these rods being let into the posts. The side plates are 6½ × 3½ ins. The end frames have posts and braces 6 × 3 ins. and 8 × 3 ins., with 3½-in. end plates, 6 ins. deep at the ends and 13 ins. at the middle. The corner posts are 7½ × 3 × 2 ins., and are tied to the side posts by ½-in. rods. Between the two posts are two rows of girths or belt rails, 4 × 3⅞ ins. in the ends and 4 × 2⅞ ins. in the sides. The outside sheathing is of vertical planks ⅞ × 4 ins., while the inside sheathing is of ⅞-in. planks placed horizontally. This inside sheathing is carried up to the upper girth on the sides and to the plates at the ends. On it are marked the heights for full capacity loads of wheat, corn, rye, barley and oats. The roof is supported by wooden carlines 3 ft. 2⅛ ins. apart, these carlines being 1⅞ ins. thick, 3½ ins. deep at the ends and 10 ins. at the middle. It has two layers of planking, between which is the asphalt roofing of the Drake & Weirs Co., Cleveland, O.

Fig. 3 shows the draft rigging, which is fitted between the center sills, these sills being strengthened by angle irons 4 × 4 ins., bolted under them and under the end sill. On the front of the end sill is a deadwood 4 × 11¾ ins., 3 ft. 1½ ins. long, faced by a ¾-in. iron plate and to the bottom of the deadwood is bolted the foot iron for the brake shaft. The Janney car couplers are used.

In accordance with the best modern practice in car construction, the body bolster is entirely of metal, as shown in Fig. 4. The top member is a plate ¾ × 10 ins., the ends of which are bent to form stirrups for the side sills. The lower member is a plate 1 × 10 ins. The top plate has a camber of about 1¾ ins., and the truss depth between the plates at the center is 12⅝ ins. Between the plates are three malleable iron fillers, supporting the sills and two of the truss rods, while underneath the bolster are secured the steel center plate and malleable iron side bearings. All the parts are put together with ⅞-in. bolts.

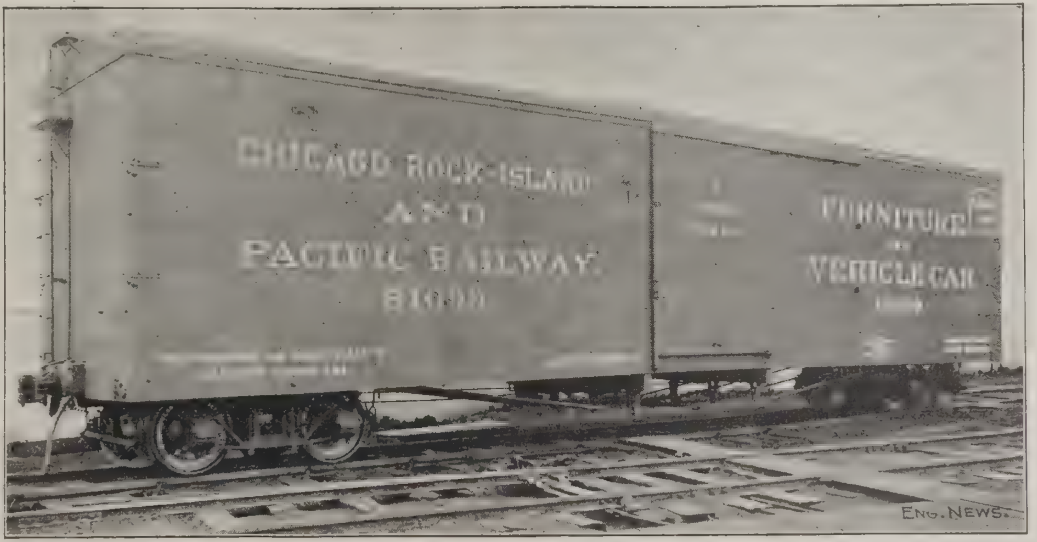


FIG. 1.—VIEW OF 50-FT. FURNITURE CAR; CHICAGO, ROCK ISLAND & PACIFIC RY.
Michigan-Peninsular Car Co., Builders.

The truck, Fig. 5, is of interest in that it is of the swing motion type, and it is built of metal throughout, having diamond frames, steel bolster, channel iron transoms and a channel iron spring plank. The side frames have top-arch bars 1¼ × 4 ins.; bottom arch bars 1⅛ × 4 ins., and tie bars ¾ × 4 ins. The columns are of malleable iron, there being but one casting for each side frame. In the column castings are formed seats for the transoms, which are 10½-in. channels 6 ft. 3 ins. long, weighing 20 lbs. per ft. They have unequal flanges, the top flange being 3⅜ ins. and the bottom flange 2½ ins. wide. These channels are set back to back, 15⅝ ins. apart. Upon the transoms are riveted the side bearings and center plate. The bolster is only 5 ft. 4 ins. long, being entirely within the frames, and is of box section, 12 × 7¼ ins. at the ends and 12 × 10½ ins. at the middle.

The swing motion arrangement is somewhat novel. Across the top of the transoms are two square bars, having turned ends which rest in bearings riveted to the top flanges of the transom channels. From the square part of each bar hangs a stirrup or truck hanger, whose sides are ⅞ × 4 ins., the width over the sides being 15⅜ ins. In the loop of the stirrup is a malleable iron seat for the spring plank, which is only 5 ft. long, being entirely clear of the truck frames. The hangers are given a slight inclination outward from the top, and two safety hangers are provided which are riveted to the transom channels and would support the spring plank in the event of the breakage of either or both of the truck hangers. The spring plank is a 13-in. channel, with 4-in. flanges, and weighs 31½ lbs. per ft. It is 5 ft. long, and at each end is a nest of four coiled springs upon which rests the bolster.

Malleable iron is used extensively throughout these cars, for such parts as post and brace seats, truss-rod struts, bolster filling pieces, truck columns, spring plank seats and saddles, side bearings, etc. As an example of these castings we show in Fig. 6 the malleable iron poling pockets which are fitted to the corners of the cars, on the sills. All these fittings were supplied by the National Malleable Castings Co., of Toledo, O.

The cars are fitted with the Westinghouse brake, the reservoir and cylinder being placed below and between the two intermediate sills, near the middle of the car. The brakeshoes are hung outside the wheels, and the arrangement of the brake rigging is very similar to that of the Illinois Central R. R. 80,000-lb. coal car, illustrated in our issue of June 16, 1898. The Bettendorf metal brake beam is used, supplied by the Cloud Steel Truck Co., of Chicago.

These huge cars are quite new, 100 of them having been built during the present year by the Michigan-Peninsular Car Co., of Detroit, Mich. They were designed under the direction of Mr. Geo. F. Wilson, Superintendent of Motive Power and Equipment of the C., R. I. & P. Ry., to whom, as well as to the builders we are indebted for information. The following is a list of the leading dimension and particulars of these cars:

Dimensions of Furniture Cars; C., R. I. & P. Ry.

Length over draw bars	54 ft. 6½ ins.
“ over deadwood face plates.	52 “ 3 “
“ over end sills.	51 “ 5½ “
“ inside	50 “ 0 “
Width over eaves	9 “ 10 “
“ over sills	9 “ 2½ “
“ inside	8 “ 8¾ “
Height, rail to under side of sill	2 “ 7 “
“ rail to under side of plate	12 “ 5¾ “
“ rail to top of running board	14 “ 0¼ “
“ rail to floor	3 “ 6¾ “
“ rail to center line of coupler	2 “ 10½ “
“ inside, clear	9 “ 3 “
Doorways	7 ft. × 8 ft. 10¼ “
Side sills.	5 × 9 “
Intermediate sills (2)	5 × 9 “
Intermediate sills (2)	4 × 9 “
Center sills (2)	5 × 9 “
End sills, (2) (section at middle)	9 × 13¼ “
Side posts	6 × 2 “
End posts	6 × 3 “
Side braces	8 × 2 “
End braces	6 × 3 “
Side plates	6½ × 3½ “
Transoms	9 × 5 “
Truss rods (4)	1½ “
Truss depth	18 “
Wheels	33 “
Journals	4¼ × 8 “
Wheelbase, truck	5 ft. 0 “
Wheelbase, total	45 “ 4 “
Distance c. to c. of trucks	40 “ 4 “
Capacity, rated	60,000 lbs.
Weight	40,400 “
Floor area	436.45 sq. ft.

◆

WOOD STAVE PIPE; ITS ECONOMIC DESIGN AND USE.

At the meeting of the American Society of Civil Engineers on Oct. 19, Mr. Arthur L. Adams, M. Am. Soc. C. E., of Los Angeles, Cal., presented a paper upon the above subject, which is, without doubt, the most complete and valuable presentation of it that has ever been made in engineering literature. Mr. Adams' complete paper occupies 32 pages in the September number of the Society's "Proceedings," and is too long, therefore, for reprinting in full in these columns. We have prepared an abstract of the most important parts of the paper and present it as follows:

The first use of a stave pipe as a continuous tube was apparently the 6-ft. pen-stock built at Manchester, N. H., in 1874, by Mr. J. T. Fanning, M. Am. Soc. C. E.; this pipe is still doing service. Round bands on stave pipe under pressure were suggested in certain letters patent in 1880, and were first extensively used at Denver, Colo., in 1883. The particular type of pipe referred to in the paper is one built continuously in the trench; of staves of variable length, having radial edges and concentric faces; and which are held together by metal bands, usually circular in section and spaced on the pipe according to the internal pressure.

The essential considerations in the design of a wood-stave pipe are as follows: The staves must be thin enough to secure complete saturation and to deflect readily to the degree of curvature employed; and they must be thick enough to prevent undesirable percolation through them. The bands must be of such size that, when spaced to give the desired factor against rupture, there will be no sensible flexure in the staves and no destructive crushing of the fiber beneath the bands. The proportions between the thickness of the staves and the strength of the bands must be such that the swelling of the wood will not produce injurious strains upon an otherwise properly proportioned band.

In discussing the source of strains in these pipes the author first takes up the initial strain caused by cinching during construction; this strain is necessary to secure practical tightness when the pipe is first filled. The requisites are a degree of compression per square inch between the staves in excess of water pressure, and uniform contact between the band and all the staves. Owing to the friction between the bands and the staves, and the compressive resistance of the wood, it is not practicable to secure the necessary area of contact, under a band of curved section, by screwing up the nut at the end of the band, without inducing an objectionably high strain. In practice the band is usually vigorously pounded at all points, as the wrench is used; this practice tends to secure the proper degree of indentation without the least residual tensile strain. The strains induced in the bands by water pressure are susceptible of positive determination by familiar methods.

The additional strain induced by the swelling of the staves is less easily determined, and exists only within certain limitations of the cinching source of strain. It may be assumed that the expanding power of swelling timber, at a given stage of compression, is well within what may be called its elastic limit, and is measured by the load necessary to produce that compression under like conditions. If, then, the staves be compressed laterally by the bands beyond the elastic limit of the saturated wood, there can be no swelling of the wood; and no increased strain on the bands from that source. But if the compression is less than the corresponding swelling power of the wood, at the degree of seasoning and compression used, the timber will swell and produce an increased strain in the bands. The amount of additional band strain thus induced is, doubtless, nearly proportional to the area of contact between the staves in the straight seams; and here the special advantage of the band of curved section becames apparent. The curved band permits a permanent compressive strain on the wood sufficient to produce a decided indentation; and the swelling of the staves, if any, and the increased compression under the band, are followed by a farther yielding of the wood; and as the band strain increases the area of contact with the band is increased by the farther indentation of the stave. With flat bands the unit compressive strain under them would almost invariably be so low that no indentation would result, and swelling strains to the full expanding power of the wood would be added to the band strains arising from other sources.

Mr. Adams then takes up the equation deduced for obtaining the permanent and temporary strains in the band. The symbols used are as follows:

R = internal radius of pipe.
r = radius of band section.
t = thickness of stave, in inches.
f = spacing of the bands between centers, inches.
S = tensile strain in the band, in pounds.
s = safe tensile strength in band, in pounds.
E = permanent sustaining power of the staves, in pounds per lineal inch of band.
E′ = temporary sustaining power of the staves, as above.
E″ = permanent swelling force of the wood, lbs. per sq.in.
E‴ = temporary swelling power of the wood, lbs. per sq.in.
P = water pressure, pounds per sq. in.
e = safe bearing power of the wood, lbs. per lin.in. band.
X = additional strain induced by band cinching, lbs.

The least band strain induced by water pressure = P R f. The permanent band strain induced by swelling of staves = f t E″. The least permanent strain in the bands of a tight pipe =

$$(X + P\ R\ f + f\ t\ E''), < R\ E.$$

Assuming $X = \frac{3}{2}\ t\ f\ P$ and substituting, we have as the least permanent value of S for a tight pipe when $P < E''$,

$$S = [P\ f\ (R + \frac{3}{2}\ t) + E''\ t\ f\ ], < (R + t)\ E. \qquad (1)$$

If $P > E''$, this becomes

$$S = [\ (R + \frac{3}{2}\ t)\ P\ f\ ], < (R + t)\ E, \qquad (2)$$

which is the equation generally used for computing band strains for all pressures.

The least temporary band strain induced on first filling a tight pipe =

$$(X + P\ R\ f + E'''\ t\ f), < (R + t)\ E'.$$

Assuming as before, $X = \frac{3}{2}\ t\ f\ P$, and substituting, we have as the temporary value of S when $P < E'''$:

$$S = [P\ f\ (R + \frac{3}{2}\ t) + E'''\ t\ f\ ], < (R + t)\ E'. \qquad (3)$$

If $P > E'''$, the equation becomes the same as (2).

From the foregoing the following equations, convenient for application, are deduced:

When $P < E''$,

$$f = \frac{s}{(R + \frac{3}{2}\ t)\ P + E''\ t}, \text{ when } s < (\ R + t)\ e. \qquad (A)$$

$$f = \frac{(R + t)\ e}{(R + \frac{3}{2}\ t)\ P + E''\ t}, \text{ when } s > (R + t)\ e. \qquad (B)$$

When $P > E''$,

$$f = \frac{s}{(R + \frac{3}{2}\ t)\ P}, \text{ when } s < (R + t)\ e. \qquad (C)$$

$$f = \frac{(R + t)\ e}{(R + \frac{3}{2}\ t)\ P}, \text{ when } s > (R + t)\ e. \qquad (D)$$

Inasmuch as stave pipe has never been used under heads where the value of P is greater than E″, and it has not as great economic value under such heavy pressures as under lighter pressures, formulas (C) and (D) have no great practical value.

The only experiments upon the sustaining and swelling power of staves known to the author are those made on Oregon "yellow fir" by Mr. D. C. Henny, M. Am. Soc. C. E.* The results are repeated in this paper in tabular form and commented upon, but the conclusions are as follows: So far as they go, these experiments demonstrate (1) That with a proper degree of compression, an ultimate permanent pressure of between 900 and 1,000 lbs. per square inch of contact with the band may be resisted by the staves. This result may be conservatively assumed to obtain in the use of all prevailing sizes of bands and of staves without regard to the character of the grain. (2) That the ultimate swelling power of the wood may be taken at from 90 to 100 lbs. per square inch of stave contact in straight seams; a result which may be affected by the spacing of the bands, since a light flexure in the stave would tend to release the strain instead of transmitting it to the bands. (3) That for water pressures exceeding, say, 94 lbs., per sq. in., and probably considerably less, hard cinching, rather than the swelling of the wood, must be relied upon to maintain a tight pipe. (4) That the yielding qualities of the wood renders hard cinching not seriously objectionable in its effect upon final band strains, with the usual factors of safety in the band, and when working reasonably close to the limit of ultimate compressive resistance of the stave.

One of the most important points to be determined from this discussion is the maximum value of e, which can be used with entire safety in designing a pressure pipe. While pressures as high as 1,100 lbs. per sq. in. have been successfully used under favorable conditions, this is not conservative enough for entirely safe construction. With thorough compression of the bands into the staves, well-seasoned lumber, skilled construction and no water-hammer, 800 lbs. per sq. in. is considered by the author as a maximum; and if there is any considerable fluctuations of pressure, or doubtful constructive skill, a much lower figure should be used.

In view of what has been said, the following values are assigned for use in the formulas here given:

E = 240 lbs. for ½-in. bands, when the fiber is fully compressed (960 lbs. per sq. in.).
E′ = say, 500 lbs., in the absence of any experiment.
E″ = 95 lbs. for 12-in. band spacing; assumed at 100 lbs. for all spacing.
E‴ = 120 lbs. for 12-in. spacing; assumed at 125 lbs. for all spacings.
e = equivalent of 800 lbs. per sq. in. of band contact, or less.

Before using any formula for band-spacing it is necessary to fix upon the size and form of section of the most economical and best band. Bands less than ⅜-in. diameter have torsional weakness and are difficult to upset. An oval form permits an increase in the value of e and costs but little more than round bands; the heavier band costs less per pound than light sections; the use of upset rods or rolled threads is always economical, and the heavier the band the fewer to be handled and the better for resisting corrosion. These are all general considerations influencing the selection.

Economy in the use of steel requires the selection of a band of such sectional area that if possible $s < (R + t)\ e$; otherwise it is necessary to use closer spacing, or more steel, than the pressure requires to secure a low value for e. By substituting for s and e, in the above equation, their proper values corresponding to bands of various standard sizes the limitations of the economic use of each may be ascertained, thus:

$$R + t = \frac{s}{e}.$$

The following table gives the minimum sizes of pipe to which specified bands are applicable without exceeding values of 650 lbs. and 750 lbs. for e:

Diameter of band.	s = ¼ ultimate st'gth, lbs.	Band pressure per sq.in., lbs.	e band pressure per lin.in., lbs.	Least external radius of pipe, ins.	Band pressure per sq.in., lbs.	e band pressure per lin.in., lbs.	Least external radius of pipe, ins.
⅜-in.	1,650	650	122	13.5	750	140	11.8
7/16-in.	2,250	650	142	15.8	750	164	13.7
½-in.	2,950	650	163	18.1	750	187	15.7
9/16-in.	3,725	650	183	20.4	750	211	17.6
⅝-in.	4,600	650	203	22.6	750	234	19.6
¾-in.	6,600	650	244	27.0	750	281	23.5

A factor greater than 4 must, therefore, be used in the steel in designing pipes of smaller diameter, if round bands are used, and the specified values of e are not exceeded. Bands of oval section give a greater bearing surface with the same degree of indentation, and permit the use of less steel for given values of e in small diameters of pipe. For this reason oval bands have been introduced and used by the Excelsior Wooden Pipe Co., of San Francisco, on a number of pipe lines.

The greatest band strains consistent with specified values of e for pipes of small diameter, are given as follows:

Int'rnl diameter.	External radius.	S = assumed working strain on band.	Factor of safety in band.	S = assumed working strain in band, lbs.	Factor of safety in band.
e = 122 lbs. = 650 lbs. per sq.in.				e = 140 = 750 lbs. pr sq.in.	
12 ins.	7.1 ins.	866 lbs.	7.6	994	6.1
16 "	9.2 "	1,122 "	5.9	1,288	5.1
20 "	11.2 "	1,366 "	4.8	1.568	4.2
24 "	13.5 "	1,650 "	4.0	.....	...

The staves used must be thick enough to prevent percolation, to resist undue flexure under the band spacing adapted, to prevent cracking or crushing of quarter-sawed staves under the cinching operation, and to afford the rigidity necessary to support the weight of the pipe and back-filling without distortion. If the size of band and band-spacing are determined in accordance with foregoing principles a maximum spacing of 12 ins. will make safe against flexure staves of the thickness generally used. The practice of running staves from 2 × 6 ins., 2 × 8 ins. and 3 × 8 ins. stock nearly meets the economic requirements of pipes designed as here set forth. These requirements would be better met, however, if 1½ × 4 ins. were used for the smallest diameters; and if the odd size, 2½ × 8 ins. were used for certain pipes of intermediate sizes between those for which 2 × 6 ins. and 3 × 8 ins. are used. The following relation between pipe diameters and size of stock is the result of careful study, the staves in each case being run as thick as the stock will permit:

---

*The Astoria Water-Works; Transactions, Vol. xxxvi., p. 18.

Pipe diameter.	Stock sizes.	Pipe diameter	Stock sizes.
10 to 14 ins.	1½ × 4 ins.	50 to 58 ins.	2½ × 8 ins.
16 " 48 "	2 × 6 "	60 " 72 "	3 × 8 "

By assigning to e the conservative value of $\frac{650}{r}$, the author submits the following table of pipe diameters, with corresponding stave thicknesses and bands. Should it be desired to use some other value for e, the needed modification can be easily made:

Economic Proportions for Pipe Design.

Nominal diameter, ins.	Staves, Stock sizes, ins.	Staves, Thickness of finished, ins.	Economic sizes of bands, ins.	s = permanent band strain, lbs.	Factor of safety in band.	e = max'm value $= \frac{650}{r}$ lbs.
10	1½ × 4	1 1/16	5/16 × 7/16	1,255	5.26	207
12	1½ × 4	1⅛	5/16 × 7/16	1,475	4.47	207
14	1½ × 4	1 3/16	5/16 × 7/16	1,650	4.0	...
16	2 × 6	1 7/32	5/16 × 7/16	1,650	4.0	...
18	2 × 6	1⅜	5/16 × 7/16	1,650	4.0	...
20	2 × 6	1⅜	5/16 × 7/16	1,650	4.0	...
22	2 × 6	1⅜	⅜	1,508	4.4	122
24	2 × 6	1⅜	⅜	1,650	4.0	...
27	2 × 6	1 7/16	⅜	1,650	4.0	...
30	2 × 6	1½	½	2,673	4.4	162
36	2 × 6	1 9/16	½	2,950	4.0	...
42	2 × 6	1⅝	½	2,950	4.0	...
48	2 × 6	1 11/16	½	2,950	4.0	...
54	2½ × 8	2⅛	⅝	4,600	4.0	...
60	3 × 8	2½	⅝	4,600	4.0	...
66	3 × 8	2 9/16	¾	6,600	4.0	...
72	3 × 8	2⅝	¾	6,600	4.0	...

The author then tabulates the features and strains in about 15 existing pipe lines; and this, while interesting, is omitted here to take up some of the construction details in accepted practice.

In making connection between the butts of connecting staves it is the prevailing practice to snugly insert a No. 12 or No. 14 steel plate, about 1½ ins. wide and slightly larger than the width of the stave used; this plate extends slightly less than half its width into each stave. The use of a bead on the stave edge is not vital to the success of the pipe, but it has some strong points in its favor. By the use of a slight bead the compression due to cinching is at first concentrated on the bead, and a uniformly tight seam is secured without the necessity for hard compression through the entire contact area—as is the case without the bead. The bead adds nothing to the cost of the pipe.

Coupling shoes of various types have been devised, and these are of two classes; those which engage the two ends in the same transverse plane, as Figs. 1, 2 and 3; and those in which the ends are not engaged in the same transverse plane, as in Fig. 4. Figs. 2 and 3 are forged shoes; Fig. 4 is cast, and Fig. 1 is malleable cast iron, and is the shoe largely used by the Excelsior Wooden Pipe Co. The author says that, when properly proportioned, Fig. 1 admirably meets all the requirements for a successful connection. Fig. 2 is considerably used on the Pacific Coast, and is forged from a rolled section. But the length of the shoe in the rear of the nuts is wholly insufficient to afford the proper degree of bearing surface on the stave to safely resist the pressure; and the bending strain at X, due to the depressing of the end of the shoe into the stave, can only be resisted by the use of a much heavier section than the tensile strains alone require. The fault lies in the use of low connecting ribs.

The forged shoe, Fig. 3, is employed on the work of the Pioneer Power Co., of Ogden, Utah. While generally well calculated to economically resist imposed strains, it necessitates the use of a welded loop, and the shoe is expensive as compared to others. The author suggests that its form could be improved, and it could be more cheaply made of cast or malleable iron, without sacrifice in other respects. The type, Fig. 4, introduces a cross-strain, or tendency to rotate about an axis vertical to the center of the shoe. Attempts to resist this tendency to rotate are generally found insufficient, and hard cinching usually results in breaking the tail-pieces or rotating the shoe and bending the bolts. The author recommends Fig. 1 as most nearly meeting requirements.

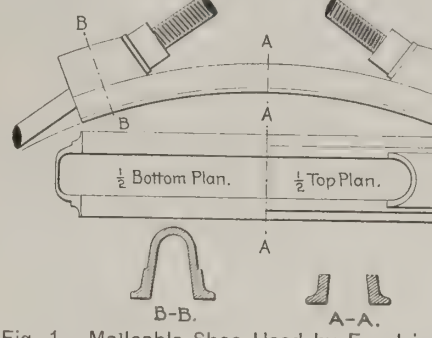

Fig. 1.—Malleable Shoe Used by Excelsior Wooden Pipe Co.

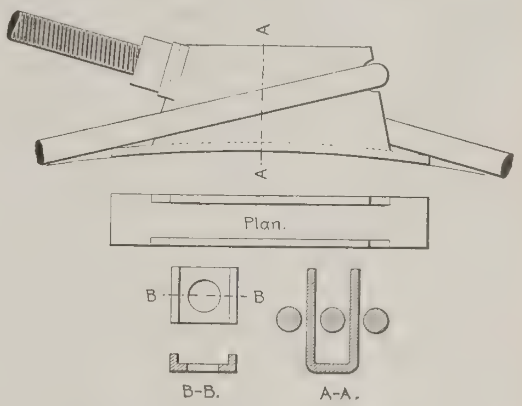

Fig. 3.—Forged Shoe Used on Pioneer Power Co.'s Pipe Line.

COUPLING SHOES FOR WOOD STAVE PIPE.

In discussing the economy of wood stave pipe he contrasts it with steel riveted and cast-iron pipe, confined to a pressure range not exceeding 100 lbs. per sq. in., which may be assumed as the practical limit of stave pipe construction. In order of merit, with reference to the three most important qualifications, he classifies them as follows:

	Cost.	Life.	Capacity.
1.	Stave.	Cast iron.	Stave.
2.	Steel riveted.	Stave.	Cast iron.
3.	Cast iron.	Steel riveted.	Steel riveted.

In placing steel pipe last in duration the author is influenced by the following considerations: The sheet metal is of less thickness than the diameter of the stave pipe bands; the same degree of care in protecting the metal can be exercised in both cases; the properly proportioned steel pipe does not eventually fail by bursting, but by the formation of rust-holes and the attendant leakage; or, the life of the steel pipe is measured by the life of its weakest point. The life of the stave pipe is determined by the life of the bands; and this is fixed by the reduction of the entire band until its ultimate strength is exceeded by the strain; say, to less than one-fourth of its original section. Stave pipe has done service in America for from 20 to 50 years in many cases, without failure from the decay of staves when proper requirements are absorbed. But steel pipe, under favorable conditions, has also done excellent service for many years.

As to carrying capacity, there are as yet but few experimental determinations in the case of stave pipe. But the experiments discussed in the Transactions of the American Society of Civil Engineers, Vol. XXXI., p. 144, Vol. XXXVI., p. 26, and for May, 1898, and reviewed at considerable length in Mr. Adams' paper, give startling results. Clean cast iron would seem to have about 90% of the carrying capacity of stave pipe; and if seriously tuberculated, the proportion is only two-thirds that of stave pipe. The steel pipe, when clean, discharges from 93%, in a 12-in. pipe, to 68% in a 6-in. pipe of the amount expected from stave pipes of the same size. If the steel pipe is tuberculated, by from 10 to 15 years' use, these discharges may fall to 74% and 54%, respectively.

The cost of any pipe is affected by market quotations on materials, freight rates, wages, geographical location, etc. But the author submits a table of comparative cost based on the following conditions: It is assumed that the wood pipe is designed in accordance with the formulas given; the steel pipe is supposed to be double-riveted on the straight seams, and single-riveted on the round, as ordinarily built, and to be coated with asphalt. The mill price for sheet steel is taken at from 1.60 cts. for No. 14 plate to 1.25 cts. for thicknesses over No. 8. The cast-iron pipe is proportioned for thickness by the Warren Foundry formula, and the price assumed per ton is $19 at Chicago, and $26 at San Francisco, as the lowest quoted. Comparative tables are given for both Chicago and San Francisco, but the latter only is here given:

Comparative Cost per ft. of Wooden, Steel and Cast-Iron Pipe at San Francisco. (Including laying, but not hauling.)

Nominal diameter.	Stave.				Steel riveted.								Cast iron.			
	Head, ft.				B. W. G., No. inches.								Head, ft.			
	25.	50.	100.	200.	No. 14.	No. 12.	No. 10.	No. 8.	No. 6.	¼-in.	5/16-in.	⅜-in.	25.	50.	100.	200.
12 ins.	$0.37	$0.45	$0.61	$0.94	$0.45	$0.52	$0.60	.....	.....	.....	.....	.....	$0.94	$0.99	$1.09	$1.31
18 "	.58	.71	.96	1.47	...	.77	.88	$1.04	$1.30	.....	.....	.....	1.65	1.73	1.89	2.21
24 "	.76	.96	1.35	2.12	...	...	1.01	1.35	1.67	$1.97	$2.51	.....	2.50	2.62	2.86	3.37
30 "	.83	1.03	1.43	2.23	...	...	...	1.64	2.04	2.45	3.10	$3.79	3.52	3.70	4.07	4.81
36 "	1.02	1.20	1.83	2.90	...	...	...	1.80	2.44	2.92	3.67	4.49	4.60	4.87	5.40	6.50
42 "	1.23	1.58	2.28	3.69	...	...	...	2.27	2.80	3.37	4.24	5.12	5.87	6.25	6.97	8.43

54 "	1.94	2.45	3.49	5.52	...	...	...	...	3.55	4.32	5.37	6.47	8.86	9.47	10.69	13.15
60 "	2.44	3.09	4.39	7.00	...	...	...	...	...	4.87	5.95	7.24	10.73	11.54	13.14	16.33
66 "	2.79	3.57	5.14	8.26	...	...	...	...	...	5.43	6.54	7.81	12.70	13.69	15.45	18.92
72 "	3.22	4.15	6.04	9.78	...	...	...	...	...	5.90	7.09	8.50	15.12	16.05	17.78	21.53

These figures are supposed to include only the common principal items of expense, with no profit to the contractor. They, are, therefore, perhaps in every case somewhat below probable cost, and are intended for use by way of comparison only. But a contract of actual quotations for particular cases would in almost every instance show a greater advantage from the use of the stave pipe than the table indicates, which assumes the most favorable conditions for the steel-riveted and cast pipe.

At the meeting of the American Society of Civil Engineers on Oct. 19, the presentation of the above paper was followed by a discussion which was opened by the Secretary, reading a letter from Mr. H. B. Patten, M. Am. Soc. C. E., City Engineer of Cheyenne, Wyo. This gave the experience of the City of Cheyenne, where in 1889, several thousand feet of 24 and 30-in. stave pipes for water mains were buried. These were only partially filled at times, and when removed 7 or 8 years later were found in bad condition. Grass roots had to a considerable extent forced their way between seams, and the staves were rotted principally on top, where the pipe was subjected to alternate wetting and drying. The pipes were also distorted, and in one place the section had changed from circular to elliptical with a vertical axis of 26 ins. and a horizontal axis of 34 ins. This reduced the section area and restricted the flow. The grass roots and other growths inside also interfered with the flow.

Mr. J. F. O'Rourke called attention to the fact that in a 6-ft. stave pipe under a pressure of 100 lbs. per sq. in., the maximum pressure set by the author, the pressure would be about the same as the pressure allowed on a steel pipe of ¼-in. thickness. It would, therefore, be necessary to have as much metal in the bands as would be necessary to make a steel pipe. This being so, he was quite certain that cast iron could be bought cheaper than stave pipe.

The chairman, Mr. James Owen, asked if the statements of the author regarding greater durability and capacity of a given size of stave pipe compared with the same size of other kinds did not seem contrary to general experience and opinion. Mr. Rudolph Hering, in considering these points, remarked that the question was one needing longer experience before it could be finally answered. The paper presented by Mr. Adams was based on more experience than appeared on the surface, and he for one considered the statements of durability quite true. He had seen stave pipes which had been in the ground 30 years, and were still as good as when put down. On the other hand, he had also seen wrought iron pipes that had been buried some time, and then exposed and subjected to weather supposed to be sufficient to cause considerable oxidization that, were barely rusted. Stave pipes should not be painted inside since the water cannot permeate the wood and keep it thoroughly wet, a feature which is necessary if rotting is to be prevented. To insure this saturation of the staves it is necessary to have the water in the pipes always under pressure. Regarding the form of band used for holding the stave pipe, experience had shown that the round or elliptical sections served best since the same section in this way exposed less surface to the weather, and there was, therefore, less likelihood of corrosion. Great care in the manufacture and placing of bands was necessary owing to the strains that they must stand.

Some wrought iron pipes which he had seen while in San Francisco, in which there was little or no uncombined carbon, seemed to stand the weather better than ordinary wrought iron pipes. These pipes were made according to specifications prepared by the Superintendent of the Spring Valley Water Co., of San Francisco.

Regarding capacity, he saw no reason why a wooden pipe properly made should not be better than a riveted steel or iron pipe. Of course, it was possible for a growth of some sort to accumulate which would materially restrict the flow. In response to a question from the chair, Mr. Hering stated that he had never heard of any chemical action between the bands and the staves.

Mr. G. W. Tillson pointed out that the rapid action of the weather upon pipes when alternately wet and dried was fully understood by the author, who expressly states that the staves must in every case be thin enough to become soaked. To show how rapidly wood rotted, unless continually saturated, he mentioned a case in Omaha where a substantial wooden sidewalk was badly rotted inside of four months, the walk being covered with ordinary earth taken from a foundation excavation. Cedar block pavement in the same city, notwithstanding the interstices were filled with gravel and tar, decayed inside of two years.

The chairman asked what were the possibilities of wooden pipes for water pipes in small towns.

Mr. J. R. O'Rourke mentioned an experience in taking up some old wooden water pipe, on Broadway, N. Y., which had been buried by the Manhattan Water Co. This pipe had been in the ground over 100 years. It was damp and water-soaked, but was not rotted, and was still serviceable. Another instance that had come under his observation occurred at the corner of Gold St. and Maiden Lane, in New York city. At this point while tearing down a building over 100 years old, they encountered oak mud sills 56 ft. long and 6 ins. thick. These timbers were just above the water line, and were in very good condition. Just above them were timbers 24 × 10 ins. which were 18 ins. above the ground water level. These timbers were perfectly sound, and not in the least decayed.

From his observation the principal difficulty with stave pipes would be the corrosion of the bands. The thickness of staves could, in his estimation, be much greater than the limits given by the author, and experience with some 3-in. yellow pine caissons, which he had recently used in connection with some foundation work, convinced him that water, even under moderate pressure, would permeate staves of considerable thickness.

Mr. J. C. Meem described a 4-ft. stave sewer which the Department of Sewers of Brooklyn had designed, but which had never been built. This was composed of 1¼-in. staves with strap bands placed every 2 ft. Outside of this the plans called for a casing of 6 ins. of concrete on top and 8 ins. on the sides and bottom. In section the whole resembled an inverted letter U. The object of this design was to preserve the roundness of the pipe and assist the clamp bands to hold the whole together.

Mr. F. W. Skinner spoke briefly of the cheapness of small wooden pipes, and described the process of boring logs, employed at a factory he had visited. The core cut out in forming large pipes was in turn bored to form a smaller pipe, thus making the cost very small, as there was little waste.

NEW FREIGHT LOCOMOTIVES FOR THE BALTIMORE & OHIO SOUTHWESTERN RY.

The introduction of heavier and more powerful locomotives for freight service, in order to ensure the greater economy in cost of transportation, which is now one of the principal aims of railway operation, as recently pointed out in our columns, is now being practiced by the Baltimore & Ohio Southwestern Ry., following the example of a number of other railways. This road has recently added to its equipment ten consolidation freight engines for service on the Ohio Division, between Cincinnati, O., and Parkersburg, W. Va. There are some rather heavy grades on this division, and it is expected that with the new engines the train load will be increased nearly 40%.

The locomotives are all alike, except that eight are simple engines and the other two are Vauclain four-cylinder compound engines. The simple engines have cylinders 21 × 28 ins., and carry a boiler pressure of 190 lbs. The compound engines have cylinders 15½ × 28 ins. and 26 × 28 ins., and carry a boiler pressure of 200 lbs. The piston heads are of cast iron, fitted with the Dunbar packing. The firebox is intended for bituminous coal, and has a brick arch, supported on studs, while the crown sheet is supported by radial stays. The grates are of cast iron, of the railway company's standard pattern. The equipment includes the Leach pneumatic double sanding jet, Sellers 10½-in. injectors, and a pneumatic bell ringer.

The engines were built by the Baldwin Locomotive Works, of Philadelphia, Pa., from designs prepared by Mr. J. G. Neuffer, General Master Mechanic of the B. & O. S.-W. Ry. The principal dimensions, etc., are as follows:

Consolidation Freight Locomotives; Baltimore & Ohio Southwestern Ry.

Running Gear:	
Driving wheels, 8, diameter	4 ft. 8 ins.
Truck wheels, 2, diameter	2 " 9 "
Journals, driving axles	8 × 12 "
Journals, truck axles	5 × 9½"
Wheelbase: Driving	15 ft. 3 "
Total engine	23 " 6 "
Engine and tender	53 " 5 "
Truck-pin to c. of leading driving wheel	8 " 3 "
Weight in Working Order:	
On driving wheels	137,000 lbs.
Engine, total	152,000 "
Tender, loaded	98,000 "
Cylinders:	
Compound engines, (4)	15½ × 28 ins. and 26 × 28 ins.
Simple engines (2)	21 × 28 "
Valve Gear.—Type	Stephenson link.
Slide valves, style	Richardson balanced.
Boiler:	
Diameter barrel, inside smallest ring	5 ft. 6 ins.
Height from rail to center line	8 " 4 "
Injectors	Sellers.
Working steam pressure, simple engines	190 lbs.
Working steam pressure, compound engines	200 "
Firebox.—Type	Radial stayed.
Length, inside	9 ft. 5 ins.
Width, inside	3 " 5 "
Crown stays, radial diameter	1⅛ "
Grate bars	Cast iron.
Fire-brick arch	Supported on studs.
Stay bolts, diameter....1-in.; pitch	4 ins.
Tubes.—Number	236
Diameter, outside	2¼ ins.
Length over tube plates	14 ft.
Heating Surface and Grate Area:	
Heating surface, tubes (interior area)	2,054.34 sq. ft.
" firebox	185.00 "
" total	2,239.34 "
Grate area	32.46 "
Miscellaneous:	
Smokestack, height of top above rail	14 ft. 7 ins.
Capacity of tender tank	5,000 gallons
Capacity of coal space	10 tons.
Brake fittings	Westinghouse-American.

TIME TESTS OF TIMBER IN COMPRESSION ENDWISE.*

By J. B. Johnson, M. Am. Soc. C. E.†

Some 6 tests were made on dry long-leaf pine blocks, 1½ ins. square and 3 ins. long, all cut from the same 2-in. plank. Sticks were first cut out 2 ins. square and 48 ins. long, and these were dressed down to 1½ ins. square, and then cut into 16 pieces each 3 ins. long, by a power cross-cut saw.

Alternate specimens were then tested in compression endwise in the ordinary manner in a Riehle testing machine, and the crushing strength determined. The intervening specimens were then loaded with certain percentages of the average two adjacent specimens, and this load left on till failure occurred, and the time noted. The load was made constant by using a geared Riehle 30,000-lb. testing machine, and mounting the specimen upon a nest of helical car springs which would deform about an inch under the maximum load upon the specimen. The time tests began by putting 95% of the breaking load on the specimen, then 90%, 85%, and so on.

The lowest time load was 65% of the breaking load. There were a number of time tests for each period, and the averages were taken, they plotted into a very smooth time curve, from which the following table is taken:

Crush'g load impos'd	90%	80%	75%	70%	65%
Time required to produce failure	10 min.	16 hrs.	36 hrs.	72 hrs.	200 hrs.

These tests were made in April and May, 1898, the material having been stored in my testing laboratory for four years and kept in the laboratory during these tests. To make such a series entirely free from moisture effects, due to changes in the hygrometric condtions of the atmosphere, all the specimens should be shellaced as soon as cut out, to hold them to a constant moisture condition. This was not done in this series of tests, and hence the above results must be accepted as approximate only.

A YACHT WITH CARBONIC ACID GAS as the motive power is being built at the ship yard of Capt. Louis N. Towne, at College Point, Long Island, N. Y. Its dimensions are: Length, 70 ft.; beam, 7 ft.; draft, 4½ ft. Compressed carbonic acid of 2,000 lbs. pressure per sq. in. will be used in a three-cylinder engine 10 × 10 ins. It is expected that the yacht will develop extraordinary speed.

---

*Abstract of a paper read before Section D, Mechanical Science and Engineering, of the American Association for the Advancement of Science, Boston meeting, August, 1898.

†Professor of Civil Engineering, Washington University, St. Louis, Mo.

A TRAIN-ORDER ANNUNCIATOR FOR LOCOMOTIVE CABS.

One of the frequent sources for railway accidents is forgetfulness or carelessness on the part of enginemen in regard to making stops at the meeting points called for by their orders. Several devices have been invented to jog the memory of the enginemen, including a train-order board with pegs to be inserted opposite the names of the meeting points, which was described in our columns some time ago.

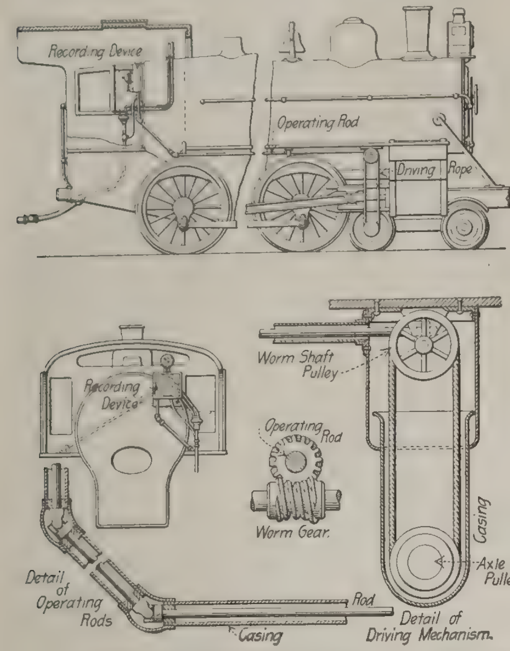

Fig. 1.—General Arrangement and Driving Mechanism of Train-Order Signal and Brake Setting Device.
Harry De Wallace, Inventor.

The device which we illustrate and describe in the present article is a step beyond other devices intended for the same general purpose, in that it automatically warns the engineman by sight and sound that he is approaching a meeting point, crossing, "slow" point, etc., while it would stop the train if he should carelessly or wilfully neglect to stop at the required places. It will at the same time show his position on the road, which is an additional safeguard in dark and stormy weather.

The recording apparatus is contained in a metal box about 10 × 10 ins., and 6 ins. deep, fitted with train-order dials, an air valve and a signal whistle. This is mounted on the boiler head or in any convenient part of the cab, as shown in Fig. 1. The mechanism is driven by rods with universal couplings, which rods are in turn driven by a bevel gear operated by a rope running around pulleys on the worm shaft and the end of one of the truck axles. The rods and driving gear are enclosed in suitable casings, as shown by Fig. 1.

A general view of the recording device in the cab is shown in Fig. 2. On the face of the box are two concentric dials, 8 and 6 ins. diameter, each graduated for 100 miles. These dials are set far enough apart to allow the hand or pointer to travel between them. The pointer is set at zero at the beginning of each run, and as the engine moves forward or backward this will show the distance traveled. On the face of the smaller dial are a number of triggers fitted with lugs which may be made to engage with the notches made in the edge of the dial at all the mile marks. In Fig. 2, the only trigger set is that at mile mark 76. When set in this position they will be released by an inclined lug on the pointer as it reaches them, the lug lifting up the trigger so as to free it from the notch, when the spring returns the trigger to its normal position. There are 15 of these triggers, allowing for that number of train orders, and they are pivoted at the center so that they may be set for any required distance or any required meeting point named in the orders.

A specially-prepared schedule card for the division on which the engine is running is attached to a holder on the box, the card being printed for westbound trains on one side and for eastbound trains on the other side. This is shown at the right in Fig. 2, the card being for the Fergus Falls Division of the Great Northern Ry., on which this device has been in use. On this card are marked the stations, sidings, crossings and other desired points on the run, together with the distance from the starting point, and the telegraph calls. The distance given is approximately one mile short of the near switch at the station or siding. Thus, if the train order requires the engineman to meet a train at Elk River, which is 40½ miles from St. Paul, the card shows 39 miles, so that the apparatus, being set for the latter distance, will give its warning at a suitable distance ahead of the meeting point.

The engineman will pull back one of the triggers convenient to that mileage and hook it in the 39-mile notch of the upper dial, where it will remain until the hand rotates and points to 39 miles, and in passing under the trigger releases it. Instantly the signal mechanism is set in motion and the signal whistle is blown by the air pressure, reminding the engineman that at a point about one mile distant, there is a siding, and that he has an appointment to meet, pass or clear for another train, or to do something else, as the case may be. If there are other triggers set for other orders at the same time, they will remain in their respective positions until the hand travels around to the mileage for which they are set. After the signal begins to sound, if the engineman hears it and is attending to his duty, he will release the signal by pulling out the button shown in the center of the dial, and also pushing in the one shown at the lower right-hand corner of the case, and prepare to make his stop (if a stop is necessary). But if he does not so release the device, showing thereby that he is attending to his duty, the signal will continue to sound while the train runs a quarter of a mile, and then the air will be automatically released from the train pipe and the train stopped before it reaches the station or point for which the trigger was set. The opposing train being similarly equipped, and the engineman being in the same condition, and affected in the same manner, his train in that emergency would also be stopped before it reached the station from the other side. If they are reminded by the signal and release it, then they will not forget their orders in the short distance they have to travel from the point of signal to the designated point. A train using this device cannot pass a point for which the apparatus is set unless it is released in the manner described.

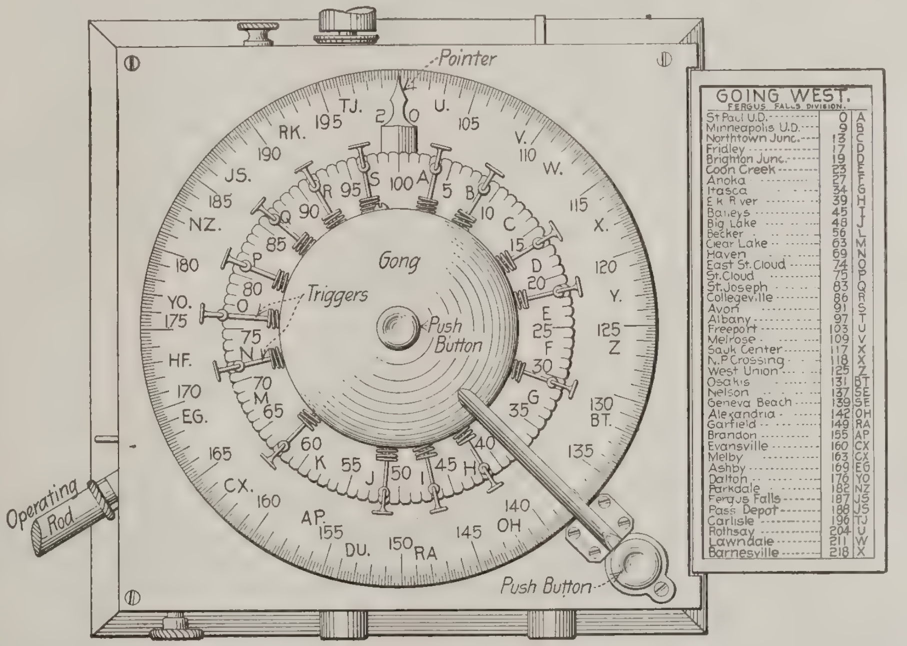

FIG. 2.—RECORDING AND SIGNALING APPARATUS IN THE LOCOMOTIVE CAB.

The setting of the trigger is done by a slight instantaneous movement, and the releasing of the signal and brake mechanism requires but one or two slight quick motions. The setting of the hand at zero at start of the run, is a very simple affair. If after setting has been made the order is countermanded, the engineman can release the trigger by lifting it up with his finger, and if necessary he can use the same (or the next one) to set for a new order given in its place for another point.

The signal consists of a small whistle, and is blown by the air pressure supplied from a valve located within the case, which is connected directly with the train pipe. It begins to blow upon the release of a trigger, and blows till the brakes are set, when it stops, unless the engineman releases it sooner. A bell or gong may be used instead.

The device requires no change or attention when the engine is reversed and run backward. Switching may be carried on for an indefinite length of time and space without alteration. The distance will be measured, the signal operated and the brakes set with the same facility and accuracy, whether the locomotive is going ahead, or backing up. Of course, when the engine backs up as in switching, the mileage is deducted. The backward distance may be added to the forward measurement, however, if desired. At night, or in stormy or foggy weather, the engineer can ascertain his whereabouts by looking at the face of the machine. If he has difficulty in finding any place on the road, he can set the device for the distance, and it will locate it exactly and inform him of his approach to it. In snow-plow work, the engineman can always tell his position when every other landmark is obscured.

As already noted, the mileage on the card is from one to two miles less than the exact distance to each station, according to whether it is level or down grade approaching the point named. This is done so that the automatic stopping of a train will occur at a safe distance from the desired point. The letters on the card are intended to be used by the dispatcher, and inserted after the names of the stations in his orders, as a check, to prevent his giving the wrong station for a meeting point. The same letters appear on the dials; a different letter is given to each five mile space.

The inventor has recently added to the signal combination, what he calls a "disorder signal." The purpose of this is to notify the engineman in case the train-order signal, or its connections, get out of order, or for any reason fail to do their work. It will also give a warning when any of its own parts become out of order. This makes the invention very reliable. If the engineman should learn to rely implicitly upon the contrivance, and it should fail without his notice, this latter attachment would let him know it at once. If it signals "out of order," he will not rely upon it or use it again until repaired or replaced.

Some time ago the inventor made a 7,000-mile test, with a full-sized working model, on the Great Northern Ry., running west from St. Paul, as far as Portland, Ore. In this long test, the device was attached to one of the large Brooks passenger locomotives in regular service, hauling the heavy and fast Pacific Coast train, and the machine is said to have clearly demonstrated the correctness of its principles, its practicability and usefulness. In July he placed an improved machine on one of the fine new Schenectady engines owned by the Minneapolis, St. Paul & Sault Ste. Marie Ry., and used in hauling the Atlantic & Pacific limited express between Minneapolis, Minn., and Gladstone, Mich. The length of run each way for this locomotive was 356 miles. Several trips were made over this distance with the train-order signal attached, and it is said to have worked very accurately. In all, the device was tested on 9,000 miles, all on long and fast runs.

The device has been patented by its inventor, Mr. Harry De Wallace, of St. Paul, Minn., to whom we are indebted for drawings and other information.

has no such engineering education at the hands of the Government as is given in this country. Instead he goes from civil life directly to the engine-room, and receives his only training there. He is promoted from time to time as he succeeds in picking up the practical part of his business. There is no preliminary technical course, of any high order, at least; and while the system may produce very good mechanics, it is not calculated to provide that thorough and scientific, as well as practical, knowledge that is now an absolute necessity to efficient service in responsible positions in the engineers' division. As a direct result of this method, the English engineer officer in the navy is regarded as not quite up to the standard of the "English gentleman"; he receives considerably less pay than line officers of the same relative grade, and the same length of service; the position is unpopular among the brighter class of young men, and the opportunities for reaching a high rank in the staff grade are so few that out of 845 engineer officers now serving in the English navy only 14 have reached the relative grade of Captain. As a contrast, there are 65 Admirals and 185 Captains among 1,676 line officers. The "Record" charges this condition to the stupidity and old-fashioned prejudices of the English Admiralty, and practically claims that the ruling line of conduct of this board is based upon a navy now obsolete. The English engineer officers are very modest in their demands for reform, and only ask that they be given executive command over their subordinates and be relieved from the present necessity of reporting the most trivial offences to some line officer.

Our English contemporary seems to think that some concession of this kind would be sufficient, and it regards as a "foolish experiment" the amalgamation of the two classes of officers, which is now proposed in the United States Navy. But the "Record" suggests no way of otherwise avoiding the inevitable conflict of authority between the line and staff officers which occurs under prevailing conditions in the navy. It is well enough to suggest that the executive power of engineer officers should be confined to the engine and boiler rooms; but in a modern warship the engineering department covers a great number of auxiliary engines and mechanical appliances which also require engineers to manage and supervise them. To carry out the suggestion of the "Record," these auxiliary engines, etc., would have to be taken away from the engineer department and placed under the charge of line officers, who, to properly perform the duty thus imposed upon them, should also be trained engineers. Under this view of the case it would be very "foolish" indeed to make any distinction in grade and authority between the two classes of officers; and the interests of the service would be best advanced by making all officers line engineers. This is exactly the amalgamation proposed in the United States Navy and condemned by the "Record."

The fact is that the proposed change in personnel in the U. S. Navy is not the result of an attempt to adjust absurd differences, as to relative rank and dignity, between the line and the staff, but is the direct outcome of a radical change in the methods of conducting naval warfare. Under modern conditions the engineer officer of thirty years ago is almost as obsolete as the sailing-master in the proper performance of duty on a warship.

The objection which has been brought against the proposed amalgamation of the steam engineer officers and the line, is that the duties of the former are technical, and those of the latter are executive, and that men cannot be expected to become proficient in both fields. This argument, however, overlooks the fact that line officers in all the junior grades at the present day are really doing technical and engineering work, quite as much as the commissioned officers in the steam engineering department. The training of the two classes of officers is identical for a large part of the course, and the special work of the young line officers in ordnance manufacture, in torpedo work, in the handling of explosives, is as truly engineering work as the work of the young engineer officers on steam engine and boilers. It is a well-known fact that many line officers who have resigned from the navy have won distinction in the engineering field. Many of the latest and best appliances employed on our warships are the invention of naval officers. They have improved the apparatus for loading 12-in. guns and for handling water-tight bulkhead doors; they have devised range-finders and have applied compressed air to the handling of turrets.

Line officers are now in charge of the electric plant, and in the daily performance of their duty are constantly handling machinery. It only requires a slight extension of their present technical training to fit them for command in the engine-room.

On the other hand, the reason which formerly existed for making the engineer officers a class apart no longer exists. The lieutenant may be as well fitted for future positions of greater responsibility by command in the engine-room as in the turret, by the study of thermodynamics as of ballistics. He must be a competent engineer, if he is to obtain success in either case.

Diplomacy, the knowledge of men and the world, the ability to command and to successfully deal with emergencies of every kind, are all essentials in the make-up of the naval officer of high rank. But these qualities come with time and experience, and are not the direct results of academic training. As the officer gravitates toward a position of command, he will be relieved by younger men of active service in connection with the mechanism of the ship, no matter where located; but he would always possess that invaluable condition in all positions of command—a personal and intimate acquaintance with the duties of his most important subordinates and the possibilities of his ship as a fighting machine.

The successful conduct of our late war by the naval arm of the service is largely due to the thorough training of our naval officers, and their methods and their success have wrung praise from unwilling naval authorities. But the handling of the engines of the "Oregon," in her unprecedented sea-voyage, and the serving of the guns at Manila and Santiago, were alike the work of engineers, and the results reached were alike due to mechanical means; under these conditions there seems to be no good reason why any distinction should be made in pay or position between the officers who did the one piece of engineering work and those who did the other. The evolution in naval warfare has made engineering knowledge the essential, all-important requisite in the naval officer. Every warship must now have its practical mechanics, electricians and trained assistants of all kinds, and men of this class now form the bulk of the crew. But just as the old naval commander was a sailor in command of sailors, it now requires an engineer of a high degree of training to properly direct his mechanical assistants and to handle a ship in which practically every movement is controlled by intricate mechanism.

LETTERS TO THE EDITOR.

Relative Corrosion of Iron and Steel.

Sir: In your issue of Oct. 20 I note a query regarding the relative rate of corrosion of iron and steel and a request for discussion from anyone having experience with the two metals. I would call your attention to a discussion of the subject by me to a paper by Prof. A. H. Sabin in Trans. Am. Soc. C. E., Vol. XXXVI., December, 1896.

Since that was written I have had another examination made of the plates after two years' exposure, with the same general result.

My observation of these plates would not support the statement of your correspondent that steel is much more subject to corrosion than iron. but rather the contrary, that iron was the more susceptible of the two metals.

Yours truly,
L. M. Hastings,
City Engineer.
Cambridge, Mass, Oct. 21, 1898.

[In the discussion referred to, Mr. Hastings tells how he practically tested the effect of water and soil upon uncoated and protected plates of steel, wrought iron and cast iron, and gives the results. Taking the uncoated plates alone, we find those of steel and wrought iron were 6 to 10 ins. square and 5-16-in. thick; the cast iron was about 1 in. thick. These plates were carefully weighed and placed in the water in the pump conduit. This water was a mixture of brook and pond water, fairly soft and containing comparatively little acid. After one year's immersion the plates were examined on Oct. 8, 1896. The two uncoated wrought-iron plates were badly tuberculated and rusted and one of them was "the worst in the lot." The two uncoated steel plates were rusty and tuberculated but "not so badly as iron." The uncoated cast-iron plates were badly rusted and tuberculated. The percentages in increase of weight due to corrosion were as follows: For the two wrought-iron plates, 1.5 and 3.1%; the two steel plates, 1.1 and 2.1%; the two cast-iron plates, 1.0 and 0.96%. The wrought-iron plates buried in sand and in clay also showed greater increase in weight than steel plates similarly placed. Mr. Hastings concludes that, subjected to the action of water, unprotected plate iron was effected the most; steel plate to a less degree, and the cast iron least of all.—Ed.]

Conditions in Havana.

Sir: In fulfilment of the half promise which I made you before leaving for Cuba I now send a few lines from this city. In the first place, all friends of humanity will be glad to know that, largely due to the enormous quantities of food supplies shipped to this port from the United States and Mexico since the raising of the blockade, the evidences of intense misery and starvation have almost disappeared from Havana and its environs. I think any one revisiting Havana, a stranger to the events of the last four years, would be simply struck with the less degree of animation and movement in the streets and the greater number of beggars as compared with his previous recollection.

The streets of the city and the adjoining suburbs of Cerro and Jesus del Monte are about in their normal condition of cleanliness—or filth. The copious rains which are still falling (2.40 ins. were reported in five hours the other evening) are performing the work of the street cleaning department with considerable success, so that Havana at present is as clean as ever, be that saying much or little.

Outside of the city, to the west and south, through the region bounded by the springs of Vento, Mariel, Guanajay, Marianao and the Playa, which is included in the "zone of cultivation," no signs of want and starvation exist. A large part of this territory is under cultivation, and herds of horned cattle and pigs are to be seen. The people look in as good condition as to health and clothing as ever, and demonstrate to a remarkable degree their powers of rapid recuperation. The unfortunate victims of a previous cruel regime are at rest, and the survivors are regaining health and hope. No doubt by looking for them cases of still living victims might be found in a condition worse than death, but it would be necessary to go off the beaten track to find them. I believe that the worst and most permanent effects of past privation will be found in the broken nerves and lowered vitality of the formerly well-to-do inhabitants of Havana and other large Cuban cities. As you know, a large and strong commission, appointed by the President. among whom is Col. Waring, of New York, are now sitting in Havana, and much and radical improvement may be expected if their recommendations shall be carried out. The duties of the commission, as you will recollect, embrace not only the arranging for the landing and encampment of the incoming American troops, but the sanitation of Havana as well.

Speaking broadly and ignoring numerous exceptions, it may be said that the great body of the Spanish population of Havana are desirous of annexation to the United States as giving security to their commercial operations and enhanced value to their real estate. An exception may exist on the part of merchants, especially retail merchants, who are carrying large stocks and dread the competition of American rivals with large capital and low prices. Among the Cubans I should say that the most enlightened and truly patriotic also desire annexation, realizing the difficulty of erecting an independent nation upon a territory somewhat less in extent than the State of New York, and with a total population of at the outside one and a half millions, of which one-third are negroes, and perhaps one-third of the remainder Spaniards or Spanish sympathizers. Among those Cubans who are still dreaming of independence—a noble though unrealizable dream—I think very few are to be found outside of the insurgents still in the field, who do not ardently desire an American protectorate until perfect order and tranquility are established. Does not this really involve a permanent protectorate?

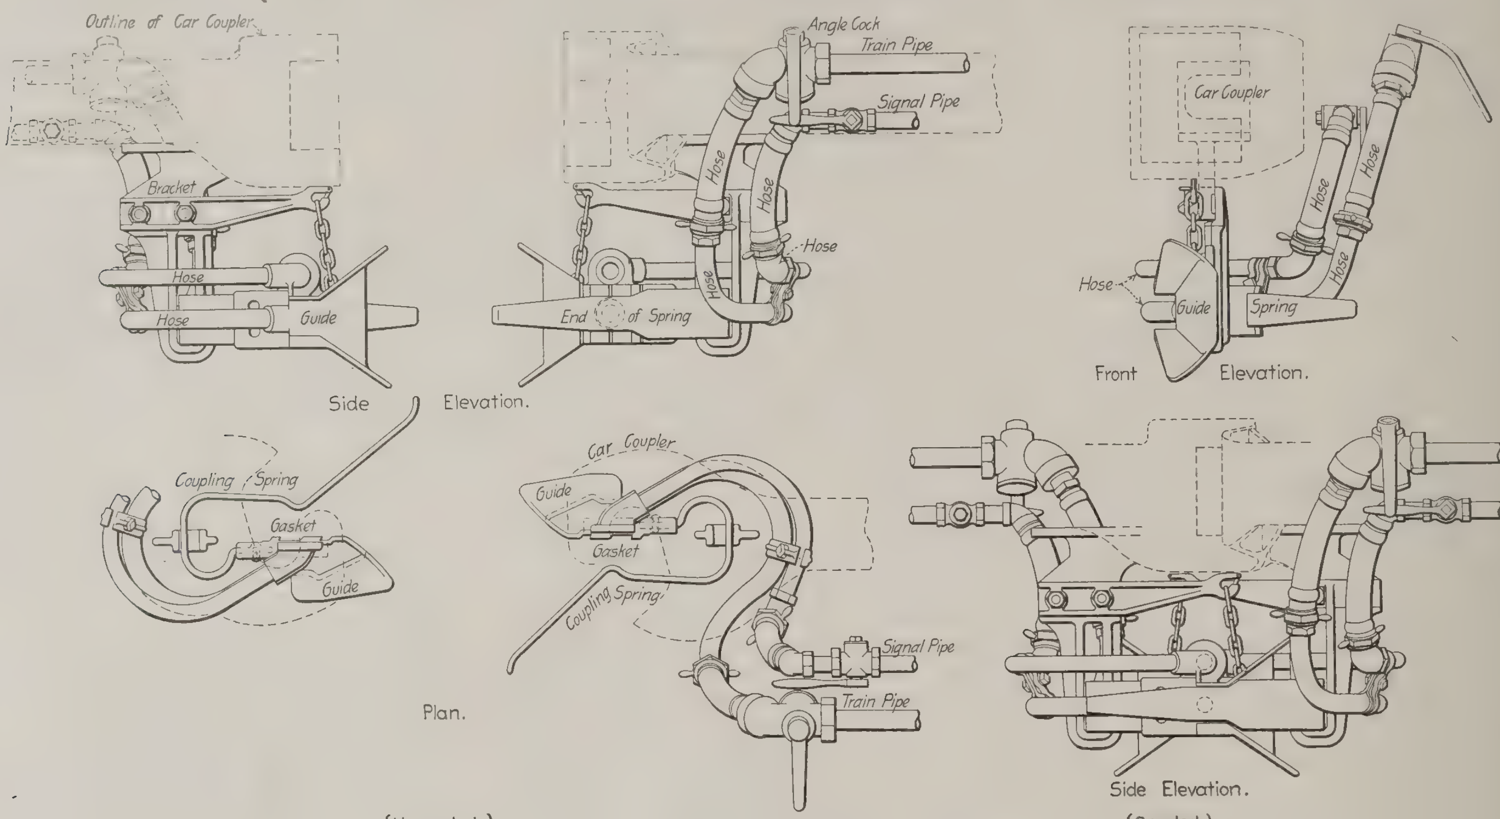
As to business opportunities and private enterprises of all kinds, the whole subject may be disposed of at once by stating that nothing can be safely undertaken until the Spanish troops have been withdrawn, the Cuban troops disbanded, American garrisons established and a able order of things set up, so that titles can be secured, franchises awarded and business carried on upon business principles. It is the object of the various commissions now in Havana to forward these desirable conditions, and it is to be hoped that their efforts will be promptly sustained by our Government. E. S. G.

Hotel Pasaje, Havana, Cuba, Oct. 21, 1898.

◆

AUTOMATIC COUPLERS FOR AIR BRAKE HOSE.

The general introduction of air-brakes and automatic couplers on railway equipment has naturally been followed by attempts to couple automatically the air-brake hose at the same time that the cars themselves are coupled. While various forms of apparatus have been devised for this purpose, but little practical success has been obtained, partly on account of the cost and complication of the apparatus, but mainly, it seems to us, for the reason that the conditions of operation are not such as to demand automatic action. Automatic car couplers were introduced largely to eliminate the danger to life and limb incident to coupling moving cars by hand, but the brake hose cannot be coupled until the cars are already coupled, and are very rarely connected up while the cars are in motion in the yard. There would be somewhat greater safety and a certain saving in time (particularly in uncoupling), but not enough probably to warrant the expense of applying and maintaining an apparatus which would require to be inspected almost as frequently as the ordinary hose coupling, in order to ensure that it is in proper condition and properly coupled. The claims made, however, include a minimum cost of maintenance and a large saving in hose.



(Uncoupled.) (Coupled.)

FIG. 1.—AUTOMATIC COUPLER FOR AIR BRAKE AND SIGNAL PIPES.
Automatic Air & Steam Coupler Co.; St. Louis, Mo.

It will probably surprise many of our readers to know that automatic hose couplers are in regular every-day service, though to a limited extent, and we are indebted to Mr. N. F. Niederlander, President of the American Brake Co., St. Louis, Mo., for particulars of the coupler which is manufactured by that company for the Automatic Air & Steam Coupler Co., of St. Louis.

This device, shown in Fig. 1, is attached to the underside of the car coupler by a bracket, to which is bolted a slotted hanger which supports the coupling spring, and also an arm carrying a chain which supports the coupling head. A short length of hose attached to the existing train-pipe fitting connects by means of a union nut with a pipe which enters the coupling head directly back of the registering rubber gasket. The coupling spring being free in the slotted hanger, and the short hose and chain being flexible, full and free movement is allowed to meet the variations in height of cars and the positions of couplers on curves. The flaring guides or wings on the back of the coupling head, and the projecting end of the coupling spring guide the heads into proper position for coupling under any conditions. The gaskets are so placed on the face of the coupling heads that neither is touched by the opposite member until the coupling is made. This protection of the gaskets is effected by means of an incline groove and strip on the face of the coupling heads, which parts interlock when the gaskets are in position to register. Provision is made to couple with the ordinary hand hose coupling by means of the union nut at the lower end of the short hose. In uncoupling, when the car couplers are released the brake coupler heads will readily separate as the cars are pulled apart.

Fig. 1 shows only the air-brake, and air-signal pipes fitted to the coupling head. The steam pipe fittings are separate and can be readily attached and detached. For freight service the brake hose attachment only need be used. This apparatus has been used on the Wabash R. R. and the Atlanta & West Point R. R. It has been in use for over three years on a passenger train equipped with the brake and signal coupling, and for about a year on two passenger trains equipped with the brake and steam coupling. Several freight cars have also been equipped with the air coupling above. Mr. George C. Smith, President and General Manager of the Atlanta & West Point R. R. and the Western Ry. of Alabama, informs us that the automatic coupling for air and steam hose on passenger cars, and for air hose on freight cars, which has been in use for more than a year, has shown very satisfactory results. This road has two passenger trains equipped with the apparatus, and last spring it was applied to 50 freight cars.

Another apparatus for the same purpose, which has as yet been tried only to a very limited extent, is the Walter automatic air-coupler, invented by Mr. Wm. J. Pugh, of Muscatine, Ia. In this apparatus, shown in Fig. 2, the coupling head is suspended from, but not rigidly attached to the drawbar, the thrust in coupling being taken up by a telescopic strut behind the coupler. A short vertical piece of hose connects the train pipe with the opening on the outer side of the coupling head. In this device, as in the one already described, the gaskets of the joint between the two heads are not forced into contact until the openings register, or coincide with one another. The patents on this latter device are owned by the Walter Automatic Air Coupler Co., 605 First National Bank Building, Chicago, Ill.

◆

A NEW METHOD OF PUMPING BY COMPRESSED AIR.

The accompanying illustration shows in an elementary way the principle of pumping water or other liquids, or semi-liquids, which has been adopted in several different forms of pumping apparatus that are now being put on the market by the Pneumatic Engineering Co., 100 Broadway, New York city. They are made under patents issued to Elmo G. Harris, Professor of Civil Engineering in the School of Mines of the University of Missouri, Rolla, Mo., who is well known as a writer on compressed air, especially in its relation to pumping.

Hitherto in the application of compressed air to the elevation of liquids confined in tanks a large part of the applied power was lost on account of the necessity of allowing the tank full of compressed air to escape into the atmosphere before the tank could be again filled with water.

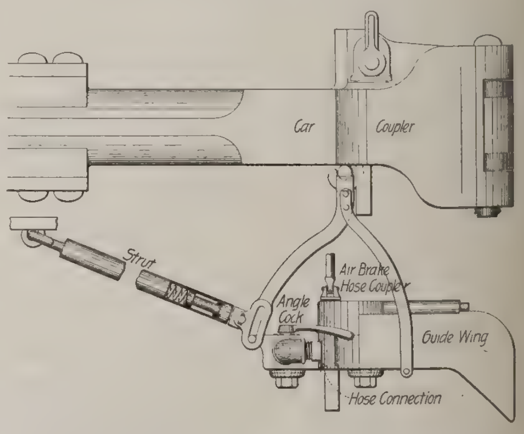


Fig. 2.—Automatic Coupler for Air Brake Pipes.
Walter Automatic Air Coupler Co., Chicago, Ill.

This loss is avoided in Prof. Harris's system by utilizing the stored energy of the compressed air, which would in the older systems be thrown away, to assist in doing the work of the air compressor. The figure shows how this is accomplished. There are two tanks which are alternately filled and emptied. When one tank is full air is admitted directly from the compressor until the water has all been discharged, then an automatic switch valve is turned so as to allow the compressed air remaining in the tank to pass to the suction side of the compressor. When the switch is set as in the figure the air is drawn out of the right hand tank and forced into the left hand tank. The charge of air in the system is so adjusted that when one is emptied the other is just filled. At that moment the switch will reverse the pipe conditions so that action in the tanks will be reversed. Several proposed practical applications of the system are described in a small pamphlet issued by the company, and to which we would refer any of our readers desiring further information.

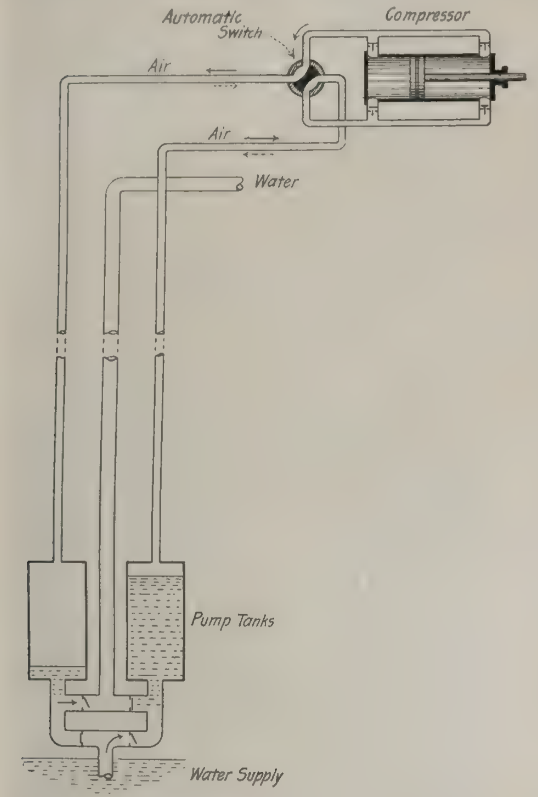

Diagram Illustrating Method of Pumping Water by Compressed Air,
Prof. Elmo G. Harris, Inventor.
Pneumatic Engineering Co., 100 Broadway, New York, Manufacturers.

THE MANUFACTURE OF SILK in the United States, says the Treasury Bureau of Statistics, amounted in 1860 to $6,607,771 in value; in 1870 it was $12,210,662; in 1880, $41,033,045, and in 1890, $87,293,454. It is now estimated that the silk production of the United States amounts to about $150,000,000 per annum in value. Meanwhile the importation of manufactured silks has rapidly fallen: from $38,686,374 in value in 1890, to $25,523,110 in 1898. The raw silk is imported; the amount in the fiscal year ending June 30, 1898, being 10,315,161 lbs., valued at $31,446,800, as compared with $18,918,283 in the previous year. This large increase is partly due to the fact that a number of cotton factories in New England and the Middle States have recently substituted silk manufacturing machinery in place of cotton. Our manufacturers are now exporting silk goods. In 1878 these exports amounted in value to only $19,032; in 1898 the silk exports were valued at $297,074. That there is room for growth in this export business, however, is made evident by the English export of silk manufactures, which amounted to about $5,690,805 in 1897; though this value was $13,321,220 in 1888. German exports have also decreased from $45,000,000 in 1889 to $26,000,000 in 1897. France still heads the list of silk manufacturing countries, and holds its own with a value of $52,283,700 for the silk manufactures exported in 1897. While our manufactures, in 1860, supplied only 15% of the silk goods used in the United States, to-day they furnish 85% of the consumption.

FAST TIME TO AUSTRALIA from New York has been made by the "Fort Salisbury," of the American and Australian Line. This ship, of 4,404 tons register, sailed from New York on Aug. 26 and arrived at Adelaide on Oct. 15; this is 50 days, or the shortest trip yet made between these ports. This line now sends a steamer every third week.

12 NEW STEAMSHIPS are under construction for the Hamburg-American Line, costing about $20,000,000. They are intended for transatlantic service and will ply between Hamburg and New York, Philadelphia and Baltimore. The largest of these vessels is being constructed by the Vulcan Company at Stettin for passenger service between New York and Hamburg. She will be 687 ft. long, 67 ft. beam and 45 ft. depth of hold, with 16,000 tons. Her engines will have 34,000-HP., giving an estimated speed of 24 knots. It is expected to complete the "Deutschland," for such is the name of this enormous vessel, in time for the Paris exposition in 1900.

THE NICARAGUA CANAL CONCESSION expires on Oct. 20, 1899, according to the late decision of a commission of Nicaraguan lawyers convened by President Zelaya. The concession was originally ratified by the Nicaraguan Congress on April 20, 1887, and granted to the Maritime Canal Co. of Nicaragua. But an official act of the Government of Nicaragua declared that the ten years within which the company obligated itself to complete the interoceanic canal commenced on Oct. 20, 1889. This act was signed and officially agreed to by the Minister of Public Works of Nicaragua, and by John Hall, official agent in Nicaragua of the Maritime Canal Co., in the presence of Mr. Mizner, then U. S. Minister to Nicaragua.

THE DEEPENING OF CERTAIN NAVIGABLE creeks on Long Island seems likely to be required of New York city by an act of the last legislature of the State of New York. This act provides that where any city or village diverts fresh water streams from any tide water creek or estuary which were previously navigable for boats of 20 tons burden and by the diversion are rendered unnavigable for that class of boats the city or village in question must dredge the creek or estuary. The constitutionality of the act, known as the Wallace bill (Chap. 469, Laws of 1898) has just been affirmed by Justice Johnson of the Supreme Court, in session at Jamaica, N. Y. The case in which the decision was rendered appears to involve some creeks in the town of Hempstead. It is yet to be established by the court, we presume, whether navigation has been actually affected by diversion for the Brooklyn water supply, which supply is now a part of that of Greater New York.

THE HENNEPIN CANAL is progressing, and the Illinois River division is said to be practically completed, all the locks and dams having been built. On the eastern division the line of the canal has been definitely located from the Illinois River to the feeder junction, 28 miles. The land for the first 24 miles has been condemned and paid for and enclosed by a barbed wire fence. All masonry on the eastern eight miles and the earthwork on the canal trunk and highway bridges is complete. Contracts have been let for the construction of miles 9 to 24 inclusive. Lock foundations 8 to 21 inclusive, and all work on the culverts of this section are complete. All earthwork on miles 9 to 16 is finished with the exception of approaches to locks and highway bridges and filling behind lock walls and the concrete masonry of locks 8 to 18. Highway bridges 1, 2, 3, 4 and 10, including approaches, have been completed. On the western section the route from the feeder junction to the Mississippi River is approved. Nearly four miles of canal trunk are completed, together with locks 36 and 37 and Girard lock, north and south dams, and railway and highway bridges. The right of way has been located from feeder junction to Rock River. The land for the main line of the western section, in Bureau county, will soon be condemned. The location of the feeder line along the Sterling route has been approved. All the right of way for the feeder except one piece of land (which has been condemned), has been secured. Proposals have been opened for constructing earthworks along the first eight miles of the feeder.

THE PATENT LITIGATION concerning the use of aluminum in the manufacture of steel, which has been in the courts nearly four years, has been decided in favor of the United States Mitis Co., complainants, against the Carnegie Steel Co., Limited. The Carnegie Co. appealed from the decision of the lower court, which enjoined it from using the patent, and now that the Court of Appeals has upheld that finding it is said that the Carnegie Co. has taken a license under the patent and made settlement for past infringement.

A NEW ABRADING MATERIAL equal to emery in hardness, according to the claims of Mr. Floryanowicz, the Russian inventor, is made from fire-clay. The clay is thoroughly washed, mixed in a pasty mass, dried and then burned at a temperature of about 2300° F. The described result is a uniformly hard product with a hardness of 8 to 9 on the Mohr scale; this is equal to that of emery. The burned clay is crushed and used for making wheels, etc.

A CIRCULAR SAW FOR CUTTING STONE is being employed in the construction of the buildings for the Paris Exposition. It consists of a steel disk over 6 ft. in diameter, which has about 200 diamonds set in its rim. The saw is mounted upon a suitable shaft, and driven by steam power at about 300 revolutions per minute, for hard stone, at which rate about one foot per minute can be cut. For soft stone steel teeth are used, with diamonds every fifth tooth, and the rate of advance is about 3 ft. per minute. It is estimated that the stone is cut in this way at from ⅛ to 1-10th the cost of hand labor.

NOTES FROM THE ENGINEERING SCHOOLS.

Colorado State Agricultural College, Fort Collins, Colo.—A new mechanical engineering laboratory, 40 × 60 ft., costing $3,000, is now being erected. Funds for its completion have been subscribed by citizens of Fort Collins.

Lehigh University.—Two changes have been made in the instructors of the mechanical engineering department. Instructors Barry H. Jones and L. O. Danse resigned at the close of last term, and their places have been filled by Lucien N. Sullivan, of the Sheffield Scientific School, and John C. Peck, of the Rose Polytechnic Institute.

Dr. C. B. Dudley, of Altoona, Pa., recently delivered a lecture on "What a Chemist Does on a Railroad." Lectures announced in the course in the near future are by John C. Trautwine, Jr., Chief of Water Department of Philadelphia, on "The Water Works of Philadelphia," by Mr. R. W. Hunt, of Chicago, on "The Iron Manufacture in Sweden," and by Mr. Geo. S. Morison, of New York, on "Masonry."

During the past summer the testing laboratory in connection with the civil engineering department has been entirely remodeled. The equipment has been increased by the addition of new machines for torsion and compression tests, while the appliances for testing cement have been made very complete. A comprehensive series of tests on roofing slates has been recently completed, and the result published in pamphlet form under the title "The Slate Regions of Pennsylvania." During the present year researches on methods of testing cement by flexure and impact will be undertaken.

Cornell University.—A new chemical laboratory building 65 × 130 ft., three stories and a sub-basement, is now being erected. It will stand to the north of Morse Hall, the present chemical building, and will be connected with it by bridges from the first and second stories. It will be devoted chiefly to assaying and to research work in inorganic chemistry.

Trinity College, Hartford, Conn.—It is announced that a course in gas engineering will be established next year.

Washington and Lee University, Lexington, Va.—A course of electrical engineering has been established, with Mr. Robert E. Hutton as instructor. Mr. Hutton is the manager of the Lexington Light & Power Co., and is a graduate of Johns Hopkins University.

THE MELTING POINT OF CAST IRON.*

By R. Moldenke,† E. M., Ph. D.

In the rapid development of the art of founding one point seems to have escaped general research, not because it was not recognized, but because the proper appliances were lacking. This is the question of melting and casting temperature, a question all foundrymen deal with daily, and which for some branches of the art means either a successful cast or an utter failure.

The question of whether silicon affects the condition of the carbon contents of a casting or not is coming up again, as it does periodically, analyses by the dozen being quoted to substantiate statements made on either side, and yet we see only an occasional statement that the temperature conditions were as nearly the same as possible. What proof is there of this? The writer has taken the temperature of a ladle of iron which to the eye seemed as hot as melted steel, and yet another ladle full of iron of a different composition, which was dull red, contained the hotter metal of the two. Again from the same tap differences in temperature were found running nearly 200°F. The castings made with the two extremes in this case, though of the same silicon contents, differed widely in the proportion of graphite to combined carbon for the same thickness of section.

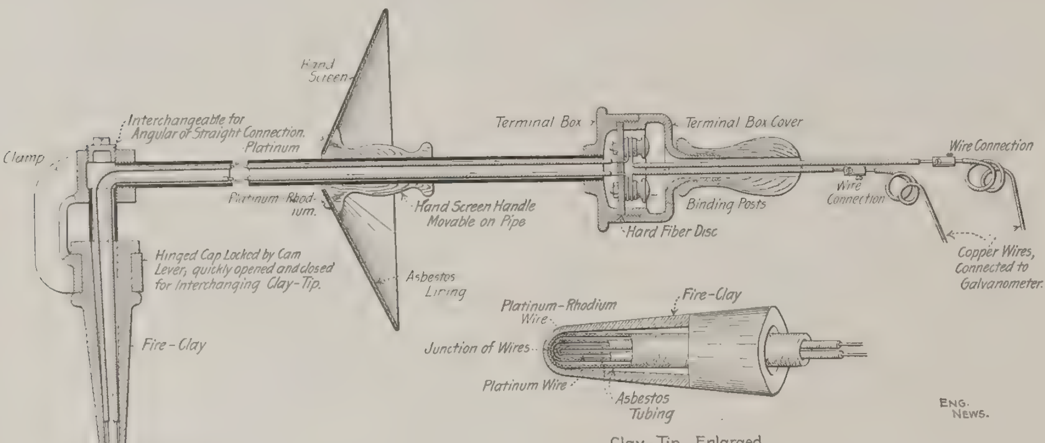
No wonder we are told that the silicons do not play so important a part. In one of the determinations described later on, a piece of cast iron was placed side by side with some ferro-chrome, both being under the same cupola conditions. The comparatively thick piece of cast iron heated quickly and melted before the thin piece of ferro-chrome was thoroughly red hot. Thus it will be seen that the eye is a most inaccurate instrument for measuring high temperatures.

---

*A paper read before the Pittsburg Foundrymen's Association, Oct. 24.

†48th St. and A. V. Ry., Pittsburg, Pa.

Those who cast heavy work know the danger of pouring either too hot or too cold, many are the devices made use of to test the heat of a ladle full of melted iron. Since these methods are empirical at best, how will we know at least approximately the temperature of our melt? Only by a device capable of withstanding such a severe usage. In looking about for such an instrument the attention of the writer was naturally directed to the latest and admittedly the best form of pyrometer for very high temperatures, the Le Chatelier. This consists essentially of two pieces of wire of a slightly varying composition, a heating of the junction of which produces a current of electricity proportioned to the degrees of heat applied. The amount of this current is measured by a suitably calibrated galvanometer, and thus we can read off the heat at any convenient distance rapidly and with a surprising degree of accuracy.



Clay-Tip, Enlarged.

FIG. 1.—SECTION OF LE CHATELIER PYROMETER AS MODIFIED FOR MEASURING TEMPERATURE OF MOLTEN IRON.

A New Pyrometer.

Unfortunately, this wonderful instrument, one wire of which is of platinum, the other of an alloy of platinum and 10% of the rare metal rhodium, cannot be immersed directly in the melted iron—there would soon be an end to this expensive thermo-couple. The long porcelain tube which protects it when used in kilns is worse than useless in a ladle full of metal, and so at the suggestion of the writer the Pittsburg representative, the Vulcan Mfg. Co., set about remedying the matter and devising some protective cover which would allow experiments of this kind to be carried out readily. The outcome, while not having the advantage as yet of an extended period of trial, was, nevertheless so happy a solution that it is presented to-night for the first time and to the Pittsburg Foundrymen's Association with the hope that much of value may be learned with it, not only in our daily work, but also in connection with the many intricate problems still before us which await solution at the hands of those willing to give their time and energy to such an exacting study.

Fig. 1 shows a section through the instrument. The platinum wire will be noticed running from the terminal box through an iron pipe ending at the inner side of the point of the clay tip. Here is the button made by the fusion to the other wire of platinum and rhodium alloy which runs back, parallel to the platinum wire, to the terminal box. Both wires are covered with asbestos to insulate them from each other and from the iron frame as well as to serve as a protection in case the tip breaks while in the molten iron. The interchangeable connection holding the clay tip allows it to point out straight for use in small ladles or in experimenting, or it may come down at right angles for taking temperatures in large ladles full of metal. A third form, not completed in time for illustration purposes, has a ball and socket joint which allows the tip to stand out at any angle. A movable shield lined with asbestos protects the hand.

Fig. 2 shows two of the styles of the pyrometer, and Fig. 3 the method of using the angular form. In the terminal box are placed the connections which allow wires of any convenient length to run through the handle and connect with the galvanometer. The galvanometer itself is a "D'Arsonval," specially gotten up and calibrated for industrial purposes. The original form with the reflecting mirror, and capable of reading to one-half degree at these high temperatures, was found too cumbersome and delicate for factory use.

The sensitiveness of the couple, even though protected by a refractory material, is such that plunging it cold into the melted iron the correct reading is obtained in 1¾ minutes. When heated up to redness beforehand, however, this time is reduced to not many seconds.

It would be beyond the scope of this paper to show the many uses to which such an instrument can be put in the steel and iron trade. On the question of annealing alone it will pay for itself in a short time, and when its capabilities in foundry practice come to be investigated and generally understood, one more safeguard will be added to those already helping us to increase the efficiency of our plants.

Test of the Melting Point of Various Irons.

The material experimented with was gathered for several years, some of it being furnished by Mr. Jos. Seaman, Mr. Thomas D. West and Mr. J. E. McDonald, members of this Association, and the especially interesting alloys by Mr. R. McDonald, of the Crescent Steel Co.

There were 48 pig irons, embracing both foundry and Bessemer brands as well as softeners, made with coke and with charcoal, both cold and warm blast. Seven of the 15 cast irons were of the shape seen in Fig. 4, being melted right from the tip. The balance were of the sand and chill rolls made by Mr. West in his recent experiments. Two steels and nine alloys of chromium, tungsten and manganese with iron, complete the list of 73 specimens.

The melting was done in an assay furnace converted for the time into a cupola. A jet of steam entering the stack in the side near the top induced the blast, the air being drawn in all around the bottom. In this form it is really the "Herberz" cupola of European fame and excellent for small diameters. A hole was broken into the wall just below the charging door, which must be kept closed when not used. This hole allows the introduction of the pieces of pig iron, etc. After heaping up enough coke to last for some time, the piece of pig iron (of full section and about 5 ins. long), was driven into the bed, surrounded by incandescent coke and the opening closed with a tile. After it was red hot the tile was removed, the pyrometer inserted and pushed against the center of the pig where the borings were taken for the analysis. The temperature as registered by the pyrometer rose rapidly, then more slowly, remaining stationary while the iron melted slowly. Then, as the point finally became uncovered, the temperature jumped up, going above 2,000° F. In this way the results noted in the accompanying table were obtained.

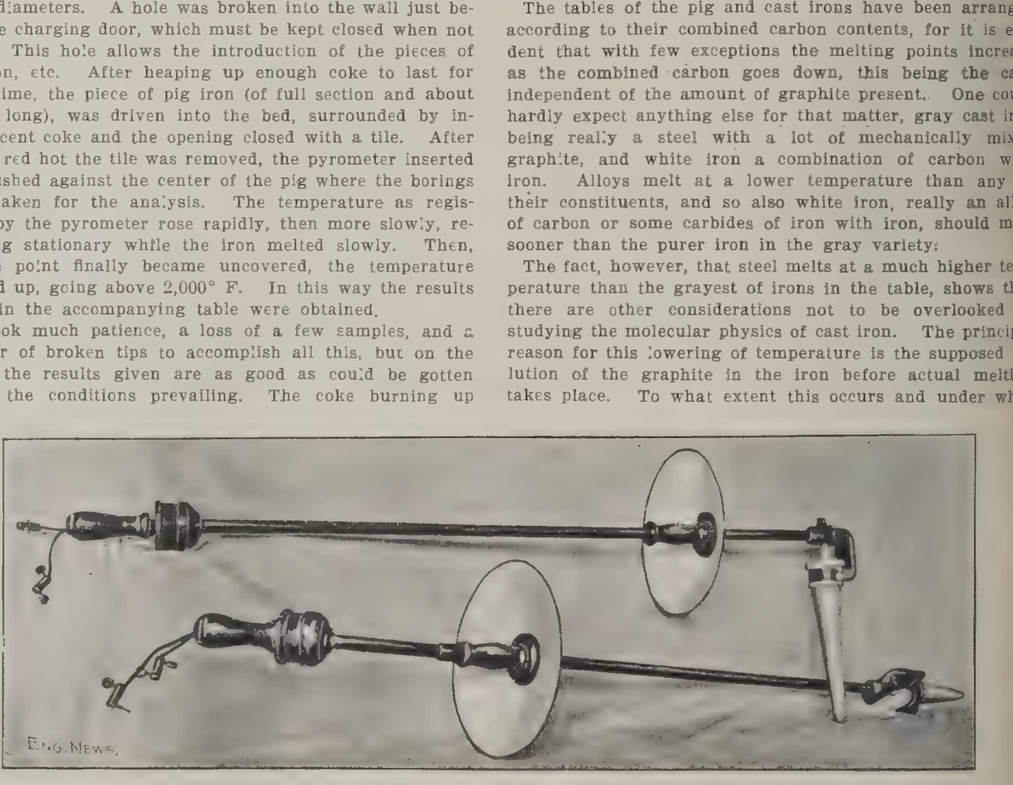


FIG. 2.—PERSPECTIVE VIEWS OF "ANGLE" AND "STRAIGHT" PYROMETERS.

It took much patience, a loss of a few samples, and a number of broken tips to accomplish all this, but on the whole the results given are as good as could be gotten under the conditions prevailing. The coke burning up would let the iron drop a little, and a failure to adjust the pyrometer to suit (the opening being closed by a piece of sheet iron, to prevent undue cooling by air drawn in), meant a break in the tip, which, while not affecting the results, caused subsequent delay and trouble.

The following general observations were made: The white irons held their shape, the iron running from the sides and bottom freely, leaving smooth surfaces. The gray irons became soft, dropped in lumps, leaving a ragged surface. Ferro-manganese samples became soft and mushy, exhibiting a consistency of putty before finally running down. Ferro-tungsten behaved most marked. As it melted it acted like white iron, but instead of chilling quickly it ran through the coke, coming down the spout in thin streams like white hot quicksilver, only setting after collecting in a pool in the pan of sand.

The cupola was fluxed heavily with fluor spar to take care of the ash, for it was a case of a furnace full of incandescent coke and only one piece of iron in it. The accompanying tables give the results:

TABLE I.—Melting Points of Various Pig Irons.

The tables of the pig and cast irons have been arranged according to their combined carbon contents, for it is evident that with few exceptions the melting points increase as the combined carbon goes down, this being the case independent of the amount of graphite present. One could hardly expect anything else for that matter, gray cast iron being really a steel with a lot of mechanically mixed graphite, and white iron a combination of carbon with iron. Alloys melt at a lower temperature than any of their constituents, and so also white iron, really an alloy of carbon or some carbides of iron with iron, should melt sooner than the purer iron in the gray variety.

The fact, however, that steel melts at a much higher temperature than the grayest of irons in the table, shows that there are other considerations not to be overlooked in studying the molecular physics of cast iron. The principal reason for this lowering of temperature is the supposed solution of the graphite in the iron before actual melting takes place. To what extent this occurs and under what circumstances is not known, but may account for the difference in the melting points of steel and gray iron.

Again, in melting steel in the cupola commercially, an absorption of carbon from the fuel takes place, the melting point is doubtless lowered a little, and the results obtained are tangible, even though care must be taken to get the whole of the charge down before pouring. In the air furnace the steel absorbs carbon by contact with the pig iron charged and melts off, the wasting of wrought iron or steel poking bars used for rabbling giving evidence of this occurrence.

The writer is especially pleased to see the full corrobora-

63	2080	1.81	1.36	11.70	1.00	......	......	Remelted ferro-silicon No. 5, cast into sand roll (Mr. West).

tion of Mr. West's elaborate experiments with the melting of white and gray irons. The contrast is remarkably sharp, and on the whole it shows us that science and practice go hand in hand admirably, no matter what the field may be. Whatever theories may develop regarding the melting of iron, whatever the effect of high or low phosphorus, silicon, manganese and sulphur may be shown to be on the melting point of an iron eventually (the present series of irons not being well enough adapted for this phase of the question), the results here given are, it is hoped, of sufficient value to stimulate further research of practical value to the founders of cast iron.

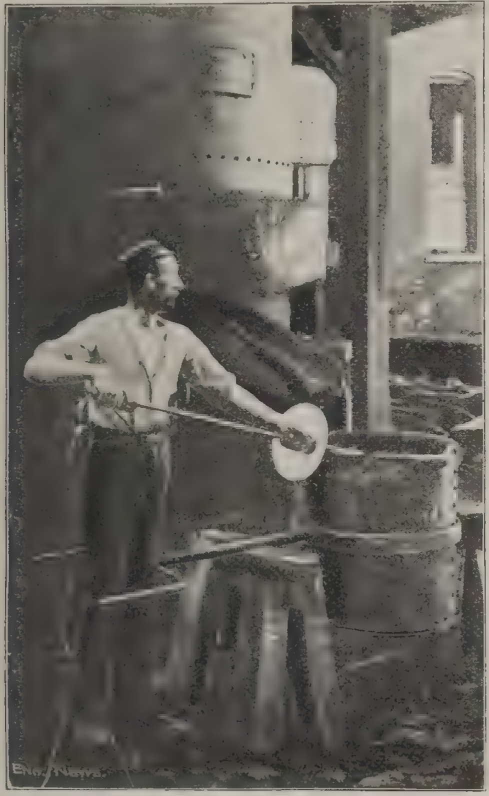

Fig. 3.—Testing Temperature of a Ladle of Molten Iron With Angle Pyrometer.

BOOK REVIEWS.

PURIFICATION OF THE OHIO RIVER WATER AT LOUISVILLE, KY. Report to the President and Directors of the Louisville Water Co., by George W. Fuller, Chief Chemist and Bacteriologist to the Louisville Water Co.; formerly Biologist in Charge of the Lawrence Experiment Station, State Board of Health of Massachusetts; Member of the American Chemical Society, etc. Published under agreement with the directors. New York: D. Van Nostrand Co. Cloth; 4to.; pp. 461; many tables and eight full-page plates. Price, $10.

For the past three years the attention of a large number of those interested in water purification has been directed to certain investigations of the subject at Louisville, commonly referred to as the Louisville experiments. At the start it was generally understood that these investigations would be limited to mechanical filtration and that the results would be available to the public within a year or less. But both the scope and length of the investigation was extended. Certain so-called electrical methods of water purification and of producing coagulation were included, together with more detailed studies of sedimentation, and the final report was not presented to the company by Mr. Fuller until two years after he assumed charge of the tests. Another year elapsed before the report, advance sheets of which have just been received by us, was off the press. More than one city has postponed the adoption of a much-needed system of water purification, largely to await the result of the Louisville experiments. The report now before us is a monumental piece of work, which does great credit to the Louisville Water Co. and its officials, to Mr. Fuller and his assistants, and to the several companies and gentlemen who met the expense of installing and operating the test plants. At the beginning of this review we wish to caution our readers that while this report marks an era in the development of water purification in some respects more notable than the special report on "The Purification of Sewage and Water," published by the Massachusetts State Board of Health in 1890, the Louisville studies, like those at Lawrence, were confined to the waters of one river and mostly to one general method of purification. It is true that the Ohio River at Louisville is in many respects typical of a large class of water supplies in the West and South, as is the Merrimac at Lawrence of many water supplies in the North and East. But it should be constantly kept in mind that there are variations in each class, due to local conditions, especially in the Southern and Western waters, which demand special investigations for each source of supply if the highest efficiency and economy of purification are to be obtained.

TABLE III.—Tests of the Melting Point of the Same Irons Cast in Sand and Cast in Chills.

No.	Combined Carbon.	Graphite.	Fracture.	Melting Point.	
57	1.60	3.16	Gray	2210°F	same ladle.
49	4.67	.03	White	2000	
58	1.57	2.90	Gray	2250	same ladle.
50	4.20	.20	White	1990

52	3.90	.16	White	2000	

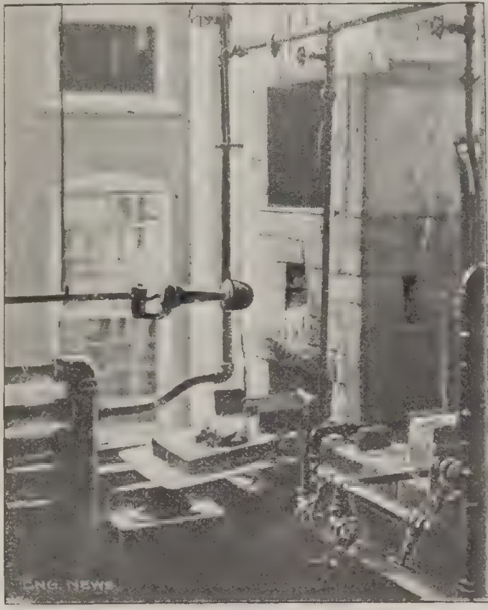

Fig. 4.—Experimental Cupola Showing Piece of Cast-Iron to be Melted, on the Tip of the Pyrometer, Before Thrusting it Into the Furnace.

Perhaps it should be stated, although most of our readers must know it, that the problems presented in the purification of the Ohio River water are the removal of suspended matter, in the most widely varying quantities, and also the removal of bacteria, some of which are of sewage origin. The water is not well suited for boiler purposes, and while the removal of mud improves it in this respect, some of the methods proposed add to the corroding and incrusting qualities of the water, necessitating a careful study of this phase of the subject.

Mr. Fuller took charge of the investigations on Oct. 1, 1895. The plan then being carried out was to test certain commercial systems of water purification on a working basis, each system to be designed for a daily capacity of 250,000 gallons, which was then the unit employed by the mechanical filter companies. The proprietors of each system were to install and operate their respective plants without further expense to the Louisville Water Co. than that involved in pumping the water and in testing the results by means of a proper engineering, chemical and biological staff. Three companies entered the tests: The O. H. Jewell Filter Co., of Chicago; the Cumberland Manufacturing Co., of Boston, proprietors of the Warren Filter, and the Western Filter Co., of St. Louis. Each company installed a 250,000-gallon gravity filter and the Western Company installed in addition a pressure filter of the same capacity. Later on tests were made of electrical methods of testing water submitted by the John T. Harris Co.,of New York,and Palmer & Browrell of Louisville. There was also tested a polarite filter and accessories, submitted by Mr. John MacDougall, of Montreal, this system being known abroad as the Howatson, and as the International process. While the Western pressure filter, the electrical methods of treatment and the polarite system are described and the results given in detail, none of them were considered as at all suitable for Ohio River water and they are not included in the final summaries. The systems so included are the Warren, Jewell and Western gravity filters and independent studies made by the Louisville Water Co. on sedimentation alone, sedimentation aided by coagulation, filtration and coagulation, the best coagulant, and the electrolytical production of coagulants. An appendix contains a technical description of the methods used for the collection of samples of water, the principal features in the methods of analysis and tables for the conversion of the various unit quantities employed. The eight full-page plates show a plan of the experiment station, plans and sections of mechanical filters and typical areas of the strainer floors of the filters.

TABLE IV.—Melting Point of Iron Alloys and Steel.

No.	Melting Point.	Carbon.	Silicon.	Manganese.	Chromium.	Tungsten.	Remarks.
64	2450°F.	1.18	.21	.49	....	....	Steel
65	2350	1.32	.29	1.27	3.40	6.21	Steel
66	2280	......	......	....	....	39.02	Ferrotungsten
67	2240	......	......	....	....	11.84	Ferrotungsten
68	2255	5.02	1.65	81.40	....	....	Ferromanganese.
69	2210	6.48	.14	44.59	....	....	Ferromanganese.

73	2180	1.40	......	....	5.40	....	Ferrochrom

The outline given above conveys an idea of the general scope of the investigations and report, but the exhaustive character of the tests, the detail in which the apparatus, methods employed and results obtained are presented and the judicial spirit shown in drawing the conclusions can be gathered only by a careful reading of the report. Each system of purification is described with a minuteness almost sufficient to serve as specifications for duplicating it. The difficulties experienced in operation and the changes made to overcome them are given. The log of the tests is presented almost in full. And, finally, all the accumulated evidence is carefully weighed and the results obtained are clearly set forth, both as relates to the efficiency and the cost of operation of each plant.

The final conclusion of the report, which relates especially to mechanical filtration, as the term is commonly understood, is as follows:

> The general method of subsidence, coagulation, and filtration is applicable to the satisfactory purification of the Ohio River at Louisville; but, as practiced by the Warren, Jewell, and Western systems during these tests, its practicability is very questionable if not inadmissible. By removing the bulk of the suspended matters from the water, large reductions could be made in the size of filter plant, amount of coagulant and cost of operation. On the basis of 25,000,000 gallons daily, these reductions when capitalized at 5% would represent about $700,000. There is no room for doubt but that for a less sum than this satisfactory provisions for subsidence as outlined herein could be provided, which would not only aid in furnishing a filtered water of better quality, but would also give the water consumers a better service in other regards.

This conclusion, when separated from the discussion leading to it, needs to be supplemented by the statement that for the Ohio River water, with its varying character and occasional vast amounts of suspended matter, the systems in question need a number of modifications, the chief of which is greatly increased facilities for sedimentation. The only other conclusions which space permits mention of here are that sulphate of alumina is the best coagulant for use at Louisville, and that it can be bought much more cheaply in its ordinary commercial form than it can be prepared electrolytically.

THS BUFFALO MEETING OF THE AMERICAN INSTITUTE OF MINING ENGINEERS.

The 75th meeting of the Institute was held in Buffalo, N. Y., beginning on Tuesday evening, Oct. 18. At the first session, held in the Public Library Building, addresses of welcome were made by the Mayor of the city and other prominent citizens, which were responded to by President Kirchhoff. Mr. F. P. Ricketts read a paper on "Slips and Explosions in the Blast Furnace," which was illustrated by lantern slides. An exhibition of stereopticon views was then given by Mr. Theodore Dwight, including several pictures taken at night and some photographs colored in the toning solution. This was followed by an informal reception.

The Wednesday morning session was devoted to the reading and discussion of a paper on "Multiple Tuyeres for Blast Furnaces" by B. F. Fackenshal. The discussion was a long one and was of much interest to blast furnace managers, many of whom were present. In the afternoon a steamboat excursion was taken on the lake. Visits were made to the Great Northern Elevator, the Union Iron Works and the Buffalo Furnace Co.

Sessions were held on Thursday morning and afternoon for the reading and discussion of papers. The morning session opened with the reading of a long list of names of members recently elected. A paper by Mr. Frank Firmstone on "Notes on the Forms Assumed by the Charge in the Blast Furnace" was presented. It had been previously printed and distributed to the members, but none of those present cared to discuss it. Mr. Bertrand S. Summers' paper on "Modern Cupola Practice, with Special Reference to the Physics of Cast Iron," which had also been printed in advance, was then taken up, and quite a long discussion followed, including written communications from absent members. The discussion showed that experts in foundry practice are still at variance in regard to what is called in the paper the "silicon fad." The ideas of the paper were strongly commended by some and as strongly condemned by others. Mr. W. R. Webster's paper on "The Relations Between the Chemical Constitution and the Physical Character of Steel" was then discussed at some length. This was followed by a brief discussion of Mr. W. H. Blauvelt's paper, "A Description of the Semet-Solvay By-Product Coke Oven Plant at Ensley, Ala." Mr. C. C. Upham then read from manuscript a paper on "The Effect of Sizing Upon the Removal of Sulphur from Coal by Washing." The Secretary, Dr. Raymond, made brief statements concerning some of the papers that had been prepared for the meeting but which there was not time to discuss, and other papers were "read by title." The morning session was rather poorly attended, but the afternoon session was only an apology for a meeting. Mr. Blue was to read his paper on "Corundum in Ontario," and as few of those present cared whether there was corundum in Ontario or not and the afternoon was a delightful one in which to make trips around the city, it was only by considerable urging of the men scattered around the hotel vestibule and parlors that an audience of about a dozen was collected to listen to the paper, which was a long one and was read from manuscript. It is a paper that will be a credit to the "Transactions" when it it published, but is not the kind to be read in full before an audience even of mining engineers.

The Institute is to be complimented upon the progress it has made during the past ten years in the direction of a proper system of treating its professional papers at the meetings, but it is still a long way behind the practice of other societies. The papers were divided into four classes, viz., 13 papers which had been printed in advance of the meeting and mailed to members, five papers in type but not finally corrected, proof copies being furnished on application; eight papers not in print, to be presented by the authors, or in their absence by the secretary; three papers read by title only for subsequent publication and discussion. The programme of the meeting contained this interesting announcement concerning the papers: "It is impossible to say precisely at which session any given paper will be presented, much depending upon the presence of authors and other circumstances." Nothing could be better calculated to discourage attendance at the professional sessions of the meeting and to decrease the number of those attending the meeting.

Notwithstanding the lack of interest in the sessions the meetings of the Institute as a whole are fairly well attended considering the great extent of territory, the whole world in fact, over which its members were distributed. Over 160 were registered as in attendance at the Buffalo meeting, including ladies and guests. Socially the meeting was a great success, as all meetings of the Institute are. The excursions to various places in Buffalo by different small parties were numerous and full of interest. All of Friday was given up to these excursions. On Friday evening the whole party went to Niagara Falls, where a session was held in the International Hotel to listen to Mr. F. H. Davis' paper on a "New Method of Drilling Holes of Large Diameter in Rock." On Saturday excursions were made to places of interest around the Falls, including the electric power plants and various manufacturing establishments in the vicinity.

We give below brief notes concerning the papers presented at the meeting:

1. The Kytchtym Medal. By Dr. Persifor Frazer. Philadelphia.—This was a brief paper describing a souvenir medal cast at the Kytchtym Iron Works in the Eastern Urals, on the occasion of the visit of the International Geological Congress, which met in Russia last year. The medal is a fine example of medal work in cast iron, showing great perfection of detail. Analyses of the iron and of the ores from which it is made were given.

2. Modern Cupola Practice, with Special Reference to the Discussion of the Physics of Cast Iron. By Bertrand S. Summers, Chicago, Ill.—This paper was printed in condensed form in our issue of Oct. 6.

3. The Relations Between the Chemical Constitution and the Physical Character of Steel. By Wm. R. Webster, Philadelphia, Pa.—This paper is chiefly a resume of previously published papers on the subject. Mr. Webster gives tables of both of his own investigations and of those of Mr. H. H. Campbell, Prof. H. M. Howe, Mr. A. C. Cunningham and others. His concluding remarks, given below, are of timely interest:

> In this practical age it will be asked, "What is the actual value of all this, and is it worth while to bother any more about it?" The answer is that already the steel-maker depends more and more every year on the very points that we have been discussing, and the engineer should know what he is doing when he uses both chemical and physical limits in his specifications. Is it to be wondered at that to-day we have specifications in which the chemical requirements do not all agree with the ultimate strengths specified? This in the ordinary home-orders may make very little difference, as it is an easy matter to investigate and make proper modifications required, but in specifications from foreign railroads or engineers at a distance, for material on export orders, it is a very different matter. There is no time to refer questions of this kind, and the inspector is sometimes forced to condemn material that he knows from experience is all right. It may give better physical tests than were called for, but not conform to the chemical requirements in the particular specifications in question, though it would meet both the physical and chemical requirements of our leading engineers and railway companies in this country. Some of these foreign specifications are so worded, and the requirements are such, that it is not safe for an American manufacturer to bid on the orders. This may be due in part to their not understanding all of the conditions under which the tests are to be made. In other cases it seems as though modifications must have been made on previous orders, either in the chemical requirements or physical tests called for, as no steel was ever made that would meet all the requirements of chemical and physical tests in some such specifications.
>
> Many export-orders for rails call for phosphorus not over 0.6%, while the sulphur is allowed a much higher limit, or not specified at all. This low phosphorus cuts out several of our largest steel works, whose material will meet all of the physical tests called for, being low in sulphur and under 0.10% phosphorus, and giving entire satisfaction to our leading engineers and railroad companies. The foreign manufacturers of basic Bessemer steel and low-phosphorus acid Bessemer steel are working the low-phosphorus clause for all it is worth, just as our manufacturers would do under similar circumstances; but we, as engineers, want to know if there is any good reason for this distinction, which is made on account of local conditions, and if the high sulphur is not as undesirable as the phosphorus would be up to the limit of 0.10% usually allowed in this country?
>
> This is a matter that should be thoroughly discussed and on which opinions should be secured from our leading engineers; for it of no use for the manufacturers to give their opinion unsupported by the experience of users of their rails. It is just here that the effect of the different elements plays an important part. Our manufacturers know from experience that as their phosphorus is a little higher than the limit of 0.06% referred to, they must keep the other elements inside of given limits to produce the best results in the finished rails. This is done successfully, and a rail is produced that will meet the requirements of the drop-test and give satisfaction in use. I do not wish to be understood as advocating high-phosphorus, but my position is that rails which will meet all the varying conditions in this country will meet all that is required of them when put in use in other countries. If one examines the methods of manufacture of rails in this country and those in other countries, then visits the countries where our rails are being introduced, and gets accurate information as to the service they are giving, he will be convinced that there is a great future for America in the export business in rails.
>
> The conditions with regard to the material for bridges are about the same. Foreign specifications, in many cases, provide that only acid open-hearth steel can be used. This has already prevented our bridge builders from bidding upon thousands of tons of bridge work, although in some cases they have accepted the requirement of acid open-hearth steel, and have taken the orders. In other cases they have explained that our Government is using the basic open-hearth steel; that in the manufacture of it the works here start with an iron very much lower in phosphorus than is ordinarily used, and that the resulting steel is much more uniform. This has had a great deal of weight, and the use of basic steel has been allowed in some cases. In other cases new specifications have been adopted after investigation in accordance with the best American practice, which allows the use of either basic or acid open-hearth steel. I refer to this matter at length as it is of the greatest importance to our engineers and manufacturers, as well as to all others who wish to see our export trade developed.
>
> The continued discussion on the physics of steel is broad enough to take up any specifications on home or export orders that may be brought forward; the uniform methods of testing and methods of manufacture and rolling that will improve the finished products. It is of the greatest importance to establish the quality of American material abroad, and to have on record all facts regarding the same, both from the engineers' side and the manufacturers', and I know of no better channel for doing this than the American Institute of Mining Engineers.

4. Slips and Explosives in the Blast Furnace. By F. B. Richards, Cleveland, O.—This paper was presented by the author at the first session on Tuesday evening, and was illustrated by lantern slides. It is of especial interest to blast furnace managers, some of whom discussed it at the session on Wednesday.

5. Multiple Tuyeres. By Dr. R. W. Raymond.—This paper also relates to blast furnace practice. It describes the Gaines tuyere, which has a horizontally elongated discharge opening, and which is claimed to have some advantages over a tuyere with a round nozzle.

6. Note on the Forms Assumed by the Charge in the Blast Furnace, as Affected by Various Methods of Filling. By Frank Firmstone, Easton, Pa.—This is a very fully illustrated paper giving the results of a long series of experiments carried on at the Glendon Iron Works to determine the method in which the stock distributes itself in the upper part of the furnace when different sizes of top and of bell and hopper and different methods of filling are used.

7. A Description of the Semet-Solvay By-product Coke Oven Plant at Ensley, Ala. By W. H. Blauvelt, Syracuse, N. Y.—This paper was presented by the author at the session on Thursday morning. It was illustrated by drawings and photographs showing the plant recently erected by the Tennessee Coal, Iron & R. R. Co. It consists of 120 ovens, and when in full operation is expected to produce from 420 to 460 tons per day, or as much as is produced by 300 beehive coke ovens. The plant will require 732 hours' labor per day, as compared with 1,020 hours for the beehive ovens. Besides the saving of labor there is the saving due to the value of the by-products, fuel gas, tar and sulphate of ammonia.

8. The Effect of Sizing Upon the Removal of Sulphur from Coal by Washing. By Chas. C. Upham, New York City.—This paper discussed the advantages of fine crushing and sizing by screens before washing to remove pyrites from coal. It was noted that the finest pyrites will float on the surface of water, and by screening before washing a large portion of this pyrites may be removed which would otherwise go with the washed coal.

9. Note on the Use of the Tri-Axial Diagram and Triangular Pyramid for Graphical Illustrations. By Prof. Henry M. Howe, New York City.—The author describes the use of the equilateral triangle diagram in plotting the total heat of fusion of silicates of lime and alumina, and its great advantage over the di-axial diagram for plotting the relation of any quality to the percentage composition of a substance composed of three constituents. He also shows that a pyramid with an equilateral triangle for a base and of a height equal to the altitude of the triangle may be used for graphically indicating the relation of any quantity which depends on four variables whose sum is constant, such as the heat of fusion of a slag composed of four constituents as silica, lime, alumina and magnesia.

10. Graphic Records of the Screening of Crushed Materials. By Prof. Courtenay De Kalb, School of Mines, Kingston, Ont.—The author has made a series of experiments on crushing ore of different kinds and screening it through sieves of different meshes, plotting the results so as to show the percentages of different sizes of the crushed material. He finds that the curves so plotted show practically identical characteristics for all the different ores, and only by varying the conditions of crushing were variations in the curves obtainable. This result was not expected.

11. Mill Practice of the Utica Mills, Calaveras Co., California. By W. J. Loring, Angels Camp, Cal.—This paper describes what is believed to be the best practice, in regard to cost, yet reached in California quartz milling.

12. A New Essay for Mercury. By Richard E. Chism, City of Mexico.—This is a new process for assaying ores containing mercury, which is accurate to 0.01%. The ore mixed with fine iron filings is heated in a small crucible over an alcohol lamp, and the vapor of mercury distilled is collected on a piece of thin, clean silver foil which covers the crucible. A silver dish containing water is placed over the foil to keep it cool.

13. The Influence of Bismuth on Brass and Its Relation to Fire Cracks. By E. S. Sperry, Bridgeport, Conn.—A brief abstract of this paper was given in our issue of Sept. 29, p. 208.

14. Experiments on the Sampling of Silver-Lead Bullion. By G. M. Roberts, Murchison Gold Fields, Western Australia.—Numerous experiments recorded in the paper lead to the conclusion that samples taken by chipping out of the top and bottom of each ingot almost always give a result lower than the actual value of the bullion. The only really accurate samples are the dip-sample from the kettles and the saw sample made by sawing through the ingot.

15. The Elimination of Impurities from Copper Mattes in the Reverberatory and the Converter. By Edward Keller, Baltimore, Md.—This is a reply by Mr. Keller to the discussion of his paper presented at the Atlantic City meeting.

16. A Modification of Bischof's Method of Determining the Fusibility of Clays, as Applied to Non-Refractory Clays, and the Resistance of Fire Clays to Fluxes. By H. O. Hofman, Boston, Mass.

17. Does the Size of Particles Have Any Influence in Determining the Resistance of Fire Clays to Heat and to Fluxes? By H. O. Hofman and B. Stoughton, Boston, Mass.—These two papers describe experiments made at the Massachusetts Institute of Technology. The query of the title of the second paper is answered in the negative. There is only a slight difference in the results obtained from mixtures made as those used in making bricks, blocks, pots, etc., and from the same mixtures ground fine, as is the usual custom in laboratory tests.

18. Notes on the Tunnel of the Melones Mining Co., California. By W. E. C. Eustis, Boston, Mass.—This paper is not yet in print. Dr. Raymond made a brief statement concerning it, and says that it shows some extraordinary records of rapid tunnel driving.

19. A New Method of Drilling Deep Holes of Large Diameter in Rock. By F. Harley Davis, New York city.—The author describes a new form of rotating rock drill, which he had invented while in Australia and had largely introduced in that country. It cuts out a core about 4 ins. in diameter, and does very rapid work in sandstone and limestone. An exhibition of the working of the drill was given in Buffalo, and its performance was highly praised. We hope to give an illustrated description of this drill in an early issue.

20. Hubnerite in Western Arizona. By William P. Blake, Tucson, Ariz.—Hubnerite is a manganiferous variety of wolframite. It compares most favorably with any wolframite as a source of tungsten, being very pure and free from sulphides and arsenides. It may prove to be of value in the manufacture of tungsten steel.

21. The Superficial Alteration of Western Australian Ore Deposits. By H. G. Hoover, Coolgardie, Western Australia.—This is a very brief paper. Its practical bearing is on the exploitation of new gold regions. Ores frequently show a transition from free milling to refractory ores, with increased depth, and disregard of this fact has brought many gold mining companies to ruin.

22. Notes on the Mines of the Frontino and Bolivia Company, Colombia, S. A. By Spencer Craigie, Mariana, Brazil.—These notes give a brief account of some gold

mines in Colombia. one of which, with a poor plant, giving only 50% extraction, nets a profit of $25,000 per month. The author says that there is probably no mining field of richer promise than that of Colombia.

23. Corundum in Ontario. By A. Blue, Toronto, One.—This paper was read from manuscript by its author. He gives an interesting history of the discovery of corundum of excellent quality in Ontario, and of the exploration of the whole area, which is of considerable extent, in which it is found. The deposits may prove to be of great value.

24. Mineral Lode Locations in British Colombia. By William Branden, Helena, Mont.—This paper is a brief statement of the laws of lode locations in British Columbia, which are far simpler and more satisfactory than those of the United States. From 1884 to 1892 the Mineral act was modeled after that of the United States, but was revised and greatly improved in 1891, and further amended in 1896 and 1897.

The following papers are not yet in print and were read by title:

25. The Evolution of Mine Surveying Instruments. By Dunbar D. Scott, Ironwood, Mich.

26. Note on the Operation of a Light Mineral Railroad. By James Douglas, New York city.

27. The Alluvial Deposits of a Dry Country. By T. A. Rickard, Denver, Colo.

* * *

ANNUAL CONVENTION, ASSOCIATION OF RAILWAY SUPERINTENDENTS OF BRIDGES AND BUILDINGS.

First Day's Sessions.

The eighth annual convention of the Association was held at Richmond, Va., Oct. 18, 19 and 20, 1898, the place of meeting being Murphy's Hotel. About 35 members were present at the opening session. Including the ladies and other guests, the total attendance was probably not far from twice this number. Besides a considerable amount of routine business, the convention had scheduled for consideration eleven special committee reports, and considerable other work of a technical nature, including as the principal item the discussion of the various committee reports presented at the previous year's meeting. In a number of instances this review of the previous year's work brought out valuable additional information. The list of the present year's reports was, however, shortened by the failure of two of the eleven committees to report; otherwise the programme already printed in these columns (Eng. News, Aug. 25, 1898) was carried out in full.

The first business following the opening exercises was the election of new members, 21 of whom were added to the rolls. In his address, the President called attention to the excellent work which had been done by the Association in the past, and mentioned with some pride that, taking into account the small membership and slender resources available, its technical work compared favorably with that of other societies. The reports of the Secretary and the Treasurer showed the Association to be in good financial condition, it having a surplus of $219 cash on hand with all debts paid. The total receipts during the past year were $1,[illegible]57. After some further routine business, the convention proceeded to the consideration of the special committee reports. It being the custom of the Association simply to read these reports at the first day's sessions and reserve their discussion for the second day's proceedings, they will be considered in connection with the discussions presented further on in this record of the convention's work.

The entire remainder of the first day's sessions after reading these reports was occupied with the discussion of the committee reports presented at the Denver, Colo., convention of 1897. Only two of these reports called out much discussion, viz., "The Most Suitable Material for Roofs of Buildings of all Kinds," and "Floor System on Bridges, Including Skew Bridges." In regard to roofing materials, the general concensus of opinion was that for station buildings of the first class nothing was superior to slate shingles. Regarding the best roofing material for shops, round houses, freight sheds, etc., the opinions and practice of different members differed widely, and pine or cedar shingle, gravel and tar, felt with gas tar and sand, asphalt, tile, granite felt, were all well spoken of. For roundhouse roofs, however, iron or steel was considered a poor material, and any material in fact which depended upon iron nails or other iron fastenings, was regarded as objectionable. Some of the members had used both slate and wood shingles, with copper nails, and had experienced no trouble from the destruction of the nails.

The discussion on bridge floors was confined largely to the method of placing guard rails and fastening them to the ties. Not much that was new was brought out in addition to the original report, and after transacting some routine business the first day's proceedings were concluded.

Second Day's Sessions.

The principal technical work of the convention was contained in the proceedings of the second day, when the discussion of the special committee reports came up. The first report considered was that on

Pile Rings and Methods of Protecting Pile Heads in Driving.

The committee considered the best protection for pile heads during driving to be a 1 × 3-in. iron ring. It was recommended that these rings should be made of iron hammered from old car axles. Such rings,1 × 3 × 14 ins. diameter would cost about $1.75, as compared with $2 when made of the best bar iron. One hammered ring would also last to drive 75 oak piles and 300 cedar piles, as compared with 50 oak piles and 200 cedar piles for a bar iron ring. A pile driver tool car should carry ten 15-in., thirty 14-in., ten 13½-in., and ten 13-in. rings, or 60 rings altogether. In fitting the pile ring, it was recommended that the pile should be chamfered down at least 5 ins. from the end, making the diameter of the head at the top such that the ring would just catch on and be driven home by the first blow of the hammer.

The face of a pile hammer should be concaved to a depth of 1½ ins. at the center and run out to nothing at a distance of 2 ins. from the edge. This form of hammer face acted to drive the fiber of the wood down slightly over the edge of the ring, and to make a neat fit of the hammer. The best weight of hammer was 3,300 lbs. The fall of this hammer should not exceed 12 ft. in driving cedar piles, nor 20 ft. in driving oak piles; short, quick blows will drive a pile as fast as long slow blows, and there will be much less danger of fracturing the pile. Piles should be neatly trimmed of knots and sharpened to a 4-in. square point for hard driving. Care should be taken not to overdrive piles. When, with a 3,300-lb. hammer, the penetration is not over 1 in. for a 10 ft. fall, the fall should be reduced to 6 ft., and the pile carefully driven until the penetration is only ¼-in., when the driving should be stopped.

The use of an iron cap or bonnet is not practicable for driving piles in trestles, as it interfered with getting the pile close to the stringers, but where it can be used freely the device is an excellent one. In driving piles through shale rock or soapstone, where shoes are required, the best shoe is four pieces of old car truck arch-bar iron welded together, with the end drawn to a point and the four arms flared out to fit the four sides of the pile, to which they are attached by spikes through punched holes.

The discussion divided itself into a consideration, first, of the recommended method of protecting the head; second, of the concaved faced hammer, and, third, of the best form and material for the shoe. Most of the members who spoke concurred in the committee's recommendation to use a single ring for protecting the pile head, and to chamfer the head down to the diameter of the ring. The practice of some simply to place the ring on the top of the pile head and drive it into place without removing the outside material was regarded as objectionable, in causing slivering or the splitting off of the outside in slabs often several feet long. Mr. Wm. O. Eggleston (Chic. & Erie), spoke in favor of using a cap or bonnet to protect the pile during driving, and thought that there were very few cases in which it could not be employed to advantage. Referring to the same device, Mr. A. Shane (C., C., C. & St. L.) stated that in a test made by him a gain in speed of fully 20% had been obtained in actual work by its use. The choice of the members seemed to be about equally divided between hammers having concave faces and those having flat faces. The use of the wrought-iron point, recommended by the committee was pretty unanimously objected to, a cast-iron point with a good socket for the end of the pile being generally preferred. Mr. C. M. Large (Erie & Pitts.) and Mr. A. E. Killan (Intercolonial) both stated that their experience had been that the strap point mentioned would frequently split the pile in hard driving, and accordingly they preferred a cast-iron socket point or shoe. The next report was that of the committee on

Cost and Manner of Putting in Pipe Culverts.

The report showed quite a diversity of practice in employing and constructing pipe culverts, on the 30 railways from which information was obtained regarding the subject. The kinds of pipe culverts used and the maximum and minimum sizes employed were as follows:

	Cast-iron.	Wr't-iron.	Steel.	Cement.	Vit. pipe.	Wood.
No. of road using....	24	2	3	2	14	1
Maximum size, ins...	24	60	48	..	48	72
Minimum size, ins. ..	8	30	36	..	12	24

The majority of roads built end walls for all pipe culverts, but others employed them only for certain kinds of pipes, or under certain conditions only, while a few did not use them at all. In putting in pipe culverts to replace timber culverts, the general practice was to make an open cut, supporting the track on stringers resting on piles or mud sills, but some roads tunneled deep embankments, and in a few cases the pipe was pulled through the old wooden culvert, the space between the two being finally tamped full of earth. When the pipe culverts were placed where no previous opening existed, the general practice was to make an open cut, or, in the case of deep embankments, to tunnel. Little trouble was had with the breaking or flattening of cast-iron pipe culverts, except for diameters of from 36 ins. to 6 ft. On the other hand, considerable trouble of this sort seemed to be experienced with vitrified pipe and cement pipe. The means generally adopted to overcome this difficulty were to use more care in packing the earth around the pipe. In the case of large size cast-iron pipe, it was the practice of some roads to place wooden or iron shoes inside and let them remain until the ground was settled firmly. In one case the remedy adopted was to line broken cast-iron pipe with a ring of paving brick. The costs of different kinds of pipe culvert per lineal foot were given by the report as follows:

Creosoted Stave Pipe Culverts; Southern Pacific Co.

Diam, ins.	Cost per lin. ft.
24	$1.06*
36	2.11
48	2.42
66	4.70
72	4.90

*This does not include cost of laying or of portals.

Cast-Iron Pipe Culverts.†

Diam. of pipe, ins.	Material.	Labor.	Total.
18..........	$1.11	$0.16	$1.27
20..........	1.00 to 1.62	.09 to 1.08	1.76 to 2.08
24..........	1.20 to 3.32	.17 to 1.82	2.09 to 5.19
30..........	1.22 to 2.90	.23 to 1.42	3.09 to 4.67
36..........	2.51 to 3.69	.30 to 1.64	2.81 to 6.50
42..........	3.25 to 5.00	.70 to 1.98	5.08 to 5.70

Vitrified Pipe Culverts.

18..........	$0.30	$0.45	$0.75
20..........	.45	.51	.96
24..........	...	...	1.50 to 2.57

In the discussion Mr. J. B. Snow (B. & M.) stated that the usual cause of pipe culverts flattening was the failure to put in good, solid foundations and to pack the earth firmly around the pipe. Mr. A. S. Markley (C. & E. I.) stated that a frequent cause of failure in pipe culverts was leaky joints, the water from which washed holes under and around the pipe thus leaving it without support. A number of other members confirmed the statements of Mr. Snow and Mr. Markley. The next report was that of the committee on

Best Floors for Shops and Roundhouses.

The committee considered its subject under two heads, viz., roundhouse floors and shop floors, and its report was in abstract as follows:

Taking up first roundhouse floors, we find in general use: brick, concrete, granolithic concrete, cinder, disintegrated granite, cedar block, timber and plank. Of these, the four most commonly used are probably brick, concrete, plank, and cinder. In order to determine the most satisfactory floor for use in a roundhouse and the kind of material best suited for the purpose, it is necessary to consider the varying causes which combine to wear out the floor. Heavy repairs require the use of hydraulic jacks which bring great pressure to bear upon the floor adjacent to the cinder pits. To withstand the pressure requires a wide pit wall or else very firm foundation and rigid surface in the floor. In washing out boilers large quantities of water are used, much of which is spattered upon the floor. Besides this, there are numerous occasions for spilling all kinds of oil and grease. And with all, the demands for cleanliness are unceasing. Not the least of the destructive elements is the rolling of heavy trucks or driving wheels, or the dragging back and forth of jacks and large pieces of machinery. To find a material which will successfully withstand all of these destructive forces is the problem.

Your committee believes that good vitrified brick, properly laid, will give the best satisfaction in all roundhouses which are used for anything more than storage purposes. In this we have a floor that is smooth, firm, hard, and practically indestructible. It is absolutely unaffected by water, heat, oils, acids, or grease, and is easily cleaned, while one important advantage is in the ease with which it can be repaired, since any part may be taken up and replaced by common labor without the slightest injury to the floor as a whole.

The following method of laying brick floors conforms to the generally accepted practice: Assuming the soil to be firm and well drained, excavate the ground to an even surface 8 ins. below grade of desired floor. Tamp well with heavy rammers to secure a firm foundation, then fill in with good clean sand or gravel to within 3½ ins. of grade, making a crown of about 2 ins. between pits for drainage; wet this down well, tamp with rammers, and trim off with straight edge, taking care to get an even surface. Lay brick on edge close to each other and breaking joints so that tops come ½-in. above grade. After laying, roll bricks with 2,000-lb. or 3,000-lb. roller, cover the surface with 1-in. fine sand and broom it well into cracks, or fill cracks with cement grout. A concrete foundation is recommended by some, but, except in cases where the natural ground is not firm, or where the floor is to be subject to extremely heavy loads, it is not considered necessary.

The cost of brick floors in a number of isolated cases were given in the report and they ran from 6 cts. to 12.7 cts. per sq. ft., but averaged generally from 10 cts. to 13 cts. per sq. ft.

For blacksmith shops or foundries the natural earth frequently forms a very suitable as well as substantial floor. In localities where the soil is too soft in its natural state, the addition of cinders or clay will solve the problem cheaply and satisfactorily.

In machine shops the conditions are different, and here we find the recommendations almost as varied as are those for roundhouse floors. A brick floor in a machine shop answers many of the requirements, but there is good evidence in support of the objection that men cannot stand all day on such a floor or upon a surface of concrete or asphalt without feeling the bad effects of cold upon the feet. This difficulty is overcome to a large extent by the use of slatted floor racks or platforms at the machines where operatives stand. When machines are set upon a brick floor there should be special provision made for foundation. But this can hardly be urged as an objection as it is necessarily the case with heavy machines under almost any circumstances.

A bedded plank floor has recently been laid in an extensive shop plant of the Boston & Albany R. R. As this is somewhat novel, a description of the methods of building may prove interesting. The earth is well compacted and brought to the proper surface and a bed of coal-tar concrete put down in three courses. This bed is 4 ins. thick when finished. The specifications are that the stones of the lower course shall be not less than 1 in. in diameter and those of the second course not more than 1 in. in diameter. Stones of each course to be well covered with tar before laying and thoroughly rolled afterward. The finishing course to be composed of good clean sharp sand well dried, then heated hot and mixed with pitch and tar in the proper proportions. This is to be carefully rolled and brought to a true level to fit a straight edge. Roller to weigh not less than 700 lbs. on a length not exceeding 22 ins. On this finished surface of the foundation there is spread a coating ¼-in. thick of best roofing pitch put on hot, into which the lower course of plank is laid before it cools. Care must be taken to have the plank thoroughly bedded in the pitch and after laying the joints must be filled with pitch. If vacant places occur under plank they should be bored and filled. The finishing flooring is laid across the lower and thoroughly nailed. For the lower course 2½-in. spruce plank are used, and for the upper 1⅛-in. spruce plank. The cost of such a floor is given at 18 cts. per sq. ft. using spruce lumber.

For paint shops and car shops a brick floor has been found very satisfactory. Your committee believes that a brick floor generally speaking is the most economical, durable and satisfactory floor for shops as well as for round houses.

The discussion was opened by Mr. Jas. Stannard (Wabash), who stated that on his road vitrified brick floors were used for both shops and round houses. He considered them to be durabls and easy to repair, and especially convenient to take up and replace when pipe lines, etc., had to be installed or taken up from underneath the floor. The brick used was a vitrified paving brick. Mr. J. P. Snow (B. & M) had found common brick to be equal to all the requirements of round house floors. His practice was to lay the bricks flat and to grout the joints. For shop floors he considered brick objectionable on account of the difficulty of fastening heavy machinery to them and also because they were easily injured by falling tools and other heavy articles. Mr. A. E. Killan (Intercolonial) stated that his company had formerly used wood floors for shops and round houses, but they soon gave out. Vitrified brick floors were adopted later and were now used largely. The latest floor used, however, was one composed of a foundation of broken stone covered with firmly packed cinders, upon which was placed a layer of concrete with a 1½-in. top covering of cement. This floor was not much more costly than wood and had proved satisfactory so far. For shops he preferred wood floors, as workmen could not stand and work on concrete on account of the cold. A number of other members spoke, and nearly all expressed their preference for brick floors for both shops and round houses.

Round-House Smoke Jacks and Ventilators.

The committee contented itself with presenting drawings of different forms of smoke jacks and ventilators in use on various railways and with calling attention to the experience of those who had used them. From these it appeared that there was a great diversity of opinion as to the best style of smoke jack, the opinions in many cases being directly opposed to each other. The jacks illustrated comprised the standard round wooden smoke jack of the Chicago & Eastern Illinois R. R.; the Pickering wooden smoke jack (Eng. News, Feb. 18, 1897); the Chicago & Erie R. R. standard dormer ventilator; Fitchburg R. R. wooden monitor ventilator; metal telescope jack of Baltimore & Ohio R. R.; Scott ventilator; Roe ventilator; Pancoast metal ventilator; and the Portland Stoneware Co.'s terra cotta smoke jack (Eng. News, March 11, 1897).

The discussion was opened by Mr. Jas. Stannard (Wabash), who stated that, after having tried nearly all kinds of smoke jacks. he had settled down to the use of wooden jacks as being the best. He did not favor the use of a drop hood on smoke jacks. Mr. A. S. Murkley (C. & E. I.) stated that he used circular wooden smoke jacks and dispensed with painting and sanding, as he had found that the soot soon covered the interior of the jack and protected it from fire. These jacks had been in use two years and showed no depreciation. Mr. J. H. Cummin (Long Island) used wooden jacks altogether, and considered painting and sanding a waste of time and material. His jacks were square, 6 × 6 ft. at the bottom and 2 × 2 ft. at the top. He did not favor cast iron or other metal jacks. Had tried galvanized iron, lead-lined jacks, but they soon gave out. Copper jacks used to replace them had lasted two years and were yet in place. Mr. Jas. McIntyre (Erie) had in use smoke jacks made of cast iron, wrought iron and wood, and preferred the wooden jacks. A wrought-iron jack would last about five years. He had had several accidents from the drop hoods of cast-iron jacks falling, and was not in favor of using them. Mr. J. P. Snow (B. & M.) had used stoneware jacks with cast-iron hoods and had found them very durable but quite expensive. His present practice was to use the Pickering wooden jack. Mr. Wm. A. Eggleston (Chic. & Erie) had adopted the Pickering jack as a standard. Mr. A. E. Killan ((Intercolonial) had recently erected Pickering jacks. He did not think that much benefit resulted from painting the inside, as the covering of soot prevented fire, but he did paint the outside to preserve the wood from the weather. One objection to vitrified pipe jacks was the great weight they brought on the roof. Mr. Fred. Eilers (C., B. & Q.) used the Roe cast-iron smoke jack and had found that it did good work. One great advantage was the movable hood, which could swing aside without damage when an engine happened to be run out in a hurry. There was in his opinion danger from wooden jacks catching fire. The general concensus of opinion of the members named and of the others who spoke on the subject was that metal jacks and ventilators of iron or steel soon failed through corrosion. Wooden and stoneware jacks did not suffer from this cause and were therefore preferable. The wooden jack especially seemed to meet with general favor.

Cattle Guards and Wing Fences.

The report described briefly the various types of cattle guards in general use and stated that experience showed that each of them gave different results under different conditions. A guard which stopped highly domesticated tame cattle with fair success often failed entirely to hold the half-wild cattle which were allowed to run almost at free will on the western and southwestern cattle ranges. For the last kind of cattle a wide and deep pit guard—one deep enough to allow the beast to fall clear below the rails —was as satisfactory as any. No guard would turn cattle at all times.

The discussion brought out only a few points of especial interest, the principal one of which was that by whitewashing or painting white the ordinary surface guard and the wing fences adjoining it its effectiveness in stopping cattle was greatly insured. The patch of color differing from that of the surroundings served to frighten the cattle against attempting to cross. An objection which was raised to metal surface guards with pointed, sharp surfaces was their danger to brakemen called upon to run back in the dark to flag an approaching train. Mr. A. E. Killan (Intercolonial) mentioned an accident of this kind which resulted in the death of the brakeman.

Storage of Fuel, Oil and Other Station Supplies at Way Stations.

The report stated that this problem seemed to have been pretty generally neglected by railways, and recommended the following solution:

Keep office records and stationery on shelves and pigeonholes in a cupboard built for that purpose. Keep cupboard locked when not in use. These cupboards can be made at the shops. Files for tariff sheets should also be provided.

Coal stored at way stations, unless the station be very small, should be kept in a small house holding from a half car load to a car load of coal. Locate the house about 100 ft. from the station, on account of danger from fire, and, if possible, near a track, so the coal can be unloaded directly from the car through a trap-door in the roof of the coal-house. Partition off one end of the coal-house for an oil-house, of a size sufficient to suit the needs. Build a counter across one end, and cover it with zinc. Build a shallow box under the counter, and fill it with sand, so the oil will not soak into the floor. Place a ventilator in the roof to carry away all gases, and line the inside of the house with tin or zinc, to guard against fire. A shallow cast-iron pan with a grating over the top, to catch the oil while the lamps are being filled, should be placed on top the counter. This catches the waste oil. Where the size of the station warrants it, the coal and oil-house should be built of brick and provided with iron doors and shutters. No oil or coal should be stored in the freight house, as it is a constant source of danger from fire and often damages freight. Oily rags, waste, etc., should be kept in a galvanized-iron pail with a cover, to guard against fire from spontaneous combustion.

The discussion was opened by Mr. J. H. Cummin (Long Island), who stated that he provided at local stations small houses just large enough to hold a barrel of oil and resembling an ordinary dog house as much as anything. The upper half of this house was hinged and opened off the lower half like the lid to a trunk, to enable the barrel to be removed and renewed. This house was placed 100 ft. from the station. For filling lamps, a special table was placed inside the station building. This table had a top 2½ × 4 ft. with boards at the four edges projecting up 4 ins., and was lined with zinc. Mr. A. E. Killan ((Intercolonial) had recently made oil-houses for a number of small stations by cutting old box car bodies in two, boarding the open ends and placing them on suitable foundations. One car body made two houses. Mr. G. W. Smith (C., M. & St. P.) stated that his company had a series of standard oil and coal-houses for small stations which were made up in the shops and shipped to the stations as needed.

Railway Highway Crossing Gates.

The report stated that the gates in common use were either mechanical or pneumatic. In mechanical gates the arms were operated by wire connections to cranks or levers, and the great difficulty had been the freezing of the wire fast by water in the pipes. One way in which this could be prevented was to use larger size pipes and be more careful to make the connections water tight and to lay the pipe carefully. Another method of preventing freezing was to close the ends of the pipe by glands having holes making a tight fit for the passage of the wire, and to fill the pipe with oil. This device had been employed successfully in signal work. The great advantage of the mechanically operated gate was its positive action. It was considered that, notwithstanding the claims often made by their manufacturers, pneumatic gates had not proved their immunity from freezing. In order to carry the air at all the pipes had to be of fair size and laid with tight joints. The same construction would prevent pipes containing wires from freezing. In conclusion, the report described briefly the Bogne-Mills & Pneumatic Gate Co.'s pneumatic gates, the "single connection" gate of the Standard Railway Gate Co. (Eng. News, May 29, 1897), and the special lift gate employed at some of the Brooklyn, N. Y., street crossings of the Long Island R. R.

In the discussion which followed several members spoke in favor of each of the types of gates mentioned in the report, but little additional information was brought out. The next report was that of the committee on

Care of Iron Bridges After Erection, Including Best Method of Protecting Them from Salt Water Drippings.

The successful maintenance of a bridge depended upon the character and condition of the bridge to be maintained. Given a bridge in perfect condition the proper care of this bridge meant merely to keep it in as good condition as it was the day it was put up. The means adopted to do this must depend upon conditions, but above all other things the inspections should be frequent and thorough. One of the most important matters was to keep the metal well painted, and in painting much of the success depended upon seeing that the metal was carefully cleaned to receive the paint. With refrigerator cars venting their brine at various points the only successful method of protecting bridges from the drippings was to provide a water-proof decking over the metalwork. Should the car vents be placed so as to discharge midway between the rails, as had been suggested, the construction of a simple gutter to catch the brine and carry it away would perhaps be sufficient. It was considered, however, that the proper solution of the problem was to provide the cars with reservoirs large enough to hold the brine until discharged at regular stations.

In discussing this report Mr. J. P. Snow (B. & M.) gave the interesting information that his company was building a portable sand blast plant to be used in cleaning iron bridges for repainting. This plant had not yet been put in operation.

Turntable Construction.

This was one of the most complete and carefully prepared reports presented at the convention, but, on account of its length, it is not included in this report of the proceedings. Such parts of the report as are of principal general value will be abstracted in a future issue of Engineering News. There was no discussion of the report.

Subjects for Convention of 1899.

The following list of nine subjects were selected for special committee reports at the convention to be held in Detroit, Mich., in October, 1899:

(1) Most Economical Method of Painting Railway Bridges and Buildings and Best Materials to Use.
(2) Life of Different Kinds of Timbers in Bridges of Various Kinds and Advisability of Protecting it from the Weather.
(3) Best Method of Constructing and Maintaining Highway and Farm Crossings.
(4) Best Practical Sanitary Arrangements for Local Stations Where There Are No Water and Sewer Systems.
(5) Best and Most Economical Plant for Pumping Water.
(6) The Necessary and Kinds of Tools for the Equipment of a Gang of Bridge Men.
(7) Best Snow Fence, Stationary or Portable.
(8) Protection of Fire in Railway Buildings.
(9) What Repairs Can Be Made to Metal and Wooden Spans Without the Use of Falseworks and How Can They Be Made Safely?

Election of Officers.

The following officers were elected by the Association to serve during the ensuing year: President, J. H. Cummin, Long Island R. R., Long Island City. N. Y.; First Vice-President, Aaron S. Markley, Chicago & Eastern Illinois R. R., Danville, Ill.; Second Vice-President, C. C. Mallard, Southern Pacific Ry., Algiers, La.; Third Vice-President, Walter A. Rogers, Chicago, Milwaukee & St. Paul Ry., Chicago, Ill.; Fourth Vice-President, J. M. Staten, Chesapeake & Ohio Ry., Richmond, Va.; Secretary, S. M Patterson, Boston & Maine R. R., Concord, N. H.; Treasurer, N. W. Thompson, Pittsburg, Ft. Wayne & Chicago Ry., Fort Wayne, Ind.; Executive Committee, W. S. Danes, W. A. Eggleston, R. L. Heflin, F. W. Tanner, A. Zimmerman and J. H. Markley.

Third Day.

The third day of the convention was devoted entirely to sightseeing, and a number of excursions were taken to the historic places about the former Confederate Capital.

Exhibits.

Comparatively few manufacturers of railway supplies made exhibits at the convention. Among the exhibitors present, however, Fairbanks, Morse & Co., of Chicago, showed a gasoline engine air compressor and pumping plant, the compressor being operated in connection with pneumatic drills, chippers. hammers and other tools of the Chicago Pneumatic Tool Co. Another exhibit of special interest was an improved form of gasoline motor railway velocipede, made by the Sheffield Velocipede Car Co. The Norton Jack Co. showed several forms of its well-known ball-bearing jacks for heavy bridge work, and a number of other firms had catalogues and other trade literature and personal representatives present.

BIDS FOR RAISING THE "CRISTOBAL COLON" sunk off Santiago Harbor in the naval battle of July 3 will probably soon be asked by the Navy Department. This policy has been prompted, it is said, by the failure of the Merritt & Chapman Wrecking Co., to accomplish much toward raising the vessel and by the offers received from other wrecking companies to undertake the work without expense to the Government unless altogether successful. The contract with the Merritt & Chapman Wrecking Co., for raising the "Cristobal Colon" was executed on July 29 and involved the payment of $829 per day during operations. The same company has also been receiving $800 per day since July 6 under a general contract for the prosecution of wrecking operations on the Spanish ships, and has succeeded in raising the "Maria Teresa" and starting her on her way to Norfolk, where a commission will decide what additional compensation not exceeding $500,000, shall be paid to the wrecking company on her account. According to press dispatches from Washington, D. C., what the Government proposes to do is to annul the "Cristobal Colon" contract on Nov. 10, and to order all work to be concentrated on the "Reina Mercedes," which lies in still water and is capable of ready raising. Meanwhile, as already stated, the Navy Department will ask bids for raising the "Cristobal Colon" on the basis that the Government shall be involved in no additional expense unless the work is successful. This decision has been influenced to some extent by the arrival in Washington of representatives of a Swedish wrecking corporation, which succeeded in rescuing the British battle-ship "Howe" from a condition similar to that of the "Cristobal Colon." This company, it is stated, is not only confident of its ability to bring the "Cristobal Colon" and the other Spanish vessels to the United States, but is ready to guarantee the delivery of the "Maine" in the big drydock at the New York Navy Yard. The Swedish wreckers propose to take all the risks of failure without expense to the Government, and to rely, if they succeed, for compensation wholly on arbitration. The raising of the "Maine" is also proposed by the Acme Wrecking Co., of San Francisco, Cal. According to the reports, this company simply asks authority from the U. S. Government to raise the vessel, assuming itself all the risk and expense. Should the raising be successful the Government may have the vessel upon paying for the salvage; but in case it is not so disposed of, the wrecking company expects to get its money back by exhibiting the ship at the large seacoast cities.

◆

THE COAST DEFENCES OF THE U. S. are reported upon by Gen. John M. Wilson, Chief of Engineers, U. S. A. The report especially deals with temporary seacoast batteries erected in consequence of the war with Spain. In addition to thirteen of these ordered, much work was done in arming the regular fortifications. Gen. Wilson says that the operations in Cuba and Porto Rico amply demonstrate the value of coast defences, shore batteries and marine mines in resisting naval attacks, and he urges the completion of the fortifications planned, as practically insuring the safety of our principal harbors. He also points out the great value and efficiency of rapid-fire guns in such coast defences. Existing projects for sea-coast defence call for the emplacement of about 500 heavy guns of 8, 10, 12 and 13-in. caliber; of about 700 rapid-fire guns of various calibers, and about 1,000 rifled mortars. The estimated approximate cost of the engineering work connected with the installation of this armament is about $55,000,000. Since the inauguration of the modern coast defence system, appropriations have been made amounting to $19,110,333, and $5,653,000 was allotted from the $50,000,000 "defence fund." Provisions have been made for mounting 288 heavy guns, 254 rapid-fire guns and 312 mortars; or, about 57% of the projected heavy guns, 36% of the rapid-fire and 31% of the mortars. This armament is placed at 71 localities in 29 harbors of the United States. The estimates for the next fiscal year aggregate $4,917,500, for gun and mortar batteries, land, protection and repair, torpedos, submarine mines, etc. Gen. Wilson again notes the material economy resulting from Congress providing funds for the completed contracts in river and harbor work; and he says that if this system is restricted to works fully justified by the interests of commerce, it is the best yet devised. The total amount expended on the improvement of rivers and harbors, in the year ending June 30, 1898, was $17,161,799. The estimate for the year 1899 is $12,883,437 for continuous work, and $15,500,341 for projects not covered by continuing contracts. Gen. Wilson asks Congress to authorize him to present special estimates for such works as are necessary to navigation.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred, Oct. 26, on the Union Pacific R. R., near Omaha, Neb. This was a rear-end collision which resulted in the death of three employees and the serious injury of one other.

◆

SIXTEEN SAILORS WERE DROWNED in Lake Michigan on Oct. 25 as a result of the foundering of the steamer "L. R. Doty" during a severe storm. The "Doty" was a wooden vessel, built in 1893. She was 291 ft. long and 41 ft. beam with a net capacity of 1,700 tons.

◆

A BURSTING FLY-WHEEL at the Pennsylvania Bolt & Nut Works, Lebanon, Pa., on Oct. 25, injured four men, two of them seriously.

◆

THE TRAIN-ORDER ANNUNCIATOR invented by Mr. Harry De Wallace, and described in our issue of Oct. 27, needs a little further explanatiton as to the lettering on the dial and card. In addition to the graduation of mileage, the dial is divided into five-mile sections, each denoted by a letter. The same letters are also marked on the card, opposite the names of stations running in the sections. These letters are a check upon the accuracy of the train order. In sending out an order, the dispatcher uses the letter representinng the five-mile section in which the station referred to is situated. If the letter and station do not correspond, the mistake will be detected, and the dispatcher asked for an explanation. Incidentally, also, the letters on the card and dial are of assistance to the engineman in finding the point at which the trigger is to be set in accordance with the train order. The letters are the same for any division or run. Within the last few weeks the device has been fitted to an engine used in passenger and freight service on the Canadian Pacific Ry., between Winnipeg and Rat Portage. It was set for over 150 stops and signals, and proved to be as reliable on freight runs where switching was done, as on the long through passenger runs.

◆

THE PENNSYLVANIA RAILROAD CO., during the Philadelphia Peace Jubilee, carried 872 975 passengers; and, as the returns are not all in yet, it is expected that the full number will be about 1,000,000. On Oct. 27 the company brought 192,142 visitors to the city. On Sept. 15, 1887, at the celebration of the centennial of the Constitutional Convention, this company brought 195,000 people to the city; but this was before the development of the present trolley system, now bringing people from a distance. Of this crowd, 380,364 people entered the city at the Broad St. Station alone.

◆

THE VENTILATION OF THE HOOSAC TUNNEL is proposed by means of a centrifugal fan mounted at the top of the center shaft and operated by electric power from the North Adams (Mass.) Electric Co. It is stated that contracts for the work have already been let.

◆

COMPRESSED AIR LOCOMOTIVES are contemplated by the New York Central & Hudson River R. R., for hauling trains through the Fourth Ave. tunnel in New York city in order to do away with the present annoyance from smoke. The company has, it is stated, experimented with both electric and compressed air motors during the past year and one of the air motors has given such good results that it is now proposed to equip a regular train on the Putnam Division with compressed air as a motive power. Should the method prove successful in this final test it will, it is said, be utilized in hauling trains through the Fourth Ave. tunnel.

◆

THE PENNSYLVANIA R. R. TRAINSHED in Jersey City, N. J., will be lengthened by detaching the east end arch and moving it toward the river about 125 ft., afterwards filling the opening with the necessary new arches and roof framing. By thus moving the end arch it can be used as a traveler for erecting the new steelwork. The work is a part of the extensive station improvements now in progress at the Jersey City terminal of the Pennsylvania R. R. A complete description of the present train shed was published in Engineering News of Sept. 26, 1891, shortley after its completion.

◆

THE TOWER FOUNDATIONS for the New East River Bridge on the Brooklyn side of the river have reached a depth of 108 ft. below high-water and bed rock has finally been struck at this depth. With the exception of the St. Louis Bridge, where some of the caissons reached a depth of 109 ft. 8½ ins., this is, we think, the greatest depth to which a caisson has ever been sunk by the pneumatic process in America. The caisson which reached this great depth of 108 ft. was the northerly of the two caissons for the Brooklyn tower and was fully illustrated and described in Engineering News, May 27, 1897. The sinking of its sister caisson has been completed for some time. It is stated that considerable difficulty has been had by the contractors in securing sufficient help to keep the work continuous since the caisson has reached over 100 ft. in depth and for some time it was possible to keep the work up only 21 hours out of the 24. Fifteen men only could be worked at once, and the maximum length of each shift was 45 minutes. The same men could work only two shifts per day. The 24 hours work thus took fourteen gangs, aggregating 210 men, besides a foreman for each gang.

◆

A NEW NICARAGUA CANAL CONCESSION has been granted by the Nicaraguan government and was ratified by the Nicaraguan Congress, after a four days' debate, on Oct. 31. The concession grants to Edward Eyre, of the firm of Wm. R. Grace & Co., of New York, and Edward F. Cragin, of Chicago, the right to build an interoceanic ship canal, the concession to take effect when the charter of the present Maritime Canal Co. expires, on Oct. 10, 1899. The concessionaires are to form a stock company for building the canal before April 10, 1900, and 8% of all securities issued go to the Nicaraguan government. Within three years from the date of the concession its holders must open combined water and rail communication between the Atlantic and Pacific oceans. The concession is perpetual, but after 199 years one-half of the profits go to the Nicaraguan government. The concessionaires have the right to police and control the canal district and import free of duty all supplies and materials.

◆

THE CHICAGO DRAINAGE CANAL channel through Joliet, Ill., which has been the subject of litigation since last winter, seems to be still undecided as the result of the recent court decision. The nature of the trouble may be briefly stated as follows: The Trustees of the Sanitary District of Chicago having the construction of the Drainage Canal in charge and the Commissioners of the Illinois & Michigan Canal entered into negotiations on March 11, 1898, for the prosecution of the work of the drainage channel on Section 18 at its terminous in Joliet, Ill. On this section the drainage channel is identical with a portion of the existing stream composed of the canal and the Desplaines River. This stream is dammed at convenient points, the dams being numbered from north to south and producing what are called the upper and lower basins. The drainage channel was through the upper basin. At the east end of dam No. 1, between the upper and lower basins, is located the Economic Light & Power Co., which derives a water power from the upper basin, for which it pays the Illinois & Michigan Canal Commissioners several thousand dollars a year. The drainage channel plans contemplated lowering this dam 3.6 ft., but on account of the additional volume of water which this channel would furnish there would be no reduction in the water power. This, the Trustees of the Sanitary District maintain, complies fully with the law, which requires that in constructing the channel they shall not injure any water power.

The Canal Commissioners, on the other hand, claim that the law requires the height of the dam to be left unchanged, and thus give the light and power company all the benefit of the increased head of water, which will amount to about 4.800 HP. The suit has been practically to decide this question, and the decision of the court sustains the Canal Commissioners as follows:

> In crossing the canal under the power conferring authority to do so, the plans of the sanitary district contemplate passing the water through the upper basin. We therefore have a situation which must have been anticipated by the legislature, and the last sentence of section 23 becomes of controlling importance when we remember that the plans in evidence contemplate the lowering of the crest of the dam 3.6 ft. A water power right is the right to avail of the potential energy of the water falling from the highest practicable altitude as well as to the lowest practicable depth. Any diminution of either altitude or depth must result in injury to the right. A valuable water right exists at this dam, and has been available of ever since the dam was built to utilize the water flowing at that point falling from an altitude of minus 42.4 ft. below Chicago datum. Is there any physical objection to maintaining the dam at minus 42.4 ft.? In other words, is it physically impossible to make the authorized crossing of the canal and at the same time maintain the dam at minus 42.4? Without going into an examination of the evidence it is sufficient to say that I find that such impossibility does not exist, but on the contrary it is practicable to do so.

It seems almost certain that the Trustees of the Sanitary District will appeal to the higher courts for the reversal of this decision.

THE ELECTRIC ELEVATOR EQUIPMENT FOR THE CENTRAL LONDON UNDERGROUND RY.

(With two-page plate.)

In our issue of July 1, 1897, we outlined the plans for this new underground railway in London, to which more than usual interest attaches by reason of the fact that all the operating machinery will be of American manufacture. At that time we mentioned that the contract for the elevators had been awarded to the Sprague Electric Co., of New York city. It is now our privilege, through the courtesy of that company, to present a description of this remarkable electric elevator equipment, much the largest ever contracted for, which is now being installed.

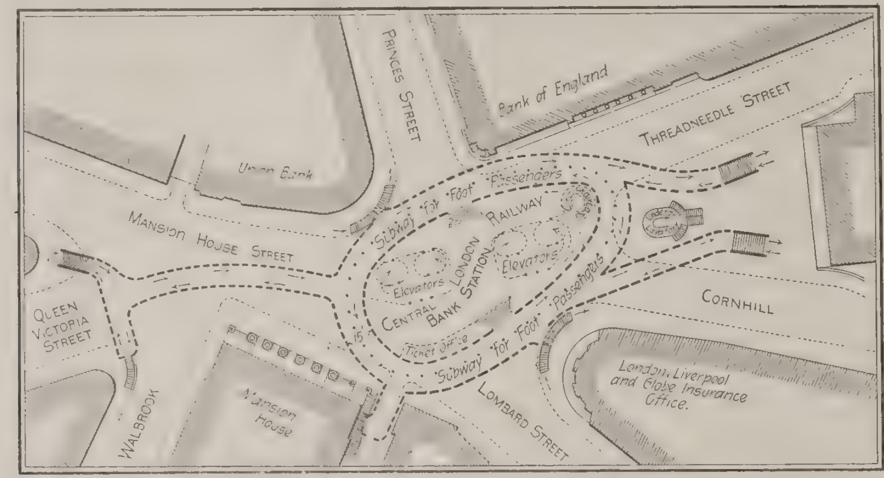

FIG. 1. PLAN OF THE UNDERGROUND STATION AT THE BANK OF ENGLAND, SHOWING STAIRWAYS AND ELEVATOR SHAFTS.

The London Central Ry. was authorized by Parliament in 1892; but owing to financial difficulties work was not begun until 1896. Since that time the excavation and construction work has been pushed until at present the tunnel work is practically completed. For the time being the section from the Bank station to the Liverpool Street station of the Great Eastern Ry., a distance of nearly ½-mile, will not be built, although the act authorizing the construction of the London Central Ry. included the right to construct this section.

The western ends of the tunnels are at Shepherd's Bush Avenue, where the entrance incline strikes the main tunnels, and from this point run almost due east under the busiest portion of London, a distance of 6½ miles. Like the other electric underground railways in London, the road consists of two parallel cast-iron lined tunnels, each carrying a single track. These tunnels are 11½ ft. diameter inside and at a depth of 30 ft. to 102 ft. below the street surface. Along the route are distributed 14 stations, and at each of these the tunnels are enlarged to 21 ft. for a distance sufficient to give platform room, usually about 320 ft. long by 11 ft. wide. At each station there are two or more entrance shafts, with stairways and 3 to 5 elevators depending upon the anticipated traffic at the station.

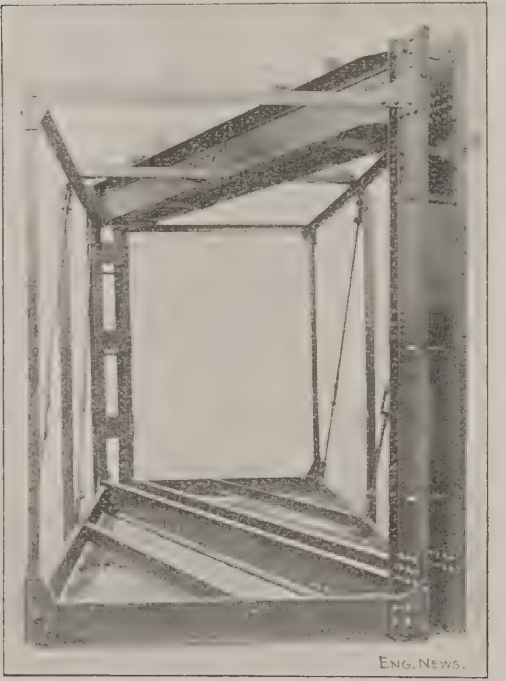

Fig. 2. View Showing the Framing of the Rectangular Type or Center Car for Three-Car Shafts.

Owing to the necessity of running under the streets, the railway not being permitted to tunnel under the city building line, the tunnels wind in and out, twisting about to a considerable extent. Some idea of the extent of this underground station construction is afforded by Fig. 1, which is the station at the Bank of England, the eastern terminus of the road. This station is naturally the largest and most important of all, located as it is in the very heart of the city. It will occupy pretty much all of the ground under the open space in front of the Mansion House, formed by the intersection of Poultry, Cornhill, Princes, Lombard and Threadneedle streets. In its construction a subway 15 ft. wide will be built around the space tangent to the building line, as is shown in the figure. This subway will be thrown open to the public as a thoroughfare, thus permitting persons to cross from street to street without the danger of being run down by cabs and carriages. The interior of this subway will be lined with white glazed tiles, and lighted by electricity. In the center of the oval thus formed will be constructed the Bank station, which will be nothing more than a large, open room, with a steel and concrete roof carried by steel columns and supporting the street pavement above forming the street of Mansion House square. Conveniently spaced about this room will be 5 elevators, which will take passengers to and from the train tunnels about 65 ft. below. Entrance to or exit from the subway will be afforded by a number of stairways, starting from the sidewalk in front of the Royal Exchange, the Liverpool & Globe Co., the Mansion House, Union Bank, etc., and leading down into the subway.

Coming now to a consideration of the elevator work, in Table I. will be found the number and diameter of shafts at each station, and the number of elevator cars, with the height of lift, together with other particulars.

The specifications received in this country by the Sprague Co., at the time bids were asked for the elevator equipment, were very meager. The main requirements, however, were as follows:

> The work included in the specifications is the find of all materials, tools and labor for the complete manufacture and installation, and, except as regards fair wear and tear, the maintenance for a period of 12 months after the opening of the railway of all the plant and appliances necessary for working the passenger lift service of the Central London Ry.
>
> The contract is to include the supply and fixing of all plant and machinery (except steam boilers) necessary for generating the hydraulic power required (if used) to actuate the lifts, for transmitting such power to each lift, and for return water mains along the whole line of railway, together with all machinery for actuating the lifts, as well as all cages, guides, safety appliances, fittings, etc., for a complete installation. If electric power is used to actuate the lifts, such power is to be taken from the company's mains, which pass through every station.
>
> There are four sizes of elevator shafts: 6 shafts of 30 ft. diameter, 12 shafts of 23 ft. diameter, 5 shafts of 20 ft. diameter, 1 shaft of 18 ft. diameter. The 30-ft. shafts are to contain 3 lifts each, 23-ft. shafts 2 lifts, the 20-ft. and 18-ft. are each to contain 1 lift only; the 18-ft. shaft lift is to resemble the 20-ft. shaft lift, but the headway, above the upper delivery floor, is the same as that of the 30-ft. and 23-ft. lift shafts.
>
> All work shall be of the highest class, to the entire satisfaction of the engineers of the Central London Ry. and the Electric Traction Co.
>
> The whole of the work shall be completed within 16 months of the acceptance of the tender.
>
> The time allowed for raising any lift from the low level to the high level platform is not to exceed 30 seconds in any case. As a general rule half the lifts at every station will work alternately with the other half at that station, but at many stations there will be times when the lifts may to some extent work at the same time. The train service is to be a 2 or 2½ minute one each way.
>
> The generating plant shall be of ample capacity for the working of the whole service, with only half of the said plant in operation and the remaining half in reserve.
>
> The steam engines, hydraulic pumps, main and return pipes, the machinery for actuating the lifts, the fittings of the lift cages, and all other necessary appliances, shall be such as will insure the highest attainable economy and facility in working and maintenance, and be least liable to breakdowns, so as to secure the safe and uninterrupted working of the lift service at all times with comfort to passengers.
>
> The contract will include the connection of the above steam engines with the boilers of the company at their depot, in the case of hydraulic lifts; and it will include the connection of all machinery to the company's electric mains in the case of electric lifts. The buildings, engine foundations, and other masonry works form no part of this contract.

In addition, a blue-print sheet giving a proposed lay-out plan for each of the four sizes of shaft was furnished. With this meager information Mr. Sprague determined to make an effort to secure the contract, and, assisted by Mr. J. R. Furman, consulting engineer, who erected the Glasgow tunnel hydraulic elevators, and was also one of the constructing engineers for the Eiffel Tower, and Mr. Charles C. Stutz, of the Sprague Co., prepared provisional plans. Accompanied by these assistants, he took these plans to Europe in May, 1897, and shortly after arrival made tender for the entire elevator equipment. Since it was necessary first to show the superiority of electric over the hydraulic elevators for the requirements of the road, against many strong prejudices, and then demonstrate that the particular plans submitted were the best, the issue was in doubt for some time, but the decision was hastened by a number of radical propositions made by Mr. Sprague. Among these propositions were:

To buy the current from the road at one penny (2 cts.) per Board of Trade unit (K-W. hour), and, conditioned on there being not less than an average total of 20,000 single trips per day of 67 ft. mean rise, to operate the elevators under contract for three years at a cost not exceeding £1 (4.86) per 1,000 single trips, or

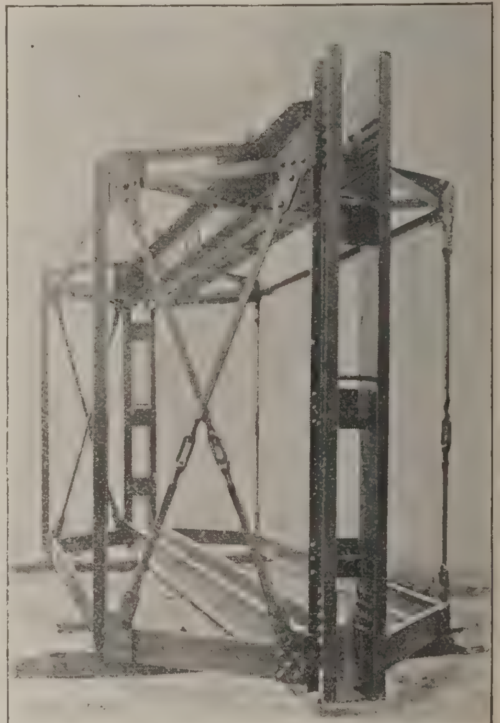

Fig. 3. View Showing the Framing of the Lozenge-Shaped Side Cars for the Three-Car Shafts.

To install a complete electrical equipment in one shaft, as against a direct or differential hydraulic with electric pumps in an adjacent one, both having the same maximum capacity, and both operating under the same loads and trips, with current from the same source, and to operate at less than one-half the cost of the hydraulic, and finally,

To make a contract conditioned upon the earliest possible installation of a complete shaft equipment, to be operated to the entire satisfaction of the representatives of both the Railway and the Traction Companies, the main equipment meanwhile to be proceeded with.

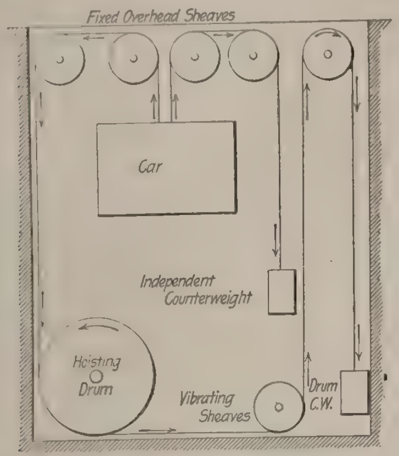

Fig. 6. Diagram Section of Shaft, Showing Arrangement of Car Cables and Counterweights.

The last condition was effective, for on June 16, only four weeks after the opening of the bids, the general details of the contract were agreed to, conditioned upon the satisfactory performance of two test elevators.

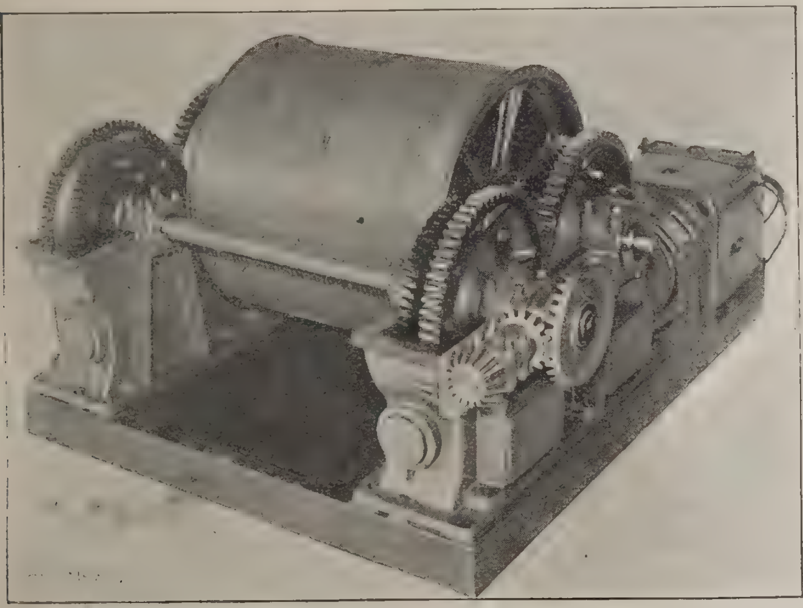

FIG. 13. HOISTING MACHINE WITH UPPER PART OF GEAR CASING REMOVED TO SHOW WORM WHEELS AND LOCKING GEARS.

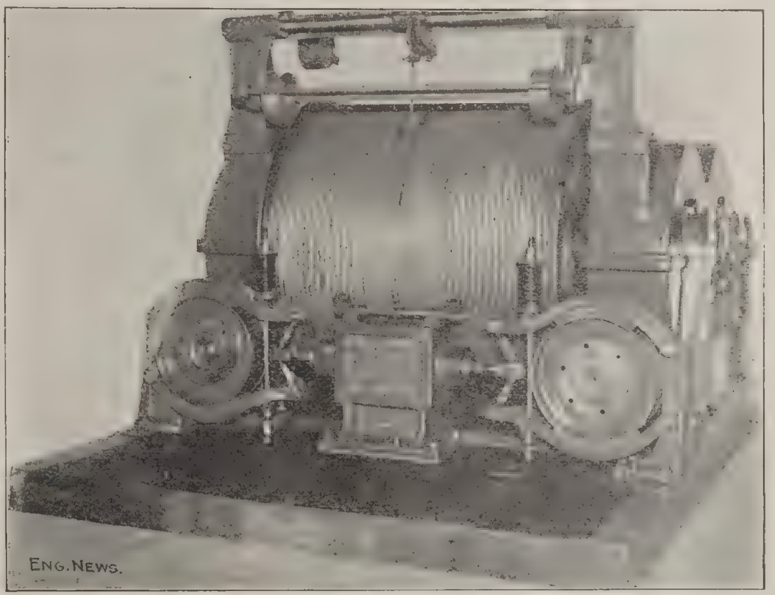

FIG. 14. HOISTING MACHINE, TYPE "S," COMPLETE, EXCEPT FOR MOTORS, SHOWING ELECTRIC BRAKE AND SLACK CABLE DEVICE.

Immediately upon getting the verbal award of the contract, supplemented simply by a letter of understanding, Mr. Sprague returned to New York, leaving Mr. Stutz abroad to collect data from which to prepare the full plans. Later a complete equipment for an 18-ft. shaft was sent from Watsessing, N. J., where the Sprague Company's works are located, to London, and installed under the direction of Mr. G. Rosenbusch, also of the Sprague Co. In the meantime, so confident was the company of the outcome of the test that plans were completed and work begun on the remaining 47 equipments. Before describing the extremely rigid tests given the specimen elevator it will be of interest to consider the plans and some of the constructional details.

Owing to the character of the soil it was necessary to make the entrance shafts circular, which made it a difficult matter to arrange elevators and stairways in them with economy of space. These shafts are all lined with segmental cast-iron plates bolted together through ribs cast around their edges, and backed with grout forced in by compressed air. They are of four sizes, as follows. (See also Table I.):

1 shaft 18 ft. diameter with 1 car having ......172 sq. ft.
5 shafts 20 " " " 1 " " ......250 "
12 " 23 " " " 2 cars each having..140 "
6 " 30 " " " 3 " two having...145 "
and 1 car having........117 "

The number of cars specified, the circular shaft and the large loads contemplated (17,000 lbs.) required cars of very unusual shapes, some of which are shown by Figs. 2, 3 and 4. Fig. 2 is a photograph of the framing for the center car for the 30-ft. or three-car shafts. The single car used in the 20-ft. shafts is of the same shape but of larger size. The extremely heavy construction noticed is necessary owing to the size of the cars and the test requirements which specified that the safety clutch on one side could be sprung without warping the car framing.

Fig. 3 is the framing for a car used at the sides of a three-car or 30-ft. shaft, and in this the heavy central frame is also noticeable. The cantilever supporting the corners and the diagonal braces in the end contribute to the massive appearance.

The cars for use in the two-car shafts have a very peculiar unequal sided form, shown to advantage in Fig. 4. These also require that the ends be supported by a cantilever. The method employed to attach the cables to the car frame, shown in Fig. 5, is simple and at the same time very satisfactory, since it permits a nicety of adjustment which equally distributes the load upon the lifting cables. At the same time the car can run closer to the sheaves at the top of the shaft, than with the ordinary form of attachment. The steel T guides for cars and counterweights are bolted firmly to the cast-iron shaft lining. The guides for the car weigh, when milled to 1-in. thick, on the guide part, 37 lbs. per yard. Special spring guide shoes are used on the cars owing to the extreme length of car framing in comparison with the height. These shoes are yielding and do not bind even when the car is unevenly loaded.

The specifications for 45 of the car frames made up of:

12 side cars for 30-ft. shafts, 6 center cars for 30-ft. shafts, 22 cars for 23-ft. shafts, and 5 cars for 20-ft. shafts, required that:

The material to be employed should be what is known as Medium Grade Steel; to have an ultimate strength of 60,000 to 68,000 lbs. per sq. in.; elastic limit ½ the ultimate strength; minimum elongation 20% in 8 ins. The use of this grade of material is to be guaranteed by the builder.

All holes are to be drilled or punched and reamed; all edges are to be planed; no welded parts will be accepted; they must be forged. Joints must come together well and not show gaps.

Rivets to permanently assemble each car are to be supplied, and 15% in excess of actual need.

After inspection all parts are to receive one coat of graphite paint.

Calculated weights, as taken from the drawings, to be on the basis: that a steel plate, 1-in. thick and 1-ft. area weighs 40.8 lbs. 2½% will be allowed on the calculated weight of plates and angles in the riveted portion of the structure.

The whole of the order is to be delivered three months from the date of award.

The car finish is plain but substantial, the sides being of oak and ceiling ornamental. Doors are provided both for regular and emergency exits.

The cable layout, or method of roping up as it is sometimes called, is diagrammatically shown in Fig. 6, in which it will be noticed that the lifting cables pass up from the car over the overhead sheaves and down to the under side of the winding drum. Wound on this drum, but in an opposite direction, are the drum counterweight cables which run under the vibrating sheaves or "vibrators," to be described later, and up overhead and down to the drum counterweight. In some cases where space is not limited this is a simple weight hanging at the end of the cables and in others it is a multiplying counterweight, Fig. 7. With this type the cables pass down under the counterweight sheaves and back up to the overhead framing; thus reducing the travel by one-half. These multiplying weights consist of a framing supporting a grooved sheave and two pendant side rods, between which are slipped cast-iron weights, each weighing 280 lbs., until the desired total weight, varying from 16,000 to 19,000 lbs., is obtained.

The rope details are interesting. They are of the best quality of mild steel, subject to approval by, and the satisfaction of, the engineers and officials of the Central London Ry., the Electric Traction Co., and the Sprague Co.

The ultimate breaking strain of ⅞-in. diameter rope is to be not less than 22 tons, and of ¾-in. diameter rope 16 tons. Such tests as the engineers require to be made at the maker's cost.

No. of strands forming each rope...................... 6
No. of wires forming each strand......................19
laid in two concentric circles, 12 outer wires, 6 inner wires, 1 center wire.
Main core round which strands are laid..hemp, well oiled.
Tensile test of each wire per sq. in.........85 to 90 tons.
Torsional test in length of 8 ins. wire..32 twists minimum.
The angles of lay for the wires and strands to be proportioned so that the rope shall be dead and free from any tendency to kink, spiral or spin.
All wires (excepting the center or core wire) to be of best cast steel, carefully hardened and tempered, and the wires and strands truly laid on their centers.

The approximate amount of rope is 110,000 ft. of ⅞-in. diameter, and 17,000 ft. of ¾-in. diameter, and the ropes are guaranteed for 12 months after the opening of the road.

The arrangement of sheaves overhead, the location of guides for cars and counterweights and the framing for the 30-ft. shafts is well shown by Fig. 8. The bottom layout or location of controllers and hoisting machinery and the relative size and position of cars is shown in Fig. 9.

We now come to the hoisting machinery upon which the success of the entire equipment is founded, and upon the working of which the continuation of the contract depended. There is not so much that is new in this very efficient machine, for it is rather an adaption of old methods with a refinement in construction of parts and details, resulting in a very perfect whole, which meets the difficult requirements of heavy electric elevator service to a marked degree.

In the first place, as will be seen from Figs. 10, 11, 12, which form the plan elevation and end view of the type "S" Duplex Tandem Worm Gear

Electric Elevator, as the machine is termed, the apparatus in its entirety is extremely simple. It is also completely self-contained, it only being necessary to attach the cables and controller wires to operate it.

Mounted upon a heavy cast-iron base are two side box-frames, seen best in Fig. 13, which, besides forming the bearings for the drum and idler shafts, form oil tanks in which the worm and worm wheels and lock gears, seen in Figs. 10, 11 and 13, are enclosed. In line with these casings, bolted to the bed plate and directly connected to the worm shafts, Figs, 10, 11, are the motors. These motors are of the 4-pole enclosed railway type. They are shunt wound, ironclad, and take current in series with each other from the feeders and the third rail. By putting the motors in series, the duty on each side of the machine is equalized for all speeds, the combination with the compensating gear arrangement later described forming an electro-mechanical couple. When running at 470 revolutions per minute they give an elevator speed of 200 ft. per minute. Fig. 15 shows the current required by the test elevator (18 ft. shaft) for running up under different loads, the current for running the car and cables alone, and the current returned to the line when the loaded car runs down. In other words, when a descending car is loaded, the motors generate and return current to the line. This factor is counted upon to materially reduce the total current consumed by the entire system.

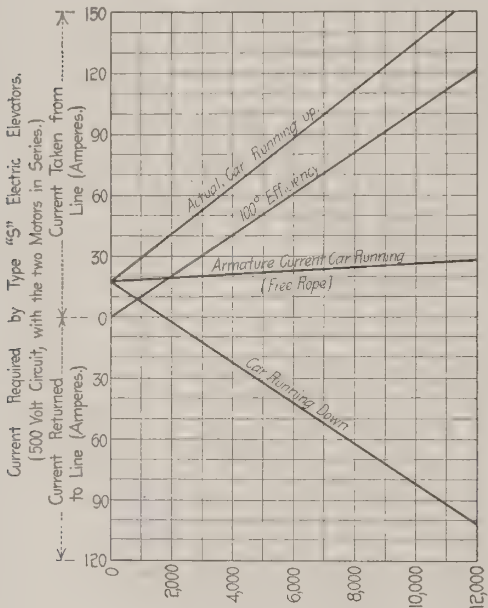

Fig. 15. Diagram Showing Curve of Relation Between Load on Car and Total Current Required for Car, in the 18-ft. Shaft.

The rest of the machine, shown in Fig. 14, consist of covers for the gears, a slack rope device, consisting of a couple of small loose pulleys mounted upon a pendulum device which holds these pulleys against the hoisting cables close to where they wind upon or off of the drum. In case the cables become slack, for any reason, the pendulum frame swings out under the influence of the weights, seen in Fig. 14, and springs a switch, thus cutting off the motor current, and also throws on the solenoid brake. This brake is clearly shown in Figs. 12 and 14, in which it will be noticed that friction pulleys are secured to the worm-shafts and are surrounded in part by two rubbing blocks held in close contact with the friction wheels by powerful coil springs. When current is passing through the solenoid contained in the metal box, seen in Fig. 14 midway between the friction wheels, the two plunger armatures are drawn in, the toggles straightened out and the brakes lifted. Any interruption of the current at once releases the armatures and allows the springs to throw on the brakes. This arrangement avoids the possibility of accident due to the breaking of a wire or the interruption of the current supply.

Referring again to the worms and gears, it will be seen in Figs. 10 and 11 that each motor drives a shaft upon which is securely doweled a right-hand and a left-hand worm which mesh with two worm wheels, one mounted upon the drum shaft and the other upon the idler shaft. There are also bolted to the worm wheels two straight gears, which are larger than the worm wheels, and mesh together, as is quite clearly shown in Fig. 13. The motors are arranged to run in opposite directions, both running in for raising, or out for lowering. In this way there is no side thrust on the drum bearings, and the usual end thrust, present with the ordinary arrangement of worm and worm wheel, is taken care of by the two worms mounted upon each driving shaft; the thrust of each worm just balancing that of the other. In this way the thrusts and side strains are so nicely balanced that the item of friction, usually a heavy one in this type of gearing, is greatly reduced. Another item contributing largely to the satisfactory operation is the use of the rotary cut worm. To assist in a full understanding of this Fig. 16 is given in which this worm and wheel is contrasted with a worm and wheel representing what may be termed ordinary practice. The greatly increased bearing surface is so well shown that no further explanation is necessary. In cutting these worms, blanks of the proper outside dimensions are mounted upon a vertical shaft, and a multiple cutter composed of a number of steel tools clamped radially to a circular disk, so that from the front the cutter resembles a gear wheel, is revolved at just the speed it would turn if driven by the worm about to be cut. The cutter is then gradually and automatically advanced until the worm has attained the proper depth and shape. To cut the worm wheel the operation is reversed and a steel worm, which has been carefully cut in the way described, is milled across the thread parallel with its axis until a cutter resembling a very large tap is formed. The worm wheel blank is then tamped on the disk, where in the former instance were the steel tools, and slowly advanced, both cutter and wheel blank revolving at the proper ratio. The pairs thus formed fit so snugly that they cannot be dropped together like the ordinary worm and wheel, but must be dropped in at an angle and turned into place. The function of the wheel straight gears is to lock the worm wheels at all times in their proper relative position. Considerable care is necessary when erecting these machines to fit the two pairs of gears and four worm gears and have the opposing thrust just balance.

One other feature of which mention must be made is the automatic idlers, vibrating sheaves, or "vibrators," as they are called, shown best in Figs. 10, 11 and 12. These are two large sheaves, each loosely mounted upon sleeve nuts which travel upon the right and left-hand screw. This screw is positively driven from a bevel gear on the extra gear shaft outside of the gear casing, Figs. 10 and 13. The pitch of the screw thread is such as to cause the vibrating sheaves to feed the rope upon or take it off of the drum at just the proper angle. The vibrator is complete in itself, and may be placed at any reasonable distance from the machine, it only being necessary to make the shaft between the winding machine and the vibrator the proper length.

In this type of machine the maximum net pull which can safely be excited upon the lifting ropes is 12,000 lbs., although the pull will not generally exceed 9,500 lbs. The rest of the load will be balanced by the counterweights which have already been described.

The safeties employed are the usual Sprague jaw clamp with certain slight modifications demanded by the unusual size and weight of cars and loads. These clamps, shown in Fig. 17, are at the bottom and at each side of the heavy car framing. They consist of a pair of heavy levers arranged to clamp the guide rails between their short arms like a pair of pliers, when their long arms are forced apart by wedges. Ordinarily, the wedges are held back, but any unusual car speed trips a catch and allows the five-coil springs, seen in the figure, to force the wedges between the rollers on the long end of the clamps which squeeze upon the girders with a force proportional to the ratio of the lever arms, the angle of the wedges and the power of the springs. In calculating the dimensions of the safeties for the elevators in question the loaded car was assumed to weigh 40,000 lbs. This amount had then to be supported by friction between the clamp jaws and the guide rails. The coefficient of friction was assumed as 15%, and the total pressure on the guide rails had, therefore, to be about 260,000 lbs., or 130,000 lbs. on each side, which made 65,000 lbs. on each clamp shoe. The ratio of long to short arm being 3,555 to 1, and the wedge 18 to 1, the total multiplication was 63.33; and $\frac{65{,}000}{64}$ gives approximately, 1,000 lbs. as the necessary spring pull. It will be noticed that there are five springs, each of which requires 250 lbs. to compress it, ¼-in. or 1,000 lbs. for a 1-in. compression. In service the five springs will be compressed 5 ins., and the jaws then adjusted to clamp the guide rails firmly. A further compression of 5 ins. will then be made, making 10 ins. in all or 2 ins. per spring. It will be seen that when the safeties are sprung, each spring will expand 1 in. in setting up the jaws against the guides and still have 1 in. per spring or 1,000 lbs. to clamp with.

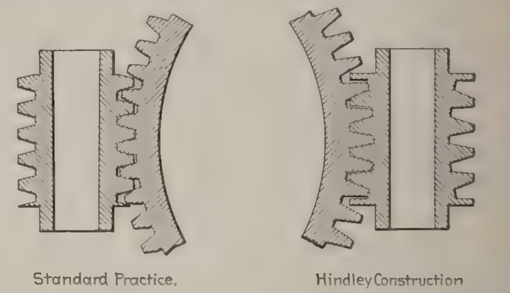

Fig. 16. Section of the "Hindley" Worm and Wheel used in the Type "S" Electric Elevator, and the Usual Form of Worm and Wheel.

To avoid any possibility of a mistake in design, a factory test was made of one of these safety clamps by springing it under working conditions (1¼-in, compression, 1,200 lbs. spring pull) upon a short section of standard guide rail. The whole was then put in a hydraulic jack and the guide rail forced one way and the clamp the other. 12 tons, or 24,000 lbs., were required to move the clamp. This would make 48,000 lbs. for both. Working backward, this gives a friction coefficient of 0.156, a close check upon the value used (0.15). The test was repeated both with the rails dry and when they were slushed with grease, and no difference was found in the results.

The clamp jaws are faced with steel with diagonal grooves cut one way across their faces. In determining the area of these faces 2,000 lbs. per sq. in. of metal in contact was assumed as the safe allowable compression.

As a further test, all parts were carefully measured, and the safety sprung 24 times as it would be in service. The measurements were then repeated while under the heaviest pressure, and no difference found.

As an additional guard against accident to passengers the oil buffers, seen in Fig. 17, are placed on all cars and counterweights. These are large and heavy dash pots, the plungers for which have tapering grooves cut in their outside surface. The grooves being large at the lower end permit the oil to flow rapidly past, thus allowing a rapid car settlement when the buffer first strikes. However, as the plunger settles the grooves narrow, less oil can pass, and the settlement gradually becomes slower, much the same as with an air cushion.

The controller by which the car is stopped or started is a small circular box about 6 ins. in diameter and 3 ins. deep with a square shank hub projecting from the center of the front of the cover upon which the operator slips a small handle when he desires to run the car. Inside are 6 contact points, two contact arcs, a lever and a spiral spring, which always returns the lever to the off position, when the operator lets go of the handle. This switch is represented diagrammatically in Fig. 18. The various points, 1, 2 and 3, connect by means of a flexible trailing cable with the controller, located at the bottom of the elevator shaft, which is nothing more nor less than a heavy resistance cut in or out of the motor armature circuits by a small "pilot" motor in turn operated by the car switch. If the operator turns the handle to the left, as shown in dotted lines in the figure, until it comes into contact with the arc, the main circuit is closed and the elevator motors started up and allowed to run slowly. No change occurs when the arm touches point 1. By continuing around until 2 is touched, the small pilot motor begins to turn the arm which cuts out the armature resistance, with a resulting increase of elevator speed. The amount cut out can be regulated by the length of time the switch arm in the car is held on 2. If allowed to remain any length of time all the extra armature resistance will be cut out; and the armatures be thrown directly across the line. Should the operator desire to reduce the speed he touches point 1, which reverses the pilot motor, cuts in resistance and hence reduces the car speed. This gives entire control of the car, permitting a faster or a slower speed without breaking the main circuit. Point 3 increases the speed still further by cutting out part of the field winding.

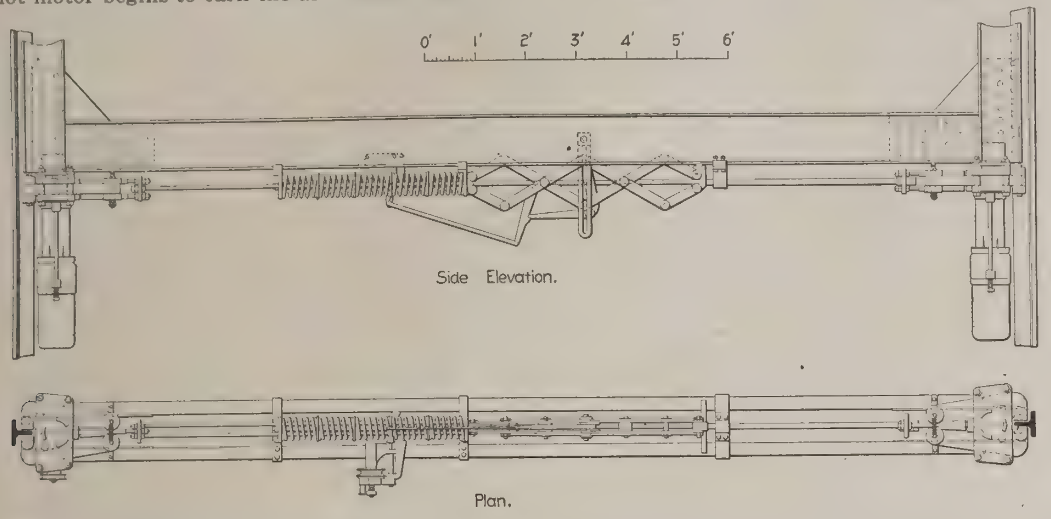

FIG. 17. CONSTRUCTION OF THE SAFETY CLUTCH USED ON ALL ELEVATOR CARS OF THE CENTRAL LONDON RY.

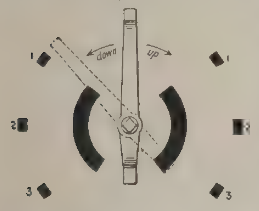

Fig. 18. Sketch of the Switch in the Elevator with which the Operator Controls the Car.

The current required to operate the controller is very small, varying from ⅓ to ½ ampere. As a safeguard, the controller is arranged to automatically return to the off position in case the current on the main circuit fails or the car runs into the automatic stops at the upper or lower limit of travel. In addition the limit stops open the main circuit, thus affording almost absolute protection against accidents due to ignorance or improper operation by the elevator tender, while the safeties and oil buffers guard against cable breaks, etc.

As a further precaution, a large factor of safety was used throughout all calculations. For steel, a safe working load of from 12,000 to 12,500 lbs. per sq. in. was allowed, while for cast iron the limit was placed between 1,700 lbs. and 2,000 lbs.

As already stated, one of the elevators was set up in England and subjected to a series of tests, some of which were exceptionally rigorous and unusual.

The most important were as follows:

1. A running test of 16 hours with an average unbalanced load of 3,000 lbs.; that is, 7,000 lbs. in the car and 4,000 lbs. on the counterweight. The average current consumption was 10 K-W. hours per car mile, or 15,840,000 ft. lbs. of work done with 26,542,800 ft. lbs. of electrical energy.

2. A load test with as high as 12,000 lbs. unbalanced load, counterweight was overloaded 5,000 lbs. and 17,000 lbs. of cast iron was placed in the car. During this test the total current averaged 150 amperes.

3. A running test of the safety devices, during which the car was loaded with 14,000 lbs., giving an unbalanced load of 10,000 lbs. It was run down the shaft at full speed, and the safeties were tripped which stopped the car so suddenly that the car or free counterweight jumped up, thus making a total load on the safeties of 25,000 lbs., 14,000 lbs. load and 11,000 lbs. the car weight. The test of the cable slack device consisted in stopping the car by the safeties and noticing how much cable ran off the drum before the automatic stop same into action. In this test 3 ft. was the maximum unwound from the time the safeties were sprung until the hoisting apparatus stopped. At another time the safety on one side was sprung with the car evenly loaded, and again with the load eccentrically placed, first on half of the car near one guide rail, and then on one side of the line drawn between the guide rails.

4. It was assumed that the pilot motor would fail to operate and the car was allowed to strike the limit stops at top and bottom.

5. The main circuit was broken with the car ascending and descending with no load and full load without the operator knowing anything about it. Going up with full load the stop was instantaneous, with light load there was a slight slide. Coming down, the motors generate on open circuit, and, therefore, have no effect on stopping the elevator unless the speed exceeds a certain predetermined limit, when the centrifugal governor operates, trips a switch and stops the machine.

6. Trip tests, running on schedule time, were made, and a series of 8 and 16 hour brake tests with the motors running at full rated load were also made.

One of the requirements was that an efficiency of 70% should be attained. In the contract test an efficiency varying from 70 to 75% was shown from the current at the brushes to the work on the ropes.

The tests were satisfactory in every respect, and the Sprague Company has since been shipping the other equipments to England. It is expected that the installation, which will be under the direction of engineers from the company, will be completed by the spring or summer of 1899.

In making estimates of costs of operation it was assumed that current would cost 1d., or 2 cents, per K-W. hour, and that it was estimated that 10 K-W. hours would be required per elevator mile. The average rise was assumed as 67 feet.

This gave $\frac{5,280}{67} = 79$, say 80 single trips to the mile, or 40 round trips to the elevator mile, 10 K-W. hours per elevator mile equals $\frac{40}{10} = 4$ round trips per K-W. hour; costing 1 penny (2 cents), or 1 round trip will cost ½ cent.

Again, asuming an average of ½-mile between stations, a two-minute headway and an average speed of 14 miles per hour, requiring 25 minutes for the trip one way, there will be 8,200 train stops. Each of these will require a down trip of each elevator to bring down entering passengers, and an up trip to remove passengers leaving; 8,200 × 2 = 16,400 may be assumed as the total number of one way elevator trips per day of 12 hours. There are 48 elevators and 13 stations, and 16,400 ÷ 13 = 1,260 single trips per station per day. Taking three elevators as a fair number running at each station, there will be 420 single, or 210 round trips, per elevator. For 12 hours (720 minutes) we have a trifle over three minutes per round trip as the maximum time limit. In other words, it would be necessary for each elevator to make a round trip every three minutes to meet the requirements established by the train schedule.

It is interesting to note that with the exception of the ropes, not only are the motors, the entire hoisting apparatus, the car frames, sheaves, etc., but even the heavy overhead work are furnished from America, the Carnegie Co., both in the matter of price and time, largely underbidding the English manufacturers for the beams.

For the photographs, drawings and data from which this article has been prepared we are indebted to Mr. Frank J. Sprague, former President of the American Institute of Electrical Engineers and Technical Director of the Sprague Electric Co.; Mr. Charles Pratt, Superintendent of the company's factory; Mr. G. Rosenbusch, A. I. E. E., who conducted the various tests described, and is to have charge of the entire electric installation, and Mr. Charles C. Stulz, V. D. I., in charge of the entire design and construction of the machinery called for by the contract.

◆

CAR TRUCK CONSTRUCTION AND REPAIRS.*

In my opinion the improved diamond frame or arch bar truck has come to stay for use in cars of 50,000 to 80,000 pounds capacity, and if I am correctly informed, these trucks of the above capacity are regularly used on 80% of the railways in the United States. There is, however, room for further improvement, and some of the more salient features I present for your consideration are as follows:

1. For convenience employ both bottom and top arch bars of uniform dimensions.

2. The size of arch bar should be such as to provide a proper factor of safety to carry the capacity of car.

3. In forming the angle for arch bars, have the bends made on a radius of not more than 1½ ins. instead of a radius ranging from 2 ins. to 5 ins., as done in common practice. The bending point to form the angle should start directly from the foundation of journal boxes and columns, instead of from 1 in. to 2½ ins. away. Unless this practice is followed, the arch bars when over-burdened will straighten to a line from one foundation to the other, causing a sag in the frames which increases the shearing strain on bolts and fastenings. Material that will not

stand bending to a radius of 1½ ins. without injury is unfit for use in arch bars.

4. Ream all bolts and rivet holes in arch bars and tie straps to fit bolts and rivets.

5. The wearing surfaces to support bolts through the top and bottom end of truck columns and journal box thimbles to have vertical bearings not less than the thickness of arch bars, with holes reamed to size, and abandon the common practice of applying the castings with holes roughly cored, which allows the columns to shift and the truck frames to get out of line.

6. Apply journal box bolts of sufficient dimensions to resist buffing and shearing forces, and abandon the expensive cost of forging, incident to turning up the ends of arch bars.

7. Attach brakes to truck frames where they will not be disturbed by forces radiating from the action of the bolster and springs, and eliminate the vertical or downward pull on the body bolster caused by the application of the brakes when attached to the car body.

8. Employ solid construction sufficient to hold side frames and journal boxes from being forced out of line when rounding curves and the usual switching derailments.

Bolsters.—The practice of employing a short bolster, or one not supported directly on the side frames at each end, but instead suspended from the channel transoms on swing hanger links or rigid hangers, is not the best construction for present service. Such a bolster has no support to resist longitudinal buffing shocks, execpt that of the transoms, which in turn are only supported by being riveted at their ends to the columns but not sufficient to resist service buffing forces. The short bolster and transom design of truck admits only of suspending the load from the transoms, which with age and wear deflect downward and give an inward tilting tendency to the arch bars or side frames, resulting in transferring a greater load to the back ends of the journal bearings. Investigation of this and similar construction on these lines will result in finding this to be the cause of a large percentage of hot boxes.

I would employ a bolster designed to rest directly on and in a certer line of the side truck frames, and supported between columns at each end, and in no case allow the bolster to bear against or be supported on the transoms or cross tie bars. The spring supporting the outer ends of the bolsters should also rest on a center line of the side frames, and the design should be such as would not produce an unequal ditribution of the load on the journal bearings or springs on account of the deflection of the bolster or transoms. This change in construction permits a reduction in weight and dimensions of transoms of about 30%.

Center Plates.—There has been a tendency for railways to adhere to their old standard form and size of center plates, which never had bearing surface sufficient to support even cars of 40,000 lbs. capacity. In proof of this fact you will often find cars on your repair tracks with base or flanges of the center plate cracked or settled into the wood various depths. Truck manufacturers have been compelled to employ these old center plates that were standard to the road, which have not only proved defective but have added another weakening factor to other parts on account of the base being not only too small to carry a load of the marked capacity but because it prevented solid construction. Those that are increasing the capacity of their truck should consider increasing the strength and bearing surface of their center plates proportionately.

Side Bearings.—As regards side bearings, if you are to employ a weak bolster in the truck or car body that readily deflects under loads of the marked capacity, then employ yielding or anti-friction side bearings, preferably the latter, but if your bolsters are of proper capacity to carry the load without material deflection, then the solid side bearings, which are now a serious element in producing friction, can be more safely employed.

Springs are rarely, if ever, broken through vertical action under loads, provided the bolster or load is designed to rest at all times squarely on the springs or group of springs, as lateral or torsional forces and thrusts are most destructive to both helical and eliptical forms of springs.

Brake Gear.—Power brakes, which become a necessity, furnish another destructive element to many designs of trucks unless the attachments are properly applied. To aid in reducing the load and strains on brake beams and attachments, it is necessary to connect them to truck frames instead of car body or truck bolster direct to eliminate forces resulting from the action of the bolster and springs, which, under certain conditions, have power sufficient to cause numerous defects. If properly attached to the truck frames we find that it eliminates about 72 pieces per car, reduces first cost and cost of maintenance about 45% per car as compared with the ordinary practice of attaching brakes to car body. The modern practice of attaching brakes to truck frames that admits of their being fixed to be operated concentric with the wheel, and embodying construction that prevents the side of shoe grinding away the wheel flange, and eliminating at least 60% of the causes of solid flat wheels, and, as above stated, about 72 parts per car, has proved highly satisfactory to those employing such construction. I recently counted in one train (36 cars) 84 brake shoes, with top ends of the shoes dragging against the wheels, which were worn off due to friction from 2 to 4 sq. ins.; this, together with the 72 brake beam guide pins nearly cut in two from friction, would present a proposition for us to figure the cost of extra fuel consumed annually to grind these parts away, not taking into consideration the expense incurred in loss of time, delays and accidents to trains; our train despatcher's sheets frequently note trains being delayed or making slow time with that same old excuse which is so familiar to us all, "delayed on account of heavy pulling train."

Box Lids and Dust-Guards.—A good dust-proof journal box lid and dust-guard form cheap and desirable additions to construction that prevent hot boxes and swell the economies in lubricating rolling stock. A good dust-proof lid, in my mind, is more essential than the dust-guard, as all dust lodging in the front end of box is forced under the journal by the packing spoon in hands of the oiler. As a matter of fact, worn-out dust-guards form a small factor towards hot-box troubles, but when we consider that railways have thousands of journal boxes running with imperfect dust-guards that never get hot, we are inclined to decide that the journal bearings, with loads unequally distributed thereon through faulty truck construction, are the paramount cause of 60% of the hot-box nuisance.

Metal Trucks.—Metal trucks are gradually superseding the various wood and grey iron forms of trucks. The prices of the metals that we could employ in trucks are as follows: Commercial rolled steel shapes, 1⅛ cts.; grey iron or common cast iron, 1½ cts.; malleable iron, 2¾ cts.; pressed steel from 3 cts. to 4 cts.; cast steel, 4 cts. to 6 cts. Commercial steel shapes are not only the strongest, lightest and most convenient to procure, but show for themselves a saving in first cost over other metals quoted; and from careful observation and personal investigation made from time to time during the past three years, I am convinced that these steel shapes combined with good malleable iron produce a truck, when designed on modern lines, with greater efficiency and units of strength than many other metals. In proof of this I have reports of a large number of trucks, made of the above material, that have been operated in almost continuous service for the past few months under loads of 70,000 lbs. at an expense of less than 1½ cts. per car per month. This statement does not include the cost of lubricating.*

Lateral Motion Trucks.—Lateral motion freight car trucks of the old swing hanger type, are being gradually discarded, owing to the large number of parts failing in service under heavy capacity cars. Many have replaced these trucks with the various other forms now on the market, while others, who still believe in certain economies the lateral motion trucks provide that rigid trucks do not, are now employing a more modern lateral motion truck constructed on lines which eliminate the former objectionable features, effecting a reduction of parts ranging from 150 to 300 pieces per car.

The question of introducing lateral motion in trucks, or employing one that is flexible enough to admit of its being easily adjusted to service, is seriously being considered, if not already adopted by many roads, for the reason they provide for greater economies than the common rigid form of truck. An officer on one of the large railway systems in the Northwest, whose standing as an engineer is high, is on record as saying: "We notice a great difference in favor of our improved lateral motiton truck in way of reducing flange friction against rail and the cushioning of the forces and blows on truck frames, wheels, axles, and reducing the wear on M. C. B. coupler, knuckles, etc., and especially so in our cars of 60,000 lbs. capacity and over, as compared with our rigid or swing hanger style of truck."

THE U. S. SIGNAL CORPS is officially reported upon by Gen. A. W. Greely, Chief Signal Officer U. S. A. As to the work of this corps in Cuba, the report details the arrangement and installation of electrical and other appliances for quick communications between the army and Washington. Gen. Greely intimates that the work of the corps was handicapped because it was not allowed to take to Cuba the telegraph train fitted out at Tampa. The use of the war balloon is strongly commended, and its utility was demonstrated in the campaign, but Gen. Greely disclaims any responsibility for forcing this balloon on to the skirmish line, where it caused serious loss of life by disclosing the position of the troops. The report claims for the corps the credit of locating Cervera's fleet in Santiago harbor. This was done by Col. James Allen, and later verified by Lieut. Col. Joseph E. Maxfield, both of the Signal Corps. Col. Allen telegraphed to the chief signal officer on May 19, the day Cervera entered the harbor, that "five Spanish vessels arrived at Santiago de Cuba; have notified Admirial Sampson, etc." This information was sent to the President and prompt orders were at once given for the blockade of Santiago harbor. Col. Allen continued almost daily to send valuable information from Santiago. The report deals largely with these and similar services of the Signal Corps, and Gen. Greely says that the corps failed to receive, from Gen. Shafter, even a notice that it was to participate in the Santiago campaign.

SPECIAL FIREPROOF CONSTRUCTION IN THE U. S. APPRAISERS' WAREHOUSE, NEW YORK CITY.

By Gunwald Aus, M. Am. Soc. C. E.*

This building occupies the entire block bounded by Greenwich, Christopher, Washington and Barrow Sts., in New York, and covers an area of about 53,000 sq. ft. It has ten stories and a basement, and the ridge of the central skylight is about 192 ft. above the street. The three lower floors with a temporary roof were completed in 1894 under a limited appropriation made by Congress in 1888. In 1895 Congress extended the limit of cost of the building and appropriated a sum sufficient to proceed with the construction. The walls of this building are of brick, with granite trimmings, and are self-supporting, and columns built into the walls support floors and roof.

After consultation with Mr. Theodore Cooper, C. E., it was decided to construct the steelwork of the building for an assumed "live load" of 325 lbs. per sq. ft.; that is to say, the floor beams were proportioned for the calculated dead load and a live load of 325 lbs. per sq. ft. The girders were designed for the dead load and two-thirds of the supported area covered by a load of 325 lbs. per sq. ft., it being assumed that in a building of this kind at least one-third of the floor area is kept open for passageways. The beams and girders in the roof are proportioned for the calculated dead load and a live load of 40 lbs. per sq. ft. The columns are proportioned for the dead load and two-thirds of the full live load on two floors, and a gradually decreasing percentage on all other floors. The foundations are of concrete and stone resting on a compact bed of coarse wet sand. They are proportioned so as to impart a pressure of four tons per sq. ft. to the sand under the load for which the basement columns are proportioned.

---

*Engineer of Steel and Iron Construction, Office of Supervising Architect, Washington, D. C.

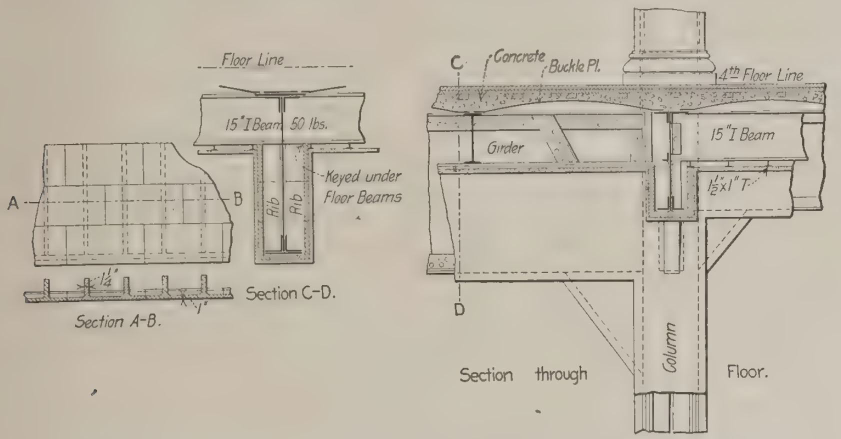

FIG. 1.—DETAILS OF FLOOR CONSTRUCTION AND COLUMN AND GIRDER FIREPROOFING, U. S. APPRAISERS' WAREHOUSE, NEW YORK.

The three lower floors are built of 24-in. I-beams supporting terra cotta arches of generally 11 ft. 6 ins. and 15 ft. 4 ins. span. A general section showing the floor construction, and a description of a test made on these arches, appeared in Engineering News of Nov. 7, 1895. While this construction is economical in cost, it is enormously heavy, the calculated dead load being from 120 to 130 lbs. per sq. ft.

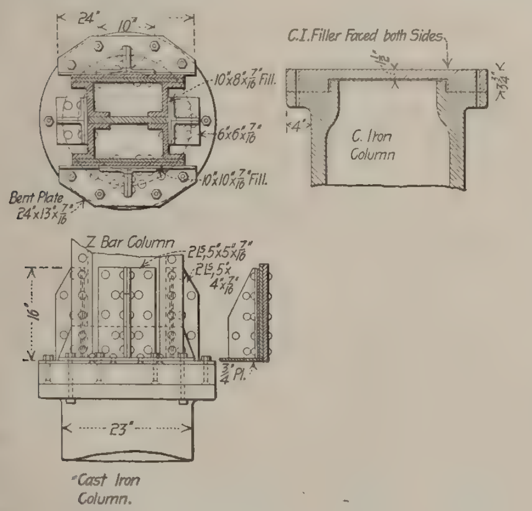

Fig. 2.—Detail of Connection of Z-bar and Cast-Iron Columns.

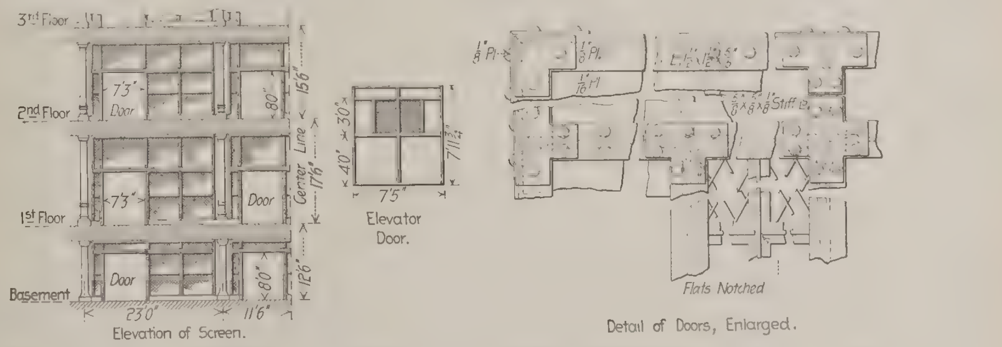
The upper seven floors are built of buckle plates riveted to the top flanges of I-beams spaced 4 ft. 7 ins. c. to c. (Fig. 1). The plates are ¼-in. thick and are covered with a coating of asphalt at least ¼-in. thick on buckles and ⅝-in. to ¾-in. thick in all valleys, so as to protect effectually both plates and beams against water leaking through the flooring. On this asphalt is a deadening of cinder concrete. From below, the beams and floor plates are protected by a ceiling of plaster on expanded metal fastened to light T-irons. The plaster selected is a comparatively new material, "Asbestic Plaster," which is manufactured from the waste material in the asbestos mines, and which appears to have splendid fire-resisting qualities.

If, however, the combined action of intense heat and cold water should destroy this ceiling, I am strongly of the opinion that no part of the solid steel floor would collapse, as its continuity would prevent any one beam from buckling, so that this floor is as nearly fireproof as it is practical to build one. The cost of such a steel floor is, of course, considerably higher than that of a concrete or terra cotta floor, but then this floor weighs only 65 lbs. per sq. ft. against 100 to 130 lbs. per sq. ft. for the other constructions, and it is certainly much more rigid.

The columns in the basement and first and second stories are of cast-iron and have terra cotta fireproofing. Above the third floor all columns are of Z-bars, Fig. 2, and have concrete fireproofing. The columns were first wrapped with expanded metal and then a 2½-in. thick layer of concrete was formed around it by enclosing the column in a wood form and tamping the concrete in place. The roof is built of cinder concrete on expanded metal. The metal was stretched on top of the roofbeams and the cinder concrete rolled in place on a wooden platform built in between the beams. On the concrete is placed a covering of asphalt 1 in. thick, put on in two layers, ½-in. thick.

A novel feature in this building which deserves to be mentioned is the fireproof, or rather fire-retarding screen, Fig. 3, which encloses the light well. This light well is 64 × 46 ft., and in it are located the ten freight elevators. In case of fire it would act like a chimney and rapidly communicate fire from floor to floor. To prevent this a screen was built. It is constructed of wire glass in iron sashes, protected on the side facing the warehouse with heavy wire netting. The elevator openings, whose doors close automatically as soon as the car leaves a floor, form the only openings in this screen. As the elevator doors are of sheet iron and are always closed, a fire will be confined to the floor where it started long enough to give the firemen a chance to put in some effective work. All openings in the outer walls are protected by corrugated steel shutters.



Elevation of Screen.

Detail of Doors, Enlarged.

FIG. 4.—HALF ELEVATION OF FIREPROOF SCREEN SHOWING DETAILS OF ELEVATOR DOORS.

The contract for the steel frame, including buckle plate floors above the third floor, was awarded to Post & McCord, of New York city. It amounted to 6,800 tons, of which 1,700 tons were buckle plates. The erection was commenced on Nov. 15, 1896, and completed on April 18, 1897. An idea of the amount of work done can best be formed from the statement that the shop rivets used weighed about 334,000 lbs., the field rivets about 210,000 lbs., and it required 6,690 gallons of red lead to paint the steel after erection. This paint was nearly all applied by a compressed air machine, which worked very satisfactorily. I am indebted to Messrs. Post & McCord for these data. Including steel and iron in the three lower floors, and other steel not included in the above contract, the grand total of steel and iron in the building amounts to over 11,000 tons.

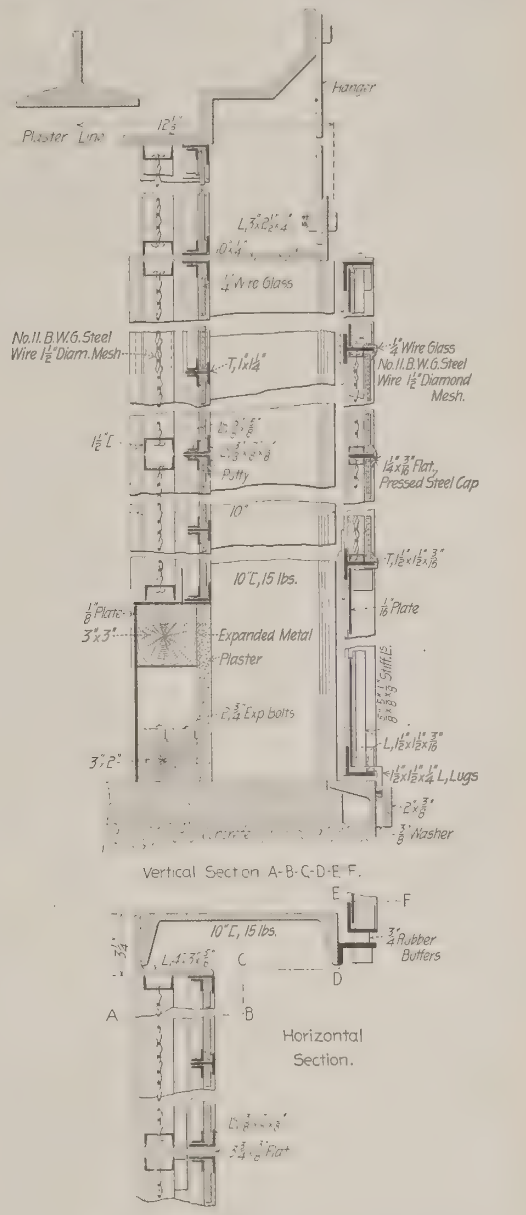


Fig. 3.—Section Showing Details of Fireproof Screen to Prevent Access of Fire to Light Shaft.

All steel above the third floor is "Open Hearth," of 60,000 lbs. to 68,000 lbs. ultimate strength. Holes in material over ⅝-in. thick were punched ⅛-in. small, and reamed to size. At the shop all steel was given a coat of linseed oil, except the buckle plates, which were given a coat of Edward Smith & Co.'s asphalt paint, as it was thought that the hot asphalt, to be put on after erection, would burn the oil. The Supervising Architect, James Knox Taylor, has kindly permitted me to publish these details.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; 6 *months,* $2.50; 2 *months,* $1.00. *To all other countries in the Postal Union: Regular Edition, One Year,* $7.60 (31 *shillings*); *Thin Paper Edition, One Year,* $6.31 (26 *shillings*). *SINGLE COPIES of any number in current year,* 15 *cents.*

In ordering changes of mailing addresses, state BOTH old and new addresses; notice of change should reach us by Tuesday to be effective for the issue of the current week. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number 328 *means that subscription is paid to the* 32d *week (that is the issue of Aug.* 11) *of the year* 1898; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line. Want noticees, special rates, see page* 18. *Rates for standing advertisements sent on request. Changes in standing advertisements must be received by Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

Our attention has been called to the fact that the heavy grain train hauled on the New York Central by a single locomotive recently and noted on p. 257 of our last issue, was not nearly as heavy as the coal train hauled from Altoona to Columbia, on the Pennsylvania R. R. on Aug. 9 last, and noted in our issue of Aug. 18. As both of these trains were of phenomenal size, however, we have tabulated the principal particulars concerning each below:

	Pennsylvania.	N. Y. Central.
Number of cars	130	81
Weight behind tender, tons	5,212	3,478
Freight carried, tons	3,692	2,000*
Distance hauled, miles	161	140
Time consumed	17 h. 13 mins.	12 h. 55 mins.
Average, miles per hour	9.4	10.8
Locomotive	Consolidation.	Mogul.
Weight on drivers, lbs.	186,000	123,000
Driver, diameter, ins.	56	57
Cylinders, ins.	23½ × 28	20 × 28

*Obtained by estimating the average weight of grain at 50 lbs. per bushel.

It may be noted that the Pennsylvania train made the run from Altoona to Harrisburg at an average speed of ten miles per hour. The maximum grade on this section was 12 ft. per mile.

◆

Another engineering association will soon be added to the already long list of such associations, and will have the descriptive but somewhat cumbrous title of the American Railway Engineering and Maintenance of Way Association. It will be open to all officers having charge of railway construction work, engineering work or maintenance of way. Mr. A. Torrey, Chief Engineer of the Michigan Central R. R., is chairman of the provisional association, which will complete its organization and adopt its constitution at a meeting next March. It is reported that a large number of officers have already signified their intention of becoming members. This association is the outcome of a somewhat unfortunate action taken by the Roadmasters' Association of America at its meeting held at Denver in September last. An amendment to the constitution was submitted, changing the name to that of "The Railway Maintenance of Way Association," on the ground that the title of roadmaster is not distinctive, and that the association has grown beyond the scope of the roadmaster's work alone. Under present conditions, the work of track maintenance is being put more and more under the direction of engineers, and is becoming a department requiring more skill and technical knowledge than is possessed by the ordinary typical "roadmaster," who is merely a foreman of high grade. Many roadmasters (or supervisors, as they are termed on some roads) are engineers, and the title of roadmaster as applied to the higher officers of this department is, therefore, falling into disuse, and the title of engineer of maintenance of way is becomong more general. For example, Mr. R. Caffrey, General Roadmaster of the Lehigh Valley R. R., who was recently president of the Roadmasters' Association, has had his title changed to that of Engineer of Maintenance of Way. It is true that all officers in charge of maintenance are eligible to membership in the Roadmasters' Association, and many engineers are members. In fact, we find 21 engineers (5 chief, 5 assistant, 4 engineers of maintenance of way, 3 resident and 3 division engineers) by a rough canvass of the list of members. It was felt by the progressive element in the association that the name should more fitly represent its present aim and membership. The conservative element, however, strongly opposed the change, being apparently fearful that the old-time "practical" roadmasters would eventually be crowded out by the "engineer." This, however, is a stage of evolution which will take place, and is already taking place, and no such action as holding on to a name can stop it. We are not sure, however, as to the wisdom of organizing an independent, and, in some respects, opposition, association, as this action will hardly conduce to harmony or good feeling between the various grades of men employed in the maintenance of way department. If all the engineers (by title or otherwise) who are now members of the Roadmasters' Association should resign and join the Maintenance of Way Association, the former would lose the most valuable element of its membership. It seems to us that a better plan would have been for the maintenance-of-way engineers to join the old association and thus gradually elevate its standing, and at the same time make the progressive element strong enough to carry out such changes in title and management as might from time to time be desirable. In a recent issue we deprecated the increase in the number of technical associations, and we are obliged to doubt the wisdom of creating this newest addition to the list.

◆

We give considerable space in this issue to description and illustration of the largest and most notable elevator plant ever constructed, that for the Central London Ry. Additional interest centers about this plant in view of the fact that the contract for the entire equipment was taken by an American company, the Sprague Electric Co., much to the chagrin of English machinery manufacturers, and that the selection of this elevator was made by English engineers after a long series of tests in which they exhausted their ingenuity in devising methods of determining the safety and efficiency of the apparatus. The selection of American elevators for so extensive and important a plant, however, was certainly to be expected, for the experience of engineers and manufacturers in the United States in the design of high speed and large capacity passenger elevators is far in advance of that of any other country.

◆

THE RESPONSIBILITY FOR THE INADEQUATE APPROPRIATION FOR THE NEW YORK CANALS.

The State Engineer and the Superintendent of Public Works of New York have recently made public their replies to the criticisms upon the work of their respective departments made in the report of the Canal Investigating Commission. These replies we have abstracted quite fully in this number, for the matters at issue are almost all of them questions of much interest to the engineering profession, and it is, moreover, the policy of this journal to give space for a fair presentation of both sides of any question in controversy.

The position of Messrs. Aldridge and Adams is substantially a denial, both general and specific, of the charges contained in the Canal Commission's report. They declare that the work has been honestly carried on by their departments, with as great efficiency as could possibly be expected; and that the Commission's charges in the main really amount to no more than an opinion on the part of the Commission and its engineers that the work could have been better done by other methods than those adopted. The difference between accusing a public officer of bad judgment, and of wilful corruption, is, of course, manifest.

Finally, Messrs. Aldridge and Adams make detailed replies to the instances in which specific irregularities were charged in the Commission's report. These matters, however, will doubtless be made the subject of further official inquiry; and it is certainly fair to suspend judgment upon them until the results of such inquiry are made known. The canal investigating commission was not a judicial body; its object was to investigate the work done rather than the personal responsibility for errors or irregularities. Its investigation, moreover, was conducted without the safeguards against error and injustice which exist in a court of law; and it is manifestly unfair to base conclusions as to the guilt or innocence of any man or body of men upon the investigation of such a tribunal.

Aside from these questions of personal responsibility, however, the controversy over the canal work has brought to light many questions of general interest to engineers. At the outset is the matter of discrepancy between the preliminary estimates and actual cost of engineering works. Messrs. Adams and Aldridge correctly say that what the voters of New York State are chiefly kicking about is that they were assured that $9,000,000 would accomplish a certain piece of work, and after they have paid over the money and it has been spent, they learn that two or three times as much will be required. It seems to be entirely clear that the responsibility for deceiving the people rests with that irresponsible body known as the Executive Canal Committee, made up of delegates from the principal commercial organizations of New York. They lobbied a bill through the legislature calling on the voters of the state to approve a state bond issue of $9,000,000 regardless of previous rough estimates in excess of this amount which the State Engineer had furnished; and they carried on a vigorous campaign to secure a favorable vote on this bill, in which they assured the people that this amount would be sufficient to complete the work.

It was hardly to be expected that Messrs. Adams or Aldridge would take the responsibility of opposing this appropriation, especially as there was then no absolute proof that the $9,000,000 appropriation might not be adequate. After the money was available the view they took was that it was their duty to perform the work ordered by the legislature, so far as the funds would permit, and they appear to have made considerable effort to bring the work within the limits of the appropriation. The first survey made in the spring of 1896 showed that the work would cost about $15,000,000; but the State Engineer ordered that the scope of the work should be restricted and everything that could possibly be delayed should be omitted, hoping in this way to keep the cost of the work down to the $9,000,000 mark.

It is a difficult question as to just when it became Mr. Adams' and Mr. Aldridge's duty to undeceive the people. That it was their duty to do this at some time is beyond question, and is proved by the fact that when the "cat was at last let out of the bag" it was on these two officials that popular condemnation chiefly descended. We believe, after careful consideration, that it was their duty as public servants to stop the expenditure of the state's money as soon as it became clearly evident that the work ordered by the legislature could not be accomplished by the funds which it had provided. If they did not go so far as to order work stopped on contracts already let, it was at least their duty to refrain from letting further contracts as soon as it became clear that the work would overrun the appropriation. Now, the first batch of contracts, amounting to $3,325,000, was let in

the fall of 1896. Bids on the second batch of contracts were received Aug. 24, 1897, and at that time, we believe, it was known to Messrs. Campbell and Adams that the work was certain to overrun the appropriation. In fact, this was publicly stated in September. Yet not only was the second batch of contracts let in the face of this knowledge, but months afterward additional contracts were let when the whole state was in an uproar over the news that the canal appropriation was inadequate. We understand that Superintendent Aldridge claims that the law was mandatory and he had no option in the matter. We know, however, of no punishment which could or would have been visited on him or the other members of the canal board had they, as soon as the real situation was apparent, stopped the letting of further contracts and saved the four or five millions still in the state treasury from going "into the ditch." We are of the opinion that had they done this they would have been supported in their action both by public opinion and by the courts.

In our abstract of Mr. Aldridge's reply to the Commission we have included a curious table which he gives in support of the statement that the preliminary estimate for the canal improvement work was no further out of the way than original estimates for other great public works have been. We have done so because we wish to combat emphatically the too common statement that engineers' estimates of the cost of works are wholly unreliable. The $9,000,000 appropriation, as we have seen, was not an estimate or even a guess of the cost of the work it was provided to accomplish. It was a guess at what the people could be induced to give—nothing more nor less. The "engineer's estimate" for the Hoosac tunnel was not an estimate in the present day sense of the word. It was made when engineering was in its infancy, and when absolutely no precedents for a work of such magnitude existed. It was a guess, pure and simple. We know of no "$12,000,000 estimate" for the Chicago Drainage Canal. If such an estimate was made, it was, we venture to say, a mere guess. As a matter of fact, the cost of actually constructing the Chicago Drainage Canal has come very close to the first official estimates of cost which were made by its Chief Engineer, Mr. Isham Randolph, at the outset of the work.

We might in a similar way review the other instances which Mr. Aldridge presents in his table; but it is not needful. What we wish to point out is that the "guess" of a promoter or a committee, or any other man or body of men, is not an "engineer's estimate." There is just one way to make a reliable engineer's estimate, and that is to make actual detail surveys, compute the quantities of materials of each kind involved, and on this basis ascertain the probable cost of the work. If the people who furnish the funds for public works prefer to take guesses in preference to engineer's estimates, they must not complain if they suffer disappointment. The Panama Canal dupes, for example, were satisfied with De Lesseps' guess as to the cost of the canal, and could not wait for engineer's estimates. They paid some $250,000,000 for their folly. The New York Capitol and the Hoosac tunnel, instanced by Mr. Aldridge, are two other pieces of work which would never have been undertaken had their enormous cost been foretold in advance.

On the other hand, such recent and notable works as the Boston subway and the Philadelphia subway are examples of large and costly pieces of engineering work, involving many features of novelty, which are carried out within the engineer's original estimate. Such instances as these show conclusively the value of careful estimates as a basis for any engineering work. The work may, indeed, proceed without them, but always at the risk of such disappointment and loss as befel the Panama investors, and has now come home to the taxpayers of New York.

LETTERS TO THE EDITOR.

Capacity Tests of Mississippi River Dredges.

Sir: In the article on "Dredges and Dredging on the Mississippi River," in your issue of Oct. 13, Table No. 2 (p. 239), seems to contain marked peculiarities in the columns indicated as "minimum" and "maximum," whereby a large number of figures in the former are in excess of those in the corresponding "maximum." Are these typographical errors, or is the table not understood by the writer?

Yours very truly,
L. Y. Schermerhorn, Pres. American Dredging Co.
Philadelphia, Pa., Oct. 22, 1898.

(The seeming discrepancy is easily explained. Each column represents one test, and the two tests for each dredge are those showing the minimum and maximum capacity, or sand pumped per hour. In the test showing the minimum capacity, however, it does not follow that all the conditions of working will be at a minimum: As an example, in comparing the two tests of the "Alpha," it will be seen that during the test showing the minimum capacity, the efficiency of the plant and the steam pressure of the boiler were higher than in the test showing the maximum capacity. Also in the tests of the "Zeta," the column for the minimum capacity shows that during this test the amount of material pumped was greater than during the maximum test, but as the amount of sand was only 8.1% instead of 14.8%, the actual capacity in sand pumped per hour was at its minimum.—Ed.)

The Advantages of Forced Blast Heating Systems for Drying Kilns.

Sir: One of our special inspectors has written to us, after a very thorough examination of premises in the South used for drying and ordering tobacco, recommending the introduction of drying kilns of the blower type as a substitute for the present method of drying by direct steam pipes. He states that manufacturers report that when once installed the process of drying by an air blast is preferable to and quicker than the steam pipe method, and he dwells particularly on the fact that in the elimination of the steam pipes from the rooms a great source of fire hazard is removed, as his inspection indicates that in no class of risks where dry rooms are used is there more universal carelessness than is found in the tobacco business. In addition to the improvement in methods, which is suggested, anything which tends materially to reduce the hazard from fire will unquestionably influence the rate which will be charged for insurance, and we write you suggesting that you call the attention of manufacturers of machinery and apparatus answering this description to the field for sales which seems to be clearly pointed out by our inspector.

You, of course, understand that we can only refer to the subject in a very general way, as the advantages of a change in system, or the reduction in the insurance rate which the change might warrant, would be determined by the conditions found in each separate property.

Yours truly,
E. L. Ballard, Asst. Secy. Continental Ins. Co.
46 Cedar St., New York city, Oct. 27, 1898.

(We believe that the general advantages of the blower system for drying kilns over the old method of drying by steam pipes directly in the kiln are now conceded by all who have given careful study to the matter. The reduction in fire hazard by this system, however, is a point which is, perhaps, not so generally understood, and the above letter is useful in calling attention to it. We may say in addition that the excess in first cost of the blower system over the old direct steam-pipe system is not so great as is sometimes claimed. With the blower system, the steam pipes are so much more efficient that a considerably smaller number of square feet of heating surface is required for a given work than is required with the direct steam system.—Ed.)

Public Improvements at New Orleans.

Sir: The City of New Orleans has just let contracts for the paving of 85,000 sq. yds. of streets, as follows: To the Compagnie Generales des Asphaltes de France (rock asphalt), at $2.49 per sq. yd.; The Ayres Land Asphalt Co., at $2.60 per sq. yd.; Belden & Seeley, or the Columbia Construction Co., of Syracuse, N. Y., the last work advertised for, at $2.10 per sq. yd. on 6-in. concrete foundation and $1.70 per sq. yd. on 4-in. concrete foundation.

We have been heretofore paying more for asphalt than any city in the county, for the reason that the Barber Asphalt Co., being the only concern in the field, enjoyed a monopoly.

The council of the City of New Orleans about a year ago passed an ordinance which prohibited the mention of any particular asphalt when bids were being advertised for. The result was that other bidders were able to enter the field and bid on every quality of asphalt. We have paid as high as $3.75 per sq. yd. for asphalt paving in the past, and up to a year ago $3.25. The low bids obtained for asphalt recently will give an impetus to street paving in this city, which is much needed, as most of our streets are paved with the square block granite or cobble stone. We would be glad to have it mentioned through the columns of your valuable paper that New Orleans contemplates letting an immense amount of street paving contracts, and would be glad to welcome all bidders.

Another work about to begin is the laying of all wires underground. The various wire companies have all their plans and specifications complete, and will begin to break ground within 30 days.

Another great work now under way is the construction of our drainage system, which will drain not only our city and lower the ground water level some 5 or 6 ft., but also drain every inch of swamp around New Orleans. The completion of this work, which will entail a cost of about seven or eight million dollars, will require some five years, and will remove the unsightly surface drainage which now prevails in our city.

A subject which is now being seriously considered by our people is the providing for the construction of a modern system of sewerage. This city granted, some years ago, a franchise to a corporation to construct a system of sewerage on plans drawn by Rudolph Hering. The company ran out of funds after building several miles of piping. The city brought suit to annul the contract or privileges. The corporation is now seeking to compromise the litigation, claiming it has plenty of funds at its back, and is willing to continue and complete construction of this sewer system. Some are in favor of a compromise and others are against; but all agree that sewerage we must have, if we desire to place this city in the rank of cities to which she belongs. The matter is now before the Sewerage Committee appointed to investigate the best measures proposed. We would therefore be glad to entertain bids, propositions or suggestions on that score.

A work of great importance about to begin is the construction by the National Government of a floating steel dry-dock for docking merchant ships and war vessels. The bids are to be opened by the Navy Department in Washington next month. Congress at its last session appropriated some $800,000 for this work.

The board of U. S. engineers appointed for that purpose have just completed their report of the survey of South West Pass at the mouth of the Mississippi. The object is to construct another jetty through South West Pass, such as was constructed through South Pass by Jas. B. Eads. This will give shipping a depth of channel at the bar of 35 ft., as compared with 26 ft. which now prevails.

Respectfully,
Sidney Story.
Equitable Building, New Orleans, Oct. 18, 1898.

Corrosion of Iron and Steel.

Sir: Your current discussion of the evidently unsettled question of the relative rate of corrosion of iron and steel reminds me that, years ago, I endeavored to secure reliable and sufficient data on the subject, to serve as a guide in practice. I found very little available material. There should be to-day much more, now that the use of steel has come to be general in all departments of engineering. The results of my researches in technical literature and reports are published in Sec. 192, Vol. II., of my "Materials of Engineering," page 328, et seq. In brief, they were.

(1) Corrosion can ordinarily only occur in the presence simultaneously, of oxygen, moisture and carbon-dioxide (Calvert).

(2) The gases of the locomotive accelerate corrosion by their peculiar acid quality, arising from their contents of sulphur-oxides; iron and steel absorbing acids somewhat greedily (Kent).

(3) Cast iron, in dilute solutions of acids, is rapidly acted upon, especially in warm water—in the flow of water of condensation from engine-condensers, for example—losing the metal, and often leaving the carbon and other matters; the piece retaining its form and general appearance unchanged, but with enormously reduced density. The metal is said by the uninformed to have been "changed to plumbago" (Calvert).

(4) Corrosion is rapidly effected with cast metal irregularly and quickly cooled in the mold, less rapidly where slowly and regularly cooled (Mallett).

(5) The rate of corrosion is ordinarily constant over long periods of time; but the removal of the rust retards oxidation as it destroys the voltaic couple composed of metal and of oxide.

(6) Hard iron, rich in combined carbon, rusts slowly. The presence of graphite or of a different quality of iron in metallic contact with it, increases the rate of oxidation —presumably by forming local voltaic couples. Hard steel rusts less rapidly than soft.

(7) Foul sea-water, as the bilge-water of a ship, corrodes iron and steel rapidly.

(8) The rate of corrosion is too variable to be stated in exact terms. The hulls of iron ships have been found to average a rate of not far from 1-16 in. in 25 years, when carefully painted. Iron roofs exposed to smoke and gases of locomotives, are sometimes ruined in three or four years.

(9) The observations of Thwaite are as follows:

The time of endurance in years may be expected to average about

$$T = W \times C L;$$

where W is the weight of metal in pounds per foot length of the member, L is its length of perimeter, inside and out, is hollow, and C is a constant, which has the following values, and the magitude of which measures the relative loss by corrosion.

Material	Water				Impure air.
	Sea		River		
	Foul.	Clear.	Foul.	Clear or in air.	
Cast iron	0.0656	0.0636	0.0381	0.0113	0.0476
Wrought	.1956	.1255	.1440	.0123	.1254
Steel	.1944	.0970	.1133	.0125	.1252
Cast iron, no skin	.23	.0880	.0728	.0109	.0854
Galvanized	.09	.0359	.0371	.0048	.0199

Average for sea water: Cast iron, in contact with brass, copper or gun bronzes, 0.19 to 0.35; wrought iron, in contact with the same, 0.3 to 0.45.

This is for unpainted metal, of course. For painted iron or steel it is safe to multiply the endurance, as above, by two or more.

The precision of the above figures would seem to indicate accurate measurements, and to settle the question as respects the various metals; but, unfortunately, the quality of the steel and the influence of varying proportions of carbon, remain unmeasured, although soft and hard steels were compared with variable results. It has been assumed by the writer that the very softest steels, which contain less of the hardening elements than common iron, would oxidize more rapidly and the harder steels less rapidly, than wrought iron; while the rate of corrosion of wrought iron is subject to great variation with the variation of the chemical composition, and the mechanical structure, of its always heterogeneous mass. Graphite in cast iron, and cinder in wrought iron make with the adjacent metal rather effective voltaic combinations, and may be assumed to thus influence greatly the rate of corrosion. Very respectfully,

R. H. Thurston.

Sibley College, Cornell University, Oct. 28, 1898.

The Power of Windmills.

Sir: Mr. Hood, in his comment in your issue of Aug. 25 on my letter on the power of wind-engines, is quite right when he says that the power developed by them is a function of their load; and this phase of the problem I would have taken up there had I not, at that time, overlooked the column of Mr. Murphy's table in which he gives the loads of the wheels upon which he experimented. On correcting the proof-sheet, however, I noticed that this most important portion of the data was given, and I then rearranged my table and added two formulae, which I had devised for use when the load was known; but the letter was published before the corrected proof-sheet reached New York.

The formula

$$N.\ HP. = 0.0001\ D^3, \tag{1}$$

where N. HP. is the net horse-power developed by a wind-engine, with an air current of 16 miles per hour, and D is the diameter of the wheel in feet; was based on the performance of wooden wheels and was not intended for the more efficient back-geared metal wheels now so largely used; and although it gives results which agree fairly well with the average run of metal wheels, as shown in my letter, it does so by reason of so many of these wheels being most improperly loaded, and does not give the results that should be expested of them under anything like favorable conditions,

$$N.\ HP. = 0.002\ D + 0.0001\ D^3 \tag{2}$$

serves fairly well as a general formula for these latter under somewhat better conditions of load, as was also shown in my letter; although if the best judgment is displayed in proportioning the load to the size of the wheel, which seems, however, to be the rare exception, much better results may be expected from the best wheels of this class.

So extremely limited have been the data which I have found available, that I am not, at this time, able to give a general formula for all sizes of wheels and all conditions of load; from that at hand, however, I have developed the two provisional formulæ given below, which, within any reasonable limits of load, agree well with the results obtained from tests made on wheels in actual service. For back-geared metal wheels 8 ft. in diameter,

$$N.\ HP. = 0.001\ L - 0.023 \tag{3}$$

while for those 12 ft. in diameter,

$$N.\ HP. = 0.0004\ L + 0.039 \tag{4}$$

in which L is the load in foot-pounds per stroke, which should not, in the former, be less than 50 nor more than 100, nor in the latter less than 250 nor more than about 850.

To compare the results of these formulæ with the results of Mr. Murphy's tests, as given in his table already referred to, let us take from that table the following 8 and 12-ft. wheels, the only ones not shamefully underloaded:

No. of Wheel.	Name of Wheel.	Diameter in. ft.	Load in ft. lbs.	N. HP. from tests.	N. HP. from formula.	Formula.
4	"Ideal"	8	50	.029	.027	N. HP. = .001 L — .023.
6	"Gem"	8	78	.042	.055	
18	"Ideal"	8	89	.070	.066	
5	"Aermotor"	8	95	.072	.072	
13	"Aermotor"	12	330	.171	.171	N. HP. = .0004 L + .039.
17	"Gem"	12	385	.149	.193	
3	"Aermotor"	12	415	.207	.205	
19	"Gem"	12	450	.162	.219	
7	"Aermotor"	12	462	.221	.224	
2	"Mogul"	12	536	.260	.253	
11	"Ideal"	12	844	.325	.377	

From the above it is seen that the results of the formulæ agree closely with those of the tests, the only discrepancy of any importance occurring with the "Gem" wheels, the tests of which show results uniformly low.

It is because of this most important condition of load not ordinarily being taken into account that the results of tests nearly always present such an appearance of confusion as to give one, not familiar with the subject, an idea that to experiment is to waste time and to attempt to discover laws is folly. It will, however, be seen from the above table that, when properly arranged, these data present a most regular appearance, and show results so consistent as to surprise, perhaps, many to whom the subject is not new.

Due to an improper load, many superior wheels have, without doubt, been condemned, while a neighboring wheel of inferior make, but more properly loaded, receives undue praise. Due also to this is the fact that large wheels often perform less work than smaller ones of no better or inferior makes. This is shown in the case of Nos. 12 and 11 of Mr. Murphy's table. Here No. 12, a 14-ft. wheel of high grade, is given a load so small that it develops but 0.125 HP., while No.11, a 12-ft. wheel of the same make, but with a better proportioned load, develops 0.325 HP.

A series of experiments much more extended than any so far attempted, and on somewhat different lines, should be made, not only because it is a subject of considerable interest, but because it is one that is growing to be of greatest practical importance, as upon the successful installation of small pumping plants, cheap in first cost and economical in operation and maintenance, depends the success or failure of great numbers of agriculturists scattered over a vast area of our country.

M. Fargusson.

Southport, N. C., Aug. 29, 1898.

(After receiving the above letter we received from Mr. E. C. Murphy a letter criticising some features of Mr. Fargusson's first letter (Eng. News, Aug. 4), which were covered by the letter above. We, therefore, submitted a proof of the above letter to Mr. Murphy, who continues the discussion with the following letter.—Ed.):

Sir: I am glad to learn from Mr. Fargusson's second letter that he appreciates the fact that the load on a windmill should be taken into account in computing its power. In his first letter he neglects the effect of load, and has to throw out of account some of the results of mills that I have tested, because "they are not consistent with one another." In his second letter he takes into account the load factor and finds that "they show results so consistent as to surprise perhaps many to whom the subject is not new."

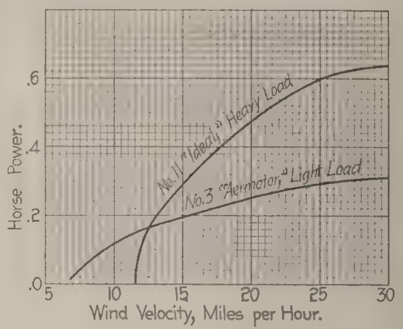
The effect of this load-factor on the power of a windmill was first published in the "Kansas University Quarterly," of October, 1895; it is illustrated by the case of a 12-ft. "power" mill in Engineering News of Aug. 19, 1897, and is quite fully discussed in "Water Supply and Irrigation Paper," No. 8.

Mr. Fargusson mentions the need of a more extended series of tests of windmills. The U. S. Geological Survey is in possession of the results of two seasons' tests in addition to those in Paper No. 8, by the writer and will publish them in due time; these cover all sizes of steel mills and several sizes of wooden ones.)They include power as well as pumping mills.

In regard to Mr. Fargusson's formula for the net power of a windmill, it does not give the total net power of a mill. The efficiency of the pump and well should be taken into account. The total power can be best found from power mills.

Prof. O. P. Hood in his remarks on Mr. Fargusson's formula (Eng. News, Aug. 25) makes a statement that may be misleading. He speaks of Mr. F. H. King getting results very different from those that I have gotten. Mr. King found the brake power of a 16-ft. mill to be 1.08 HP. in a 16-mile wind. I found the pumping power, expressed in useful work done by the mill and pump, of a 16-ft. mill No. 9, to be .433-HP. in a 16-mile mind. The loads on the mills are not given, or the make of mill, hence a just comparison of the actual power of the two mills cannot be made.

Professor Hood also gives some figures showing the useful work done by a "typical" 10-ft. mill and pump per month, in the vicinity of Manhattan, Kan. He does not state what kind of a mill this typical mill is, whether wood or steel, back geared or working direct stroke, or what the load on the mill. Permit me to give the useful work of two 12-ft. steel, back-geared pumping mills, in the vicinity of Dodge City, Kan., for the six irrigating months—April to September. The data for this purpose is taken from "Water Supply and Irrigation," Paper No. 8. The two mills selected are a 12-ft. aeromotor No. 3, and a 12-ft. Ideal No. 11. The former being a lightly loaded mill, 415 ft.-lbs. per stroke of pump, and the latter heavily loaded, 844 ft.-lbs. per stroke, the effect of difference in loading will be seen.



Horse-power Curves of Two 12-ft. Windmills, Showing Influence of Load.

The useful work in horse-power done by these mills in different wind velocities is shown in Fig. 1. No. 3 being lightly loaded will start in a 7-mile wind; No. 11 requires an 11½-mile wind to start it, but gives more power than No. 3 for all velocities above 12½ miles per hour.

The mean monthly wind movement at Dodge City for seven years, for the months, April to September, is given in Table I. The numbers in this table show the mean number of hours in each month that the wind velocity was 0 to 5 miles per hour, 6 to 10 miles per hour, etc. Thus for the month of April—if the number of hours that the wind velocity was 0 to 5 miles per hour for the seven years be added and the sum divided by 7, the quotient is the first number given in column 2.

From this table we see that at this place, for these six irrigating months, there are 140 hours per month when the wind velocity is 0 to 5 miles; 198 hours per month when it is 6 to 10 miles; 157 hours when it is 10 to 15; 109 when it is 16 to 20; 72 when it is 21 to 25; 34 when it is 26 to 30; and 22 hours when it is 31 and upwards miles per hour. The wind velocity here is 11 and upwards miles per hour for 54% of the time.

By a study of the diagrams and table we see that during the 140 hours when the wind velocity is 0 to 5 miles per hour neither of the mills will do any useful work. Mill No. 3 will start in a 7-mile wind, and will run about four-fifths, or 158 hours, out of the 198 hours when wind velocity is 6 to 10 miles per hour. This mill will run for all higher velocities. No. 11 requires an 11½ miles wind to start it, and will run for about 141 hours out of the 157 hours when wind velocity is 11 to 15 miles—it will run for all higher velocities. No. 3 will run—if in the wind—about 75% of the time, and No. 11 about 51% of the time.

The useful work done by each mill in a mean month is given in Table II. Columns 2 and 5 give the number of hours during the mean month that each mill was running when the wind velocity was as given in column 1. The power, given in columns 3 and 6, is the hourse-power taken from the diagrams Fig. 1 for the mean of the corresponding velocities in column 1. The useful work—columns 4 and 7—in ft.-lbs. is found by multiplying the power by 1,980,000 to reduce to ft.-lbs. per hour, and this by the number of hours in columns 2 or 5, as the case may be, to get the work for the particular time. The total useful work done during the mean month is 197,010,000 for No. 3, and 289,476,000 for No. 11. If we divide the first of these by 73, and the second by 75.3, these being the number of sq. ft. in the respective sail areas, we have 2,700,000 ft.-lbs. for No. 3, and 3,844,300 ft.-lbs. for No. 11; as the useful work per sq. ft. of sail area for the mean month. The former of these is only 70% of the latter, hence No. 3 lightly loaded and running about 75% of the time does only

TABLE I.—Mean Wind Movement at Dodge City, Kan., for the Seven Years 1889 to 1895.

Months.	Velocity, miles per hour.						
	0 to 5.	6 to 10.	11 to 15.	16 to 20.	21 to 25.	26 to 30.	31 and upwrds

21 " 25	72	.277	39,402,000	72	.56	79,794,000
26 " 30	34	.308	20,790,000	34	.63	42,372,000
31 & upwads.	22	.320	13,860,000	22	.64	27,918,000
Total			197,010,000			289,476,000

7-10 as much work as No. 11, which runs only about 51% of the time.

It must be remembered that this is not a comparison of the power of these mills. These figures show the actual amount of useful work these mills are doing per month, each with its own conditions of well, pump,etc. There must of course, be a reservoir to store the water pumped, so that the mill can be at work whenever there is wind enough to run it.

It must be remembered,too,that the wind velocity at Dodge City, Kan., is somewhat greater during July and August than in Eastern Kansas, and many other parts of the United States. It is quite possible that if these two mills were placed, say in Eastern Kansas, the other conditions of loads, wells, pumps, etc., remaining the same, No. 3 might do more work in some months than No. 11. The load on the mill should be suited to the wind velocity of the locality where the mill is to be used.

Respectfully, E. C. Murphy.

Lawrence, Kan., Sept. 10, 1898.

FIG 1. TRANSVERSE SECTION OF STEEL TROUGH OF BRIARE CANAL AQUEDUCT, BRIARE, FRANCE.

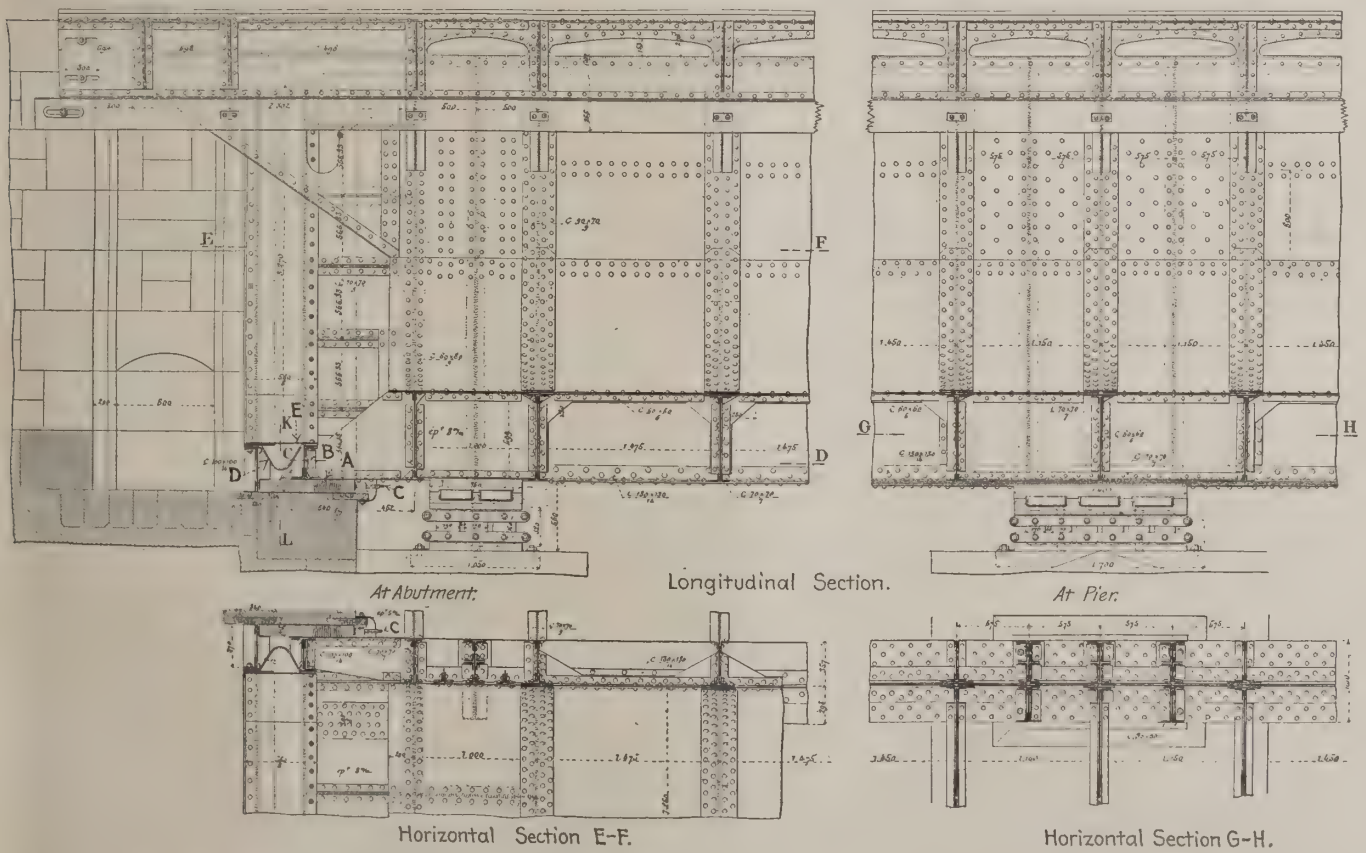

FIG. 2. VERTICAL AND HORIZONTAL LONGITUDINAL SECTIONS OF STEEL TROUGH OF BRIARE CANAL AQUEDUCT.

STEEL CANAL AQUEDUCT AT BRIARE, FRANCE.

The Briare aqueduct carries the new level recently built to connect the Loire and the Briare canals across the River Loire, near the town of Briare, France. It is 662,687 m. (2,173.6 ft.) long and 6.2 m. (20⅓ ft.) in clear width, with a depth of water of 2.2 m. (7.216 ft.), and consists of a continuous trough-shaped steel tank carried on masonry piers. Altogether there are 14 piers and 3 abutments carrying 15 spans of steel trunk 40 m. (131.2 ft.) long, and one span 12,150 m. (39.85 ft.) long. The 15 main spans cross the river Loire proper, and the single short span passes over the old line of the Loire canal, which runs parallel and close to the right bank of the river at this point. Fig. 1 is a transverse section, and Fig. 2 is a part longitudinal section of the steel trunk showing its construction and the method of supporting it on the masonry. So far as we know, this is the longest steel trough canal aqueduct ever built.

The material of the river bed at the point of crossing was a calcareous earth with interspersed modulus of chalk, below which at a depth of from 5 m. to 8 m. (16.4 ft. to 26.24 ft.) was a homogeneous calcareous tuff suitable for a foundation bed. Upon this solid layer the piers were founded, steel caissons sunk by compressed air being used to reach the proper depth. Except for the number of caissons sunk and the amount of masonry to be built this foundation work calls for no especial mention.

The more interesting features of the work are connected with the steel trough construction. This is shown quite clearly in Figs. 1 and 2. First of all the question arose whether the trough should be made continuous from one end of the aqueduct to the other, or whether each span should be independent. The continuous structure was cheaper, but in case of settlement of the foundations it would involve serious difficulties from racking strains. These difficulties would be largely avoided by constructing the spans independent, but, on the other hand, the cost would be far greater. Considering the excellent foundation bed and the very small likelihood of settlement, it was finally decided to make the trough a continuous structure. It was, therefore, fixed to pier No. 8, counting from the left bank of the river, and mounted on movable bearings on all the other piers, and at the abutments where properly-designed recesses in the masonry allow free expansion and contraction.

Referring to Figs. 1 and 2, it will be seen that the main supporting members of the trunk are the two parallel I-beams or plate girders which form its sides. These girders are 3.4 m. (11,152 ft.) deep and are spaced 7,259 m. (23.8 ft.) apart c. to c. Riveted to these girders is a bottom framing of transverse and longitudinal girders carrying the steel plate flooring or bottom of the trough. Brackets attached to the outside of the main plate girders carry the tow paths, and similar brackets on the inside support the footpath and fender timbers. Altogether the metal trunk weighs 6,935 kilos. per lineal meter without water, or 22,535 kilos. per lineal meter when filled to the normal depth of 2.2 m. of water for navigation. The total amount of steel in the structure is 3,076,647 kilos. (6,768,623 lbs.).

The manner in which the expansion and contraction of the steel trough is provided for is about the only detail not clearly explained by the drawings. Between the limits of temperature of — 20° and + 50° C, the movement at one side of the anchor pier is 216 mm., and upon the other side 246 mm. To provide for these movements the steel trough slides back and forth like a piston in recesses in the end abutments. This sliding joint is shown by Fig. 2, where A is a compressible packing held in place by the timber lagging B and the screws C; D is a sheet of rubber joining the ends of the fixed and movable troughs; and E E are sliding steel plates protruding over the rubber joint.

The total cost of the steel trunk, including the guard gates at each end and miscellaneous constructions, was 1,243,028 fr., or about $248,605. The cost of the substructure was 1,563,689 fr., or about $312,737, making the total cost about $561,342. For the information from which this description has been prepared we are indebted to a paper by Mr. Mazoyer, in "Annales des Ponts et Chausses," for July, 1898.

GEORGE E. WARING, JR.

Col. George E. Waring, Jr., one of the best known sanitarians of the country, died at his home in New York city on Oct. 29, from yellow fever, contracted while acting as special commissioner of the United States Government to investigate the sanitary condition of Havana, with the view of devising a system of sanitation which would render the Cuban capital safe for occupation by the American troops. Col. Waring had returned to New York from his duties at Havana only five days previous to his death. At the time he landed he was suffering from what was supposed to be malarial fever, and it was not until two days later that the disease was correctly diagnosed as yellow fever, when a thorough quarantine was established over the patient and his family. The body was cremated in accordance with the personal wishes of Col. Waring when alive and conforming to the regulations of the New York Board of Health in cases of death from malignant infectious diseases.

Geo. E. Waring was born at Poundridge, Westchester Co., New York, on July 4, 1833, and received his education at Poughkeepsie, N. Y. He also took a course in agriculture and agricultural chemistry under the late Prof. James J. Mapes. In 1855 his lectures on agricultural subjects attracted the attention of Horace Greeley, who made the young student the manager of his famous experimental farm at Chappaqua, N. Y. Mr. Waring remained the manager of the Greeley farm for three years, when, in 1857, he was appointed drainage engineer of Central Park, New York city. This position he held four years, during which time he designed the present drainage system of the park, and he left it only to go to the front as Major of the Garibaldi Hussars at the outbreak of the Civil War. Later Major Waring raised a squadron of cavalry in New York city which was known as the Fremont Hussars. Afterwards transferred to the Department of the Southwest, he was appointed Colonel of the 4th Missouri Cavalry.

In 1867 Col. Waring established himself in Newport, R. I., as manager of the Ogden farm, where he lived for ten years, conducting, in addition to his work on the farm, a general consulting and advisory practice in drainage and sanitation for dwellings and institutions. His name first became prominent in city sanitation and sewerage when, in 1878, he designed and constructed at Memphis, Tenn., the well-known "separate system" of sewerage which has since been inseparably associated with his name, and which he has introduced into various other American cities.

Without doubt, however, Col. Waring gained his greatest reputation, in the mind of the general public at least, by his work as Commissioner of Street Cleaning in New York city, to which position he was appointed Dec. 30, 1894. The revolution accomplished in the work of cleaning the streets of the metropolis by the systematic and business-like methods introduced by the new Commissioner are of too recent knowledge to engineers to require description here. The change in the politics of the city administration, however, threw Col. Waring out of his position on Jan. 1, 1898, although the system which he had established still remains in force in the department which he put on such an efficient basis.

When a few weeks ago it was determined to send a Government Commission to Cuba for the purpose of selecting camp sites for troops and making provision for sanitary improvements in the principal cities of the island, Col. Waring was appointed at its head. He was appointed by President McKinley on Oct. 2, and he sailed for Havana shortly afterward. In that city he spent the next few weeks making a special study of the sanitary conditions with the view of suggesting plans for perfecting them. Having completed his studies, he had returned home to submit his report to the Government authorities, when the illness which caused his death overtook him.

Col. Waring was a member of a number of scientific and technical societies, including the Institution of Civil Engineers, the Sanitary Institute of Great Britain, and the Royal Institute of Engineers of Holland, and he also belonged to the Century Club, Players' Club and the City Club, and was President of the last organization. Besides his well-known writings on sewerage, street cleaning and sanitation, Col. Waring wrote many admirable sketches of travel for the more prominent magazines. A widow and one son survive him.

THE TONNAGE AND DISPLACEMENT OF SHIPS.

At the present time, when naval matters are a source of great interest to the general public, one continually finds the terms "displacement" and "tonnage" improperly used, both in the daily press and in common speech. The confusion between the terms would not occur if their meaning were understood. "Displacement" refers to the quantity of liquid displaced by the immersed hull of the ship; and "tonnage" to the freight-carrying capacity of the ship determined by certain rules of measurement.

The displacement of a vessel is the entire weight of the hull with all its contents, according to the well-known law of hydrostatics; that a floating body displaces a weight of fluid just equal to its own weight. A ship sinks in the water to such a level that the pressure of the fluid displaced exactly counterbalances the weight of the ship.

Tonnage is figured by what is known as the Moorsom system; originally adopted by England, in 1836, and since 1865 officially recognized by all maritime nations, with some unimportant differences in the methods of measurement. The "register ton" is 100 cu. ft. of internal volume; and a ship having 100,000 cu. ft. of internal space, within the points of measurement prescribed in the English Merchants' Shipping Acts of 1854 and 1867, is said to be "1,000 tons register." This cubic ton of 100 cu. ft. now forms the unit of assessment for dock, harbor, towage and other dues. Previous to 1836 the tonnage of British ships was found by multiplying the square of the breadth by the inboard length and dividing by 94. This "old measurement," though far from exact, is still used to some extent in measuring pleasure yachts, etc. Under this old system the depth of the hold was taken as being the same as the beam; and the interest of ship-owners caused them to build ships of narrow beam and increased depth, with resultant unseaworthiness and poor sailing qualities. Abuses of this kind and the imperfections of the old system of measurement brought about the adoption of the new law of 1836, and this law was simply an elaboration of the theorem of Isaac Newton for measuring spaces bounded by irregular curves.

The Moorsom system of 1836, amended and elaborated by later enactments, provides for actual measurements of depth made at certain intervals, with the number of these intervals depending on the length of the tonnage-deck of the vessel. (This tonnage-deck is the upper deck on ships with less than three decks, and the second deck, from below, if there are three or more decks.) Transverse areas are then computed at these points in feet and decimals of feet; these transverse areas, after being multiplied by certain numbers, according to the class of ship, are added together, multiplied by one-third the common distance between the areas, and divided by 100. To obtain the "gross registered tonnage," there must be added to this the tonnage of all spaces above the tonnage-deck, the poop, deck-houses, etc. This is obtained by multiplying the horizontal area by the mean height and dividing by 100, as before.

In steamships, the space occupied by the engine-room, and the screw-shaft space considered as part of the engine-room, is to be deducted from the gross tonnage. The Merchants' Shipping Act of 1867 especially refers to the crew-space, and requires that owners provide proper accommodations for the crew before the space they occupy on a ship can be deducted from gross tonnage in estimating dues of various kinds. In freighting ships, 40 cu. ft. of merchandise is considered a ton, unless that bulk should weigh more than 2,000 lbs., in which case the freight is charged for by weight.

NOTES FROM THE ENGINEERING SCHOOLS.

Cornell University.—The annual report of President Schurman says that during the last year attendance has been greater than ever before, and, owing to the great advance recently made in the standards of admission to nearly all courses, a striking improvement in scholarship has been wrought. The "median age" of the freshmen has decreased from 19 years 11 months in 1895-6 to 19 years 7 months in 1897-8, notwithstanding the increased requirements for admission, which indicates that the high schools of the country are improving.

Under the direction of Profs. Fernow and Roth there have been arranged a full four-year course leading to a degree of Bachelor of the Science of Forestry, a one-year special course, and a one-term synoptical course. The four-year course is planned to give a thorough knowledge of all branches of the profession and to prepare men to manage and administer forest estates for private owners or for the state or national government, and also to teach the profession in the colleges, which are likely in the near future to establish chairs of forestry science and practice. This course comprises in its first two years the preparatory studies of mathematics, natural science, engineering, political economy, etc., its last two years being devoted to the purely professional subjects. The one-year special course is planned for farmers, lumbermen, and others not desiring a general scientific training, but wishing to acquire such technical and practical knowledge of forestry as will enable them to manage more intelligently and economically their own woodlands. Finally, the one-term synoptical course will meet the requirements of students of political economy and others wishing to make a brief survey of the subject of forestry as a matter of general education.

◆

THE GERMAN CANAL BILL which is to be introduced into the Reichstag during the coming session provides for the expenditure of 400,000,000 marks on canals and river improvements as follows: Midland Canal, 192,000,000 marks; Dortmund-Rhine Canal, 68,000,000 marks; 50,000,000 marks for water sheds, etc., in the Oder district; 40,000,000 marks for the Berlin-Stettin Ship Canal, and 20,000,000 marks for the improvement of the Weser River. When the scheme is executed it is announced that the main waterways of Prussia will be connected from the eastern extremity of the Empire to the harbors of the German Ocean.

◆

SEWAGE DISPOSAL AT TORONTO, ONT., is the subject of a report by Mr. C. H. Rust, Cy. Engr. He recommends the construction of intercepting sewers, on the general plan proposed by Messrs. Hering & Gray, in 1889, and the provision of purification works in addition. The cost of the intercepting sewers is estimated at $820,000. Final disposal works are estimated at $910,000 for intermittent filtration, and $720.000 for chemical precipitation, with filtration of the effluent. The annual charges for filtration would be less than for precipitation. Before deciding on a purification system, Mr. Rust advises the employment of a consulting engineer.

◆

A DECISION OF THE SUPREME COURT of Illinois recently rendered gives the City Council of Chicago, Ill., the right to insist upon compensation for street railway franchises. The decision is a sweeping one, as it established the right of compensation without any limitations. The decision was given in the appeal of the Chicago General Ry. Co. against a judgment of $2,250 given the city. The ordinance under which the railway operates imposes an annual fee of $500 per mile of track and the company refused to pay this tax.

◆

CHEAPER ELECTRICITY IN NEW YORK CITY will without doubt follow the cut in rates just announced by the United Electric Light & Power Co., of that city. About a year ago the Edison company introduced a schedule which had as its maximum one cent per 16-c. p. lamp per hour. Discounts were given to customers burning their lamps for long periods, and it was claimed that this made the cost in some cases less than ½-ct. per lamp per hour. Small customers were required to pay one cent. The schedule just announced by the United Electric Light & Power Co. starts with a maximum of ¾-ct. per lamp hour, and grades down, according to the amount of current used and the time lamps are burned, to a minimum of 1-3-ct. per lamp per hour.

◆

TO HOLD ITS RIGHTS ON THE CANADIAN SIDE of Niagara Falls the Canadian Niagara Power Co., which is controlled by the Niagara Falls Power Co., is required to pay an annual rental of $25,000 to the commissioners of Queen Victoria Niagara Falls Park. This agreement was entered into in April, 1891, and further provides that the company shall have 10,000 developed horse power and water connections for 25,000-HP. by Nov. 1, 1898. Some months ago an extension of time was asked and allowed and the company was permitted to install two 500-HP. generators in the station of the Niagara Falls Park & River Ry. It has been reported in Canada that the company would voluntarily forfeit its rights, but on Oct. 18 the semi-annual rental of $12.500 was forthcoming, thus proving the company's intention to hold its rights to develope power on the Canadian side.

◆

AN ACETYLENE GAS LIGHTING PLANT has been installed at Milford, Pa., according to "Heating and Ventilation." The plant, like the village, is small. At present there are only some 3,000 ft. of mains, 3 ins. in diameter, or less, within the village, and one or two extensions outside. There are five generators and a gasometer, located in a small building. The generator is of the Troubetzkoy type, made by the Mechanical Engineering Construction Co., 63 Fifth Ave., New York city.

◆

NOISELESS MANHOLE COVERS, as they are styled by their makers, are in use in Philadelphia, and in some other cities, we believe. The main features of the covers are to have as large a part of their area as possible composed of the same material as that used for paving the street in which they are placed and the keeping of the street and cover at the same level. Thus, in asphalted streets, where they are principally used, the whole top of the cover, except the rim, is filled with asphalt. Further particulars regarding these covers may be obtained from A. L. Greger & Co., 315 North Broad St., Pa., and the Sanitary Engineering Co., Girard Building, Pa.

STEEL WAGON TRACKS FOR COMMMON ROADS at Scranton, Pa., are under discussion. It is reported that the Abington Turnpike Road Co., through W. W. Watson, has stated that it would lay a half-mile of the track as an experiment.

◆

A MEMORIAL TO RICHARD M. HUNT, the late architect, was unveiled in New York city on Oct. 31. This memorial is a semi-circular granite and marble bench set into the wall of Central Park, on Fifth Ave., near 71st St. It was erected by a committee representing the various architectural, artistic and literary organizations that recognized the efforts of Mr. Hunt to raise the standards of American architecture.

◆

AMERICAN EXPORTS OF WIRE NAILS are commented upon in the "British Iron and Coal Trades Review." This report from the United States to Europe has grown from 1,547,078 lbs. in 1888 to 22,894,099 lbs. in the fiscal year 1898. The growth in trade is exceptionally rapid in the last two or three years. In 1895 the exportations were 4,367,267 lbs.; in 1896, 8,031,927 lbs., and in 1898, 22,894,099 lbs. These American wire nails go to Germany, France, Belgium, Netherlands, the United Kingdom, Canada, Central America, West Indies, all South America, China, Japan, Asiatic Russia, Australasia, and British and Portuguese Africa.

◆

COMPRESSED PEAT FUEL is being made by the Canadian Peat Fuel Co., of Welland, Ontario, under the patents of Mr. A. A. Dickson, of Toronto. The peat is dried in the air and then disintegrated in a breaker revolving at a high speed, and is thus reduced to a powder without unduly breaking up the fiber. The peat powder is withdrawn from the breaker by an exhaust fan into a large hopper, and from this it descends into a machine which compresses it into cylinders 2 ins. diameter and 2 ins. long, under a pressure of 30 tons. It is thus reduced to one-sixth the bulk of the raw material. The machine has a capacity of 1½ tons of compressed peat per hour. This fuel is claimed to be non-friable and weatherproof, owing to its solidity and the external glaze imparted by friction in the forming-dies. The inherent moisture of the peat is reduced to 12%, and the weight of the fuel is 83 lbs. per cu. ft., as compared with 73 lbs. for bituminous coal and 93 lbs. for anthracite coal. No prices are quoted, but the fuel is said to have been successfully tested in competition with coal.

◆

A MINING AND INDUSTRIAL EXPOSITION will be held at Coolgardie, Australia, beginning March 21, 1899, and continuing at least two months, in which American manufacturers and mining interests are especially invited to take part. It is stated that special scope will be afforded for the exhibition of mining, timber and agricultural machinery, gold saving appliances, electric lighting apparatus, bicycles, household fittings and food specialties. The British Embassy at Washington, D. C., can furnish information concerning the exposition.

◆

THE SALT MINES OF WIELIEZKA, near Cracow, Poland, were mentioned in 1044 and have been worked since 1240. The first map of the mines was made in 1638 by Martin German, a Swedish mine surveyor. The eight shafts now in existence are from 207 to 985 ft. deep and the length of the levels now open is 345.000 ft., with 115.500 ft. of underground tram-lines. Between 1772 and 1892 about 3,000,000 cu. yds. have been excavated for the extraction of salt. Machine drills are now used and compressed powder is employed in blasting; about 1.187 lbs. of powder are used per ton of salt produced. The present levels are 7¼ ft. high by 6¼ ft. wide.

BOOK REVIEWS.

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION. Proceedings of the 5th Annual Meeting, held in Toronto, Ont., Aug. 16-18, 1897. Vol. V. Cloth, 8vo.; pp. 337.

The Society for the Promotion of Engineering Education has now grown to a membership of 226. It consists chiefly of professors in engineering schools, but contains also a few engineers in private practice. It meets once a year, the meetings being held in the same place as the annual meeting of the American Association for Advancement of Science, but a few days earlier, so that members may conveniently attend the meetings of both societies. The following is a list of the principal papers and discussions in the present volume: "Engineering Laboratory Courses," by R. C. Carpenter; "A Course of Study in Electrical Engineering," R. B. Owens; "At What Point Should Students Engage in Specific Research," C. D. Marx; "Uniformity of Symbols in Engineering Text Books, Report of Committees, Methods of Teaching," W. H. P. Creighton; "Elective Studies in the Regular Engineering Courses," H. S. Munroe; "The Calculus for Engineering Students," F. W. McNair; "Chemical Engineering," J. M. Ordway; "The Teaching of Machine Design," J. J. Flather; "The Efficiency of Technical as Compared with Literary Training," T. C. Mendenhall; "A Course in French and German for Engineers," A. N. Van Daell; "The Extent to Which Metallurgy Should be Taught in Engineering Courses," M. E. Cooley; "Manual Training for Artisans," C. M. Woodward; "The Manual Training High School," T. W. Mather; "The Agricultural College in Its Relation to Engineering Education," C. S. Murkland; "Graduation Theses," I. O. Baker.

THE REPLY OF STATE ENGINEER ADAMS TO THE CANAL INVESTIGATING COMMISSION.

In our issue of Aug. 11 we published an abstract of the report presented by the Commission appointed by Governor Black to investigate the work of enlarging the Erie, Champlain and Oswego canals. A reply to that report and to the various charges made therein was made by State Engineer Campbell W. Adams, under date of Sept. 12, and we have just received a copy of this reply, a document of 89 printed pages. Inasmuch as the report of the Commission has been given publicity in our columns, we deem it only fair to present as fully as our space will permit the other side of the case as given in Mr. Adams' statement.

Preliminary Estimates of the Cost of the Work.

At the outset Mr. Adams points out the undoubted fact that the State Engineer's Department was not responsible for the fixing of the canal appropriation of 1895 at $9,000,000. The estimate of that department submitted to the Constitutional Convention of 1894, was $11,573,000, and this was specifically stated to be little more than a rough guess, since no surveys had been made or were available by which the cost of the contemplated improvement could be determined. Further, it was made on the assumption that 1 ft. could be dug from the bottom and 1 ft. placed on the banks without disturbing existing vertical or slope walls, an assumption which has proved wide of the mark. The fixing of the canal appropriation at $9,000,000, and, in fact, the drafting of the canal improvement law, was done by the Executive Canal Committee, which fixed on $9,000,000 for no better reason than that it was the largest round sum short of one represented by eight figures, and it was feared that if a larger sum were asked for the appropriation might be defeated.

Immediately after the result of the election was known, a force of engineers was made up, and set to work on the preliminary surveys and estimates. Some delay was encountered in getting sufficient men from the Civil Service Commission, and the force thus obtained was, Mr. Adams says, somewhat deficient in experience, but otherwise "unquestionably equal in personnel to any corps of equal size ever organized." This preliminary survey was cut somewhat short in deference to popular criticism of the amount of expenditures on engineering work. The estimates when finally made up in November, 1896, showed that the total cost of the improvement would be in the neighborhood of $15,000,000. This information was given to the Executive Canal Committee, but appears to have been withheld by them from the public. The State Engineer believed that these estimates included a great deal of work which, though badly needed, could possibly be deferred till further appropriations, and the estimates were returned to the engineers in the field with instructions to cut out all work that could possibly be held; this attempt to bring the work within the limits of the appropriation resulted in failure; but the State Engineer maintains it was conscientiously and honestly made. In any event the law was mandatory, and the engineers were compelled to proceed with the work, whether the funds in hand were sufficient to complete it or not.

The Specifications.

Messrs. North and Cooley, the Consulting Engineers to the Commission, criticised the specifications for the work, which were so drawn as to provide for payments to the contractor for each separate item of work done. Messrs. Cooley and North think it would have been better to have made fewer items of the work, thus lessening the amount of measurement and supervision necessary on the part of the engineers in charge. In reply Mr. Adams states that the specifications for the work were prepared as the result of extended conference between the State Engineer's office and all the division and resident engineers employed on the work, men who had been on the State canals from 3 to 30 years. He continues as follows:

> 1. The engineers suggest that this type of specification is somewhat antiquated. On the other hand it is believed that the great bulk of the public work in this country to-day is based on similar specifications, that is, a specification providing a separate rate of compensation for each of the units comprising the work, and it is still believed to be the best for this especial purpose for this reason;—it does not ask either the State or the contractor to insure against conditions which can not be foreseen, and, on the contrary, it provides for what it supposed to be an equitable compensation for the actual amount of work done—no more and no less.
>
> If the State asks the contractors to name a price for completed work to be done under risky conditions, as most of this work is done, the inevitable result would be higher prices. On the other hand, if the State asked for such prices and attempted to define the conditions in advance, and it was afterward found that those conditions developed otherwise than as stated, the contractor would surely claim additional allowance, and experience shows that the courts have and will allow such claims under such conditions whether the engineers do or not.
>
> Moreover, if these conditions prove to be less arduous than as defined, experience shows that the State would be unable to effect any saving. It is a rule that does not work both ways. Except in very rare cases, the prices for the work under these specifications are too low. The commission agrees that they "are as low as could reasonably be expected." They also admit that the resulting work is superior to similar work heretofore done on the canals. Witness the paradox: Poor specifications produce good work at low prices!

Considerable space is devoted to this subject, and Mr. Adams gives in detail his reasons for believing that it is better, in building vertical or slope walls, for example, to measure up and pay the contractor for all the work he does under the separate heads of excavation, sheet piling, masonry, back-filling, lining and embankment.

Earth and Rock Classification.

A large part of the Commission's report was devoted to a detailed account of the cases where contractors have been paid for material excavated as rock which should properly have been classified as earth. Mr. Adams is emphatic in his denial that the material in question was improperly classified. To combat the popular idea that a large part of the money on the canals has been spent in digging earth which has been paid for as rock, Mr. Adams presents figures in substantial harmony with some contained in the Commission's report, which show that the total amount of material other than solid ledge rock which has been excavated and paid for at rock prices amounts to 298,345 cu. yds. The average price for rock excavation was $1 on the middle division, $1.24 on the Eastern and $1.69 on the Western. Up to May 1, 1898, the total amount of material excavated was 6,060,097 cu. yds., of which about 731,000 had been returned as rock.

By the terms of the specification, earth excavation was declared to:

> Include removal of all clay, loam, sand, quicksand, gravel, pure, mixed or combined; boulders measuring less than one-half a cubic yard, dry vertical wall, slope wall, paving, docking and cribs, timber foundation of all descriptions and hard pan or soft or rotten rock which, in the opinion of the resident engineer, can be plowed.

Dry excavation of rock was defined to

> Include the removal of all solid or ledge rock and hard pan which, in the opinion of the resident engineer, connot be plowed, and all boulders measuring ½ cu. yd. or more.

Mr. Adams' reply to the charges of the Commission that a large amount of earth was improperly classified as rock is in general a specific denial. He avers that the plowing tests called for were faithfully made, and that records kept by the engineers to determine the cost to the contractors of excavating the hardpan classified as rock show that the cost was about the same as that of actual rock excavation. Concerning the charge that material classified as earth in one monthly estimate was afterward returned as rock in succeeding estimates, Mr. Adams says this was done to give the Resident Engineers (each of whom had about 100 miles of work under their charge) time to reach various portions of the work and reach a decision upon the nature of the material. Pending this decision, the local assistant engineers in charge returned all doubtful material as earth in their monthly estimates.

Embankment.

Under the specification there was no allowance for overhaul, but wherever materials had to be hauled over 1,000 ft. they were paid for as embankment, whether actually placed in the canal banks or dumped on spoil banks. The Commission thinks it would have been better to have paid directly for overhaul, and thinks that there has been a tendency to put material on spoil banks which would have been made use of had the contractor not received payment for the material so wasted as embankment. Mr. Adams' reply to this is that this use of the term "embankment" has been common practice on the State canal work for years, and that overhaul cannot be paid for on canal work as on railroad construction because to sort out the material suitable for putting in the banks requires hauling in all sorts of directions, and it would require a small army of engineers to record the measurements and the distances hauled. He further states that the great bulk of the excavated material from the canal prism, which it was supposed would serve for the necessary embankments, was found unfit for that purpose on its removal, and gives this as the reason why the embankment, which was only 739,374 cu. yds. in the preliminary estimate, had already, on May 1, 1898, reached 1,167,849 cu. yds.

Lining.

The Commission criticised the use of cinders as lining on some contracts. Mr. Adams holds that cinders constitute one of the very best of lining materials, and says that by their lightness, as compared with other lining materials, they have certainly saved the rebuilding of several structures that would have been forced into the canal by the weight of almost any other material available. He holds that because they could be, in some cases, obtained more cheaply than gravel by the contractor, was no reason against their use.

Money Expended for Ordinary Repairs.

The Commission estimated that about $1,500,000 had been spent for ordinary and extraordinary repairs out of the $9,000,000 appropriation, which should have been provided for from other sources; and it referred to this sum in its report as "improperly expended," Mr. Adams points out that since there was no "other fund" to draw upon, the canal engineers had to make necessary repairs from the $9,000,000 appropriation. If the work of deepening the canals endangered bridges, aqueducts and other structures, as it frequently did, it was necessary to repair them or run the risk of a break and serious damage. He contends that a real injustice has been done the Engineering Department by this statement, since the Commission knew that the work to be done was absolutely necessary.

The Commissioners' further charge that another $1,000,000 had been misspent, as a result of poor specifications, loose methods or improper management, he meets with specific denial, and declares that while absolute perfection is not attainable in any work of such magnitude, it is believed that the total amount improperly spent on the work does not equal the cost of the Commission's investigation.

Lock Improvement.

The State Engineer obtained working detail plans for three kinds of lift locks for Lockport, paying the following sums therefor:

Buffalo Engineering Co.	$19,079
Stowell & Cunningham (another style)	8,811
Dutton Pneumatic Lock & Engineering Co., for a pneumatic lock	14,500
Dutton Co., for plans for locks at Cohoes	7,000
	$49,390

The Commission held that this work was not properly a part of that contemplated by the $9,000,000 appropriation, and holds that it was not necessary to obtain complete working plans of three separate devices before choosing between them. Mr. Adams declares that the completion of the lock lengthening was mandatory by the terms of the law, and that at Lockport the only alternative to the adoption of a lift lock would be the closing of the canal for one season. He further says that when the plans for this work were ordered, it was believed that there would be money enough to build these locks from the $9,000,000 fund. After much study it was believed that three different types of lock were available at Lockport, and as none of these had ever been built it was deemed best to prepare detail plans of each type in order that an intelligent comparison might be made.

Berme Slope Walls.

Mr. Adams says that only 10½ miles of new slope wall has been built on the work, and then only where it was necessary to maintain the banks. The old slope walls could either be underpinned and saved or could be torn out to leave an earth slope. The former course was adopted, and it is believed that any other course would have subjected the engineers to severe and merited censure.

Water Supply.

Concerning the amount of excavation on the level above Lockport, Mr. Adams declares this was a necessity to give the canal sufficient cross-section to enable it to discharge sufficient water to feed the 62-mile level from Lockport to Rochester, without undue velocity of current. All the water used for milling purposes at Lockport is returned to the canal except that which is discharged into Eighteen-Mile Creek. The waste weir and waste gates discharging into this latter stream are necessary, however, to take care of surplus water, and if an honest man can be found to manipulate them, the State's interests will not suffer.

Besides replying to the general criticisms of the Commission, Mr. Adams takes up in detail and replies to many specific irregularities which were charged by the Commission. These, however, it would serve no useful purpose to present here, especially as the matter in controversy will probably be made the subject of judicial inquiry.

THE REPLY OF SUPERINTENDENT OF PUBLIC WORKS ALDRIDGE TO THE CANAL INVESTIGATING COMMISSION.

On Oct. 30 the Superintendent of Public Works, Mr. Geo. W. Aldridge, made public a reply to the charges made in the report of the Canal Investigating Commission. At the outset he calls attention to the fact that the report commends the character of the work done, and declares that the contracts were regularly awarded under actual and wide competition. He further says that the Commission "fails to find any condition, any official act, or any intimation that would warrant a suspicion that I have profited either directly or indirectly through the prosecution of this work."

Taking up the report in detail, he calls attention to the fact that the Commission did not pursue very far the question of who was responsible for the fixing of the canal appropriation at the inadequate sum of $9,000,000, and for leading the voters to believe that that sum would be sufficient for the work of deepening the canals to 9 ft. It appears to be clearly the case that the responsibility for this does not lie with either Mr. Adams or Mr. Aldridge, but with the Executive Canal Committee, and with this body, Mr. Aldridge points out, some of the members of the Investigating Commission were closely identified. He suggests a reason for the failure of the Commission to investigate this subject very far as follows:

> The member of Assembly who introduced the bill calling for the appropriation of $9,000,000, had in his desk, at the time that bill was introduced, a bill identical with that bill, except that it called for several million more dollars. The introduction of the bill was delayed pending a conference of gentlemen interested in the subject of canal improvement. The conference took place and the main subject of the discussion was as to whether the larger or smaller amount of money should be asked for. The line of the discussion did not run as to whether the work could be accomplished with the $9,000,000 instead of the larger sum, but rather which sum the people were the more likely to grant. I believe the thinking public will be able to see that there may possibly be a motive in the refusal and failure of the commission to satisfy the public on points of deception involved in the question of canal improvement. Perhaps, also, they will see that it was highly desirable, if not absolutely necessary, in order to blind the public as to the responsibility for this deception, to cast aspersions, accuse by innuendo and condemn by wholesale, officials having to do with the expenditure of the improvement funds, even though the work were well done, and even though no suspicion of dishonesty could attach to the public officials in order that they (those interested in canal improvement) might read their titles clear to further appropriations.

Continuing, Mr. Aldridge says that it is nothing strange if in the light of the experience already had with the canal work, better methods could now be suggested for doing some parts of it. "Hindsight is usually better than foresight." Nevertheless, considering the very unfavorable season in which the work had to be chiefly done in order not to interfere with navigation, he "challenges the Commission or the public in general to point to any work of similar magnitude where greater diligence has been shown or where the estimates have come as near to accomplishing the work required to be done as has been accomplished in this instance," and he presents the following comparison of the original estimates and actual costs of various notable public works:

	Cost.	
	Estimate.	Actual.
Erie Canal	$4,926,738	$7,143,789
Enlargement	23,402,863	32,008,851
Oswego Canal	227,000	565,437
Enlargement	1,926,339	2,511,992
Champlain Canal	871,000	1,746,062
Black River Canal	1,068,437	3,157 296
Hoosac Tunnel	1,948,557	20,241,842
Manchester Ship Canal	26,000,000	67,351,105
Chicago Drainage Canal	12,000,000	*37,671,652
Hudson River Improvement	2,000,000	†2,600,000
State Capitol, Albany, N. Y.	4,000,000	24,000,000

*This includes $27,303,216 already expended and an estimate of $10,358,436 to complete work.

†This amount is estimated as needed over and above the first $2,000,000.

Taking up the report seriatim, Mr. Aldridge denies that he had claimed that his responsibility for the character of the work done was limited to the masonry. He also denies, however, that he is in any way responsible for the character of the engineering work on the canals, or that he has discretion to withhold the payments to contractors upon the engineers' monthly estimates except he be in possession of convincing evidence that fraud is being perpetrated, by which the state is to suffer.

In proof that the inspectors as a whole faithfully performed their duties, Mr. Aldridge points to the Commission's declaration that "the quality of the work is generally good, and an improvement upon that heretofore done on our canals."

In reply to the Commission's criticism that there was at times delay in awarding contracts after the receipt of bids, Mr. Aldridge says that after bids were verified and tabulated, it was the practice to refer them to the State Engineer for an opinion as to whether the bids were unbalanced. Necessary absences of the officials in either department might cause some delay in the award of bids.

Mr. Aldridge defends his expenditures for advertising, and holds that the wide publicity thus secured bore its fruit in the very low unit prices under which it is admitted on all hands the contracts were let. If the competition secured by the wide advertising reduced the average price 1 ct. per cu. yd., the saving would pay the entire cost of the advertising.

Concerning the inspectors employed, Mr. Aldridge says that the entire force was subjected to civil service examinations, except at one exigency, when no candidates could be obtained through civil service methods. He denies that any inspector was appointed at any time for political reasons.

The reason why the material excavated from the canal prism was not used in raising the canal banks was that it was in most cases unfit for that purpose. It was, however, used so far as practicable to strengthen the rear of embankments.

Extra work and the overrunning of quantities in the actual work as compared with the engineer's estimate are reviewed by Mr. Aldridge, and he contends that the practice followed is that which is common in the execution of all public works, and that the State suffered no loss whatever. The carrying on of the work on the Jordan Level on a force-account basis was the only method by which it could possibly have been rushed through in time to have the canal ready for use at the opening of navigation.

Mr. Aldridge further replies to the criticisms of the Commission relative to the excavation west of Lockport, the filling of the old basin at Syracuse, and the making of "ordinary repairs" from the canal improvement fund, and concludes his report as follows:

> I wish to say finally that every expenditure from the $9,000,000 fund can be justified in a court of law. No work has been done and paid for out of the fund, excepting that which needed to be done and which is incident to the general improvement. The sweeping statement that a million dollars has been unlawfully expended I repudiate as false, as I do the other suggestion that a million dollars or more has been wasted. Because a sum aggregating upwards of two millions of dollars has been expended for work which hurried plans and surveys could not foretell as needing to be done, is not warrant for any man or any body of men to make the sweeping statement that that sum has been misspent.
>
> One of the eminent engineers attached to the commission has been so fair as to say that the whole trouble lies with the system. While I am willing to be judged by my acts I claim it as unfair that I should be held responsible for a system that has been the outgrowth of three-quarters of a century's conduct of the state's affairs. This same engineer has also said that the state engineer and myself have done as well as, and accomplished as much as, any othres could have accomplished under the same conditions; and also that the money paid out has procured as much work as could probably be expected. I desire to go farther and make the prediction that if the improvement is to be continued no better work will be obtained or less money expended for the same character and amount of work.

ANNUAL CONVENTION, AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.

The fifth annual convention of the Society was held on Oct. 26, 27 and 28, the place of meeting being the Arlington Hotel, Washington, D. C. At the opening session about 60 members were present, but the arrival of other members daily throughout the convention increased the total attendance to 75 or 80. The program was a long one, including a full score of papers, and special and standing committee reports on various questions of municipal improvements, besides the reports of officers, address of welcome, president's address, election of officers and other necessary business, which consumed the whole of one session and portions of two other sessions. In the technical part of the proceedings, the most attention was devoted to questions of sewerage and sanitation, roads and pavements, and water supply, and this report of the convention work will be divided under these three general heads, and the general head of miscellaneous without regard to the exact order in which the several reports and papers were presented. In this way all the information relating to each general phase of municipal work will be collected in one place so far as this report presents it.

Routine Convention Business.

The first session was devoted entirely to the opening exercises, and the transaction of routine business. After a few brief introductory remarks, Mr. Harrison Van Duyne, President of the Society, introduced Mr. John B. Wight, President Board of Commissioners, Dictrict of Columbia, who gave a brief address of welcome to the Convention. Mr. Wight referred to Washington as distinctly a residential city, but stated that it would possibly surprise most of the members to learn that, in proportion to its population, the city also stood fourteenth in the list of manufacturing cities of the country. Mr. Wight also described briefly the progress made by the city in municipal improvements and explained the fiscal system of the District of Columbia and the manner in which it was governed. Speaking of the improvements in prospect, he said:

> Plans are now perfected by which the steam railways will remove their tracks from the streets and do away with the objectionable and deadly grade crossings; the unsightly and unhealthy Eastern branch flats, which are such a menace to health, are soon to be reclaimed; a recent law of Congress will enable us, within a very short time, to compel every house to be connected with running water and supplied with the latest sanitary conditions; a careful study is being made of the subject, with the expectation that soon legislation will be passed enabling us to take down every overhead wire that now exists, and put it under ground.

After a fitting response to Mr. Wight's remarks, President Van Duyne read his formal address to the Convention. The President referred briefly to the meeting places of the four preceding conventions of the Society, and mentioned the value of the information which could be obtained by such visits to the different large cities of the country, and thus ascertaining by personal inspection the results of their systems of municipal organization and management. Turning to the more concrete questions of the Society's work, he said:

> At the convention held last year our committee on street paving recommended, among other things, that where a contractor was required to guarantee his work for a term of years, especially in asphalt pavement, the condition of the pavement at the end of the term should be specifically stated. The city of Newark, N. J., this year partly adopted these suggestions, and instead of paving with asphalt under specifications calling for a five-year guarantee with indefinite requirements, it now requires a ten-year guarantee under bonds given by a responsible trust company, and the exact condition in which the pavement is to be at the end of that term in order to be accepted is stated. Under the old specifications for several years only Trinidad Lake asphalt was used. Last year the bidders were limited to four different kinds, and this year, under the more severe and definite specifications, the door was thrown wide open to all asphalts. Any responsible company or individual giving approved bonds is given the contract, provided the bid is the lowest.
>
> The first asphalt laid in Newark was in the year 1890, and from that time until 1894 it cost about $2.85 per yd. This was laid by the Barber Asphalt Co., and virtually without competition. Last year the price got down to $2.35 per yd., and this year, with the ten-year guarantee, but open to all, the price has been about $1.50 per yd. The city, however, agrees to pay in addition to that amount 25 cts. per yd. for the second term of five years for maintenance and repairs.
>
> We have also required this year a five-year guarantee on oblong granite block pavement, notwithstanding which the price has been reduced from about $2.50 per yd. in 1893 and 1894 to $1.50 per yd. this year when laid on sand, and in like proportion when laid in concrete. Perhaps I should add that New York city, only nine miles away, stopped almost entirely its paving work this year, and that may have helped to reduce the price to the neighboring cities.
>
> The great advance made during the last few years in city development has taken a large amount of money, the annual outlay for expenses has been greatly increased, municipal bonds are becoming a burden, and as a natural result there is such an increase in the tax rate as to cause alarm to many citizens. During this same time in all our cities a wonderful advance has also taken place in the value of the franchises which have been given to so many companies, to use the public streets to carry on their business.
>
> These franchises are worth nearly as much as the land fronting on the streets through which their grants and privileges extend. They have a recognized value to buy and sell, and their earnings and dividends bear out that value; but when it comes to the valuation on which they pay taxes there is a wonderful drop, and the result is that they bear only a small part of the public burdens that properly belong to them, and the tax burdens of others are proportionately increased. I know of no reason why, according to the true value of these properties, they should not contribute their share to the support of the public schools, to the cost of maintaining our courts, and all the other expenses of city and state government, the same as other property.

The next business was the election of members, and 29 new names were added to the roll. The Secretary's report showed that during the past year the income of the Society had been $601.50, and its expenditures the same. In the report of the Treasurer, which followed, the fact was brought out, however, that this satisfactory showing of the Society's finances had been made possible only by the President paying $100 out of his own pocket, and by the Secretary not drawing his salary, which amounted to an additional $100. At present there was in the hands of the Treasurer an unexpended balance of $6.72. The report of the Finance Committee stated further that the present indebtedness of the Society was $210, or, deducting the $6.72 cash on hand, $203.28, and it recommended, in order to clear away this indebtedness, that the dues for the coming year should be increased to $5 for each member. Several further recommendations were made in the report of the Executive Committee, which was next read, all designed to place the affairs of the Society on a more satisfactory basis. All of these recommendations required changes in the Constitution of the Society, and the most important one was that cities should be dropped from the roll of membership and that each individual member should be charged an annual due of $5. These recommendations were adopted by vote of the Convention.

The following officers were elected to serve the Society during the coming year: President, Nelson P. Lewis, Brooklyn, N. Y.; First Vice-President, A. D. Thompson, Peoria, Ill.; Second Vice-President, P. H. Thomas, Parkersburg, W. Va.; Third Vice-President, B. H. Colby, St. Louis, Mo.; Secretary, D. L. Fulton, Allegheny, Pa.; Treasurer, John L. Kennedy, Nashville, Tenn., and Finance Committee, F. J. O'Brien, Oswego, N. Y.; F. A. Twamley, Grand Rapids, Mich., and G. S. Vichery, Bangor, Me.

By vote of the Convention, the city of Toronto, Ont., was selected as the place of meeting of the 1899 Convention of the Society.

Sewerage and Sanitation.

Report Upon the Utilization of Sewage of Vienna, Austria.—This was a translation by Capt. Lansing H. Beach, Engineer Commissioner, Washington, D. C., of the report of the special commission appointed to investigate the question of disposing of the sewage of Vienna, Austria, by utilization and especially to study its fertilizing qualities. The report was of great length and contained numerous tables and only the very briefest summary of its conclusions is possible here. The report stated that the fertilizing material in a cubic meter of Vienna sewage was worth from 3.5 to 15.7 kreutzers, a kreutzer being worth somewhat less than 1 ct. in American money. The commission considered that direct transportation of the sewage to the available land affording an opportunity for such fertilization was not feasible, and that a reduction to powder could not profitably be accomplished. The conduction of the entire sewage to the irrigation fields by canal was recommended as on the whole the best plan, but the commission concluded that while irrigation could be successfully carried out, the system could not be conducted under methods now known at an actual profit. These conclusions, of course, related to the conditions at Vienna only.

Sewerage of Baltimore.—In this paper Mr. Kenneth Allen, Principal Assistant Engineer, Sewerage Commission, Baltimore, Md., outlined briefly the system of sewerage, or rather lack of sewerage, in the city of Baltimore, Md., and described the system recommended by the special commission appointed in 1893 (Eng. News, Dec. 30, 1897). As will be remembered the commission considered either of three plans of disposal available: (1) Dilution in Chesapeake Bay; (2) chemical precipitation, and (3) agricultural filtration. The last named was considered the most perfect method of disposal, but on account of its great cost the commission recommended diultion in Chesapeake Bay as preferable for Baltimore. Mr. Allen stated that this method of disposal was, however, seriously objected to by the oyster trade.

Proposed Sewage Disposal System for Washington, D. C.—In this paper Mr. D. E. McComb, Superintendent of Sewers, Washington, D. C., gave an interesting historical outline of the development of Washington's system of sewers from the first drainage work of 1832 until the present year. Since 1890 the work had followed in all important respects the plans recommended by the board of engineers, consisting of Messrs. Rudolph Hering, Samuel M. Gray, and Frederic P. Stearns, which was appointed by Congress to devise a comprehensive system of sewerage for the city. The amount required to carry out these plans was $3,257,635, and up to the present time the sums expended and available for spending aggregated $772,000. At the present rate of expenditure Mr. McComb stated that the completion of the system as planned might be expected about the year 1925. The paper concluded with a brief description of the rules followed in the sewer construction of the district, from which we abstract the following items:

> Sewers between 8 and 24 ins. in diameter are made of stone-ware pipes laid upon a cradle of concrete masonry, the joints being covered with a concrete enveloping band. Above 24 ins. diameter they are made egg shape until the 4 ft. × 6 ft. size is reached, which is the largest regular section; sewers above that size are considered exceptional and are designed with reference to the location and conditions.
>
> In main sewer work that portion of the sewer which is below the springing line is constructed of concrete masonry, lined with a wearing surface of vitrified brick masonry from the bottom to a line midway between the bottom and the springing line. Above the vitrified brick masonry the lining is of ordinary brickwork, the same thickness as the vitrified brick masonry. In sewers 4 ft. × 6 ft. and smaller, stone ware inverted blocks are laid in addition to the lining of vitrified and ordinary brick masonry, described above. In a few cases of sewers having light gradients, constructed in dry ground, and designed to convey sewage only, unlined concrete sewer inverts have been constructed with satisfactory results. The arches of main sewers are constructed either of ordinary brick or concrete masonry, the selection being controlled by local conditions.
>
> Concrete masonry used in pipe sewer work and elsewhere in walls less than 6 ins. thick is composed of beach pebbles, each particle of which must pass through a 1½-in. ring, mixed with an amount of mortar (composed of cement 1 part, sand 2 parts) which shall be 30% in excess of the volume of voids in the gravel.
>
> Concrete masonry in more massive construction is composed of broken stone, each fragment of which must pass through a 2-in. ring, gravel and mortar. The amount of gravel used equals the volume of voids in the broken stone, and the amount of mortar is 30% in excess of the volume of voids of the mixed stone and gravel.

Some Observations on the Effect of Flushing Devices for Small Sewers—This paper, by Mr. A. E. Phillips, Assistant Engineer, Sewer Department, Washington, D. C., described briefly a short series of experiments made in Washington to determine the action of the discharge of flush tanks in respect to the velocity and depth of the wave produced. The substance of the paper was comprised in a half-dozen or so of diagrams and will be given more fully in a future issue. Briefly stated, however, the diagrams showed the discharge to have a true piston action, that is, the discharge assumed the form of a wave and progressed in this form the whole length of the sewers tested. The velocity of this wave, its volume and length, and the steepness of its front and rear faces varied with the grade of the sewer, and with other conditions. So far as they went, the experiments demonstrated the efficiency of flush tank discharges for scouring sewers of small diameter.

Discussion.—The discussion which followed these four papers was quite brief, and was confined principally to questions by the different members to make clear parts of the papers which had not been fully understood in their reading. In reply to one of these questions Mr. McComb stated that the cost of concrete sewers, as constructed in Washington, was to the cost of brick sewers of the same size about as 7½ to 9. Mr. Phillips stated that altogether there were in use in Washington about 100 flush tanks, all placed at the dead ends of small sewers. These tanks required inspection and repairs as did any other device, and when kept in good order they worked satisfactorily.

Streets and Pavements.

The consideration of the various questions under this heading was opened by a brief paper by Mr. N. P. Lewis, Engineer of Street Construction, Brooklyn, N. Y., which treated chiefly of questions relating to the construction and maintenance of pavements along and between the lines of surface street railways. The paper described the standard street railway track constructions used in Denver, Colo., Detroit, Mich., Cincinnati, O., Minneapolis, Minn., and Washington, D. C. Following Mr. Lewis's report, came a series of tables giving the cost of repairing asphalt pavement in Buffalo, N. Y., which were furnished by Mr. Edward B. Guthrie, M. Am. Soc. C. E. These tables will form a part of the city engineer's coming report, and will be published in that document. In this same connection, Capt. Lansing H. Beach, Engineer Commissioner, District of Columbia, announced that in the coming report of the commissioners to the President, similar figures would be published for all asphalt pavements in the city of Washington. The next paper read was entitled "The Proper Curbing of Streets," and was presented by Mr. Horace Andrews, City Engineer, Albany, N. Y. This was followed by a paper entitled "A Street Extension Plan for the Entire District of Columbia," by Mr. Wm. P. Richards, Assistant Engineer, Washington, D. C.

Relative Values of Paving Materials.—In this paper, Mr. Geo. W. Tillson, Brooklyn, N. Y., presented an attempt to provide a practical working plan for determining the best paving material for any given set of conditions. He divided the desirable qualities for pavements into eight, and allotted to each a certain percentage of the total value, which was, of course, 100. From such information as he could obtain, the writer then allotted to each of the more common paving materials a numerical standing, under each heading. This gave the following table of relative values:

	Values.							
	Standard.	Granite: A*.	Granite: B.†	Asphalt.	Brick.	Belgium.	Macadam.	Cobble.
Cheapness, first cost.	15	2	4	4	3	5	7	14
Durability	21	21	17	13	13	17	7	15
Ease of cleaning	15	11	8	15	12	7	5	2
Resistance to traffic..	15	7	5	15	11	5	5	3
Slipperiness	7	6	5	3	6	4	7	5
Maintenance	10	10	7	6	6	7	3	2
Favorableness, travel.	5	3	2	5	4	2	6	0
Healthiness	13	9	7	13	10	5	5	2
Total	100	69	55	74	65	52	44	43

*Concrete Foundation.
†Gravel and sand foundation.

Tree Planting in the Streets of Washington.—In this paper Mr. Wm. P. Richards, Assistant Engineer, Washington, D. C., stated that in Washington, unlike the practice in most cities, tree planting in the streets was carried on and controlled by the city authorities. The city had a nursery, in which it raised the trees for transplanting, and on an average from 1,000 to 3,000 new trees were planted in the streets each year. The paper enumerated the different kinds of trees which had been employed, and gave their relative value for street use. In order of merit, he placed silver maple, Norway maple and Eastern plane (Platanus orientalis) side by side. In the second rank came the gingko, or maiden hair tree, and the Western plane. Last of all came the American linden, the oak and the sugar maple, which demanded more care, and were especially suitable to wide parkings.

Electric Street Lighting.—The report of this committee was made by Mr. F. W. Cappelen, City Engineer, Minneapolis, Minn. Reviewing the list of cities from which figures of the cost of electric street lighting had been collected in 1896, the report stated that information recently obtained showed that about 30 of them had reduced the price per lamp. In an appendix the report reviewed the experience had with the municipal electric lighting plant at Detroit, Mich., quoting in full the editorial on the report of the Public Lighting Commission of Detroit, published in Engineering News, of Sept. 8, 1898.

Street Cleaning and Disposition of Garbage.—This paper, by Dr. A. R. Reynolds, of Chicago, Ill., was a short and somewhat superficial study of the question of garbage collection and disposal in the city of Chicago. Mr. Reynolds considered that preferably the city should collect the garbage, but in case the work was contracted for, separate contracts should be let for collecting the garbage proper and for collecting the ashes. He also favored regulating the junk trade, so as to make it give an income to the city. The disposal of garbage, Mr. Reynolds regarded as in an experimental stage. He spoke favorably of the possibilities of Lord Kelvin's plan for producing power from the burning of garbage, and gave a variety of figures going to show the value of the commercial products contained in garbage. Mr. Reynolds, however, failed to mention the counterbalancing cost of reduction.

Discussion.—The discussion coming under this division of the convention's work was confined almost entirely to the cost and maintenance of asphalt pavements, and to the closing paper on garbage collection and disposal. Dr. W. C. Woodward, Health Officer, District of Columbia, criticized the idea of separate contracts for collecting garbage and ashes. He thought that a single contract for the collection of both much preferable, for the reason that in the winter the collections of garbage were light and those of ashes were heavy, while in the summer the exact contrary was the case, and if a single contractor made both collections, he could utilize his labor and plant more efficiently by turning them first to one task and then to the other. In Washington, householders were required to keep the garbage and ashes separate and to deposit the garbage in metal receptacles, holding not less than ten and not more than thirty gallons. The collection of garbage, ashes and dead animals was by contract at a cost of $57,000. From April 15 to Nov. 1 daily collections were made, and from Nov. 1 to April 15 the collections were semi-weekly. Disposal was accomplished by towing the garbage down the river in barges and either dumping it, or more generally ploughing it under land for fertilization. The contractor for collection was also the contractor for disposal, and owned the land upon which the refuse was thus employed. The city had had experience with two forms of crematories during the past, and neither had been satisfactory under all conditions and at all times. Mr. Woodward doubted if there was much profit in garbage reduction with present methods, providing sanitary and inoffensive treatment was ensured under all conditions.

Mr. John Jones, Street Commissioner, Toronto, Ont., stated that in that city all garbage and refuse was collected by the city, it having its own plant of carts and horses, even including its own harness-maker, blacksmiths, etc. About 120 horses and carts are employed, and the bulk of the collections were in the winter months. In summer the extra horses were employed on the street sprinkling carts. The city had two crematories for burning its garbage and refuse. He believed that the municipality itself could collect its garbage much better and more cheaply than it could be done by contract.

Water-Works and Water Supply.

The various papers coming under this heading were introduced by a brief verbal report of the special committee on the subject, of which Mr. M. L. Holman, M. Am. Soc. M. E., of St. Louis, Mo., was the chairman. Mr. Holman considered that the great question in water supply, which at present demanded attention in the United States, and particularly in the more densely settled States of the East, was the protection and cleansing of this supply from impurities. He described the work which had had to be done in Europe along these lines, and outlined briefly the theory and methods of sand filtration so extensively used abroad. In the United States, he thought, the time had arrived when National legislation for the protection of sources of public water supply from pollution should be agitated. The questions to be considered were, first, the condition of such supplies; second, the remedy to be adopted, and, finally, the best method of enforcing this remedy. He urged that the Society should take the matter up, and use its efforts to secure adequate National legislation.

Electrolysis at Dayton, O.—In this paper, Mr. Harold P. Brown, New York, N. Y., described the very thorough investigations of damage by electrolysis of water mains at Dayton, O., which were outlined in our issue of Oct. 6, 1898. The conclusions of the paper were:

> (1) It will not be a mistake to follow Dayton's example and obtain complete and accurate information concerning the electrical, chemical and mechanical condition of your pipes, especially in the vicinity of the power house. The trouble may be confined entirely to the lead in the service pipes, and in the calking of joints on your mains; but even here serious damage may result if the matter is neglected for years.
>
> (2) Do not put down any more lead or wrought iron service pipes, as these are the first victims of electrolysis, and their replacing means ruin to pavements. Use instead wooden pipe, banded with a close spiral of hoop iron and covered heavily with asphaltum. This will stand the heaviest pressure in use and is not affected by electrolysis, since the hoop iron is low in conductivity, and is not electrically connected at the joints. Its cost is said to be reasonable, and it has a successful record of many years' service.
>
> (3) Use the same kind of pipe for new mains in any district in which a railway power house is likely to be erected and heavily paint the lead calking of cast iron mains, using asphalt or peroleum wax.
>
> (4) In the danger district along these lines of electric roads and on intersecting streets put into your water and gas mains two or more consecutive lengths of these wooden pipes, so as to break the electrical continuity of the mains and thus make their resistance greater than that of the rails. Fill in the space around them with broken stone and connect with drain if possible.
>
> (5) Midway between the wooden sections on each main attach insulated pilot wires, leading to a central office. Connect similar wires to the rails nearest the pipe and make daily electrical tests at times of heavy load. If any section shows positive to the rails, cut it at once into smaller sections and call upon the railway to rebond its line upon that street. This, with the proper electrical management of the railway feeder wires and apparatus, will effectively protect your mains.

The last paper coming under this heading was by Mr. L. W. Rundlett, City Engineer, St. Paul, Minn., and was on "The Coating of Cast Iron and Steel Riveted Pipes." Mr. Rundlett gave briefly such records of experience with pipe coatings as had been brought out since his more comprehensive paper on the same subject presented at Nashville, in 1897, and published in the 1897 "Proceedings of the Society."

The discussion was quite brief, and was confined principally to the paper on electrolysis. Referring to the recommendations of Mr. Brown for preventing electrolysis Mr. M. L. Holman, St. Louis, Mo., believed that the railways should be required to provide such perfect return circuits that no electricity could get into the ground. Mr. G. H. Benzenberg, Milwaukee, Wis., believed that the proper solution of the question was to recognize the fact that some electricity would certainly get into the pipes, and should be taken care of without damage to the pipes by leading wires from them to a connection with the negative pole of the dynamo. He also took pains to make his water pipes as perfect a return circuit as possible.

Miscellaneous Papers.

Taxation and Assessment.—Mr. August Herrmann, President, Board of Administration, Cincinnati, O., presented in his report upon this topic statistics covering taxation and assessment in 29 American cities, all having over 80,000 population. The figures were very complete, and they will be referred to more fully by Engineering News when they are available for more careful study and comparison.

Municipal Data.—The committee upon this subject, the chairman of which was Mr. C. C. Brown, City Engineer, Bloomington, Ill., advocated the establishment of a bureau of municipal data by the Federal Government, whose duty it should be to collect information concerning the various phases of municipal work, including public improvements, and present a report each year. This bureau, it was suggested, should be a branch of the census bureau, which should be made a permanent bureau. The report contained forms for reports for water-works, sewerage and street improvement work. Upon vote of the convention the executive committee of the society was instructed to take the recommendations of this report under consideration, with power to act in the matter as it deemed best.

The concluding report on "Yearly Review" was presented by Mr. G. H. Benzenburg, and as its caption indicates, was a general review of the field of municipal engineering for the year of 1898.

Formulas for the Volume Enclosed by the Intersection of Two Cylinders—A New Formula for Determining the Fiber Stresses in Concrete and Steel Beams.

TWO ELABORATE RAILWAY TRAINS for the Chicago and California service were on exhibition at Chicago last week. The "California Limited" of the Atchison, Topeka & Santa Fe Ry. consists of a baggage car (without front platform), buffet smoking car, dining car, sleeping cars, and observation car, the latter having a library, writing desks, etc. The specially interesting feature of the train is that it is lighted throughout by electricity, and has little electric reading lamps with frosted glass globes, set just above the backs of the seats. The current is generated for each car by a dynamo driven from one of the axles, a storage battery supplying the current when the car is at rest. This equipment is on the Moskowitz system (Eng. News, Oct. 29, 1896, and May 27, 1897). It was applied by the National Electric Car Lighting Co., of New York and Chicago, which has equipped a number of dining and sleeping cars of this road with the same system. On Nov. 4 the new "California Limited" of the Chicago & Alton, Iron Mountain and Southern Pacific railways made a trip to Joliet and back, with a number of invited guests representing the railways and the technical press. At Joliet a visit was made to the State Penitentiary. This train is very similar to that of the Santa Fe line, but is lighted by Pintsch gas and has compartment sleeping cars in addition to the ordinary sleeping cars.

◆

THE EIGHT-TRACK DRAWBRIDGE over the Chicago Drainage Canal, which has already been the source of much friction and litigation, as noted in our issue of Oct. 20, is again to be made the subject for new bids. As the appeal to the higher courts from the recent adverse decision will consume a great deal of time, and as another adverse decision would cause serious delay, the trustees have decided to invite new bids, but only upon the Scherzer type of bridge, according to the plans and specifications now on file with the chief engineer. This will avoid the trouble arising from comparing bids on structures of different types.

◆

A CIVIL SERVICE EXAMINATION will be held on Dec. 6, at 9 a. m., in New York and other cities where there is a local board of United States civil service examiners, to fill two vacancies in the grade of electrical engineer. One of these is at Fort Caswell, Wilmington, N. C., salary $75 per month, and the other is in the Engineer Department at Large at New York city, salary $150 per month. Those desiring to enter the competition should apply at once to the United States Civil Service Commission, Washington, D. C., for application blanks, Forms 304, 375 and 394.

◆

THE NEW NAVAL DRY-DOCK, soon to be built by the government at Boston, Mass., will have the following dimensions, according to a published interview with officials of the Navy Department: Length, 750 ft.; width on floor, 80 ft.; width at top, 114 ft.; width at entrance, 95 ft.; depth to floor, 40 ft.; depth on sill, 30 ft. It will be built of granite, or concrete faced with granite. The steel caisson-gate will be about 95 ft. long, 36 ft. deep and 24 ft. beam. The pumping plant will include three 45-in. centrifugal pumps. If built entirely of granite, about 576,000 cu. ft. of cut stone and 1,390,000 cu. ft. of rubble masonry will be required; if concrete faced with granite, the quantities would be about 256,000 cu. ft. cut granite and 1,710,000 cu. ft. of concrete. Bids are to be called for in a few weeks.

FLOATING A BOW-LESS STEAMER is a feat lately performed by the Liverpool Salvage Co. The steamer "Milwaukee," a cattle carrier of large dimensions, went on the rocks off the Aberdeenshire coast of England last September. It was found that the forepart was held immovable on the rocks, and the salvage company then determined to cut the hull in two, forward of the boiler-room bulkhead, and save the more valuable part of the ship. This was done by the aid of dynamite; and after the bulkhead had been strengthened by planks and bracing the after two-thirds of the hull, with engines and boilers, was towed into the Tyne, where a new bow will be built to the "Milwaukee."

◆

JAPANESE SHIPBUILDING is being rapidly developed. The Mitsu Bishi Co., of Nagasaki, has just launched the largest steamship built outside of American or European yards. This is the "Hitachi Maru," with 11,680 tons displacement, and a sister ship is being built. At the same port a new granite dock, 371 ft. long, has just been opened. The shipbuilding company mentioned employs 2,000 men, and the "Hitachi Maru" is rated at Lloyds at 100 A1.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred on Nov. 5, at the transfer junction in Council Bluffs, Neb., in which a Union Pacific freight ran, head on, diagonally into the Omaha and St. Louis passenger train. The freight engine struck the tender and baggage car, in which were several men. One person was killed and two were seriously injured.

◆

THE DEATH OF A LOCOMOTIVE ENGINEER while on duty occurred on the Chicago & Alton R. R. on Nov. 8 near Kansas City, Mo. The train, a fast freight, was running at full speed when the fireman, who had been busy in the tender, entered the cab and found the engineer dead.

◆

THE FALL OF A MINE CAGE at the mines of the Lehigh Valley Coal Co., Wilkes-barre, Pa., on Nov. 5, resulted in the death of 7 miners and the fatal injury of 3 others. The accident is said to have resulted from "overwinding," which caused a loaded car to drop upon another car containing 10 miners.

◆

THE COLLAPSE OF A THEATER ROOF in Detroit, Mich., on Nov. 5, killed, according to reports, 15 persons. The building was in course of construction when, without any warning, the heavy roof, supported by steel trusses, fell. The top gallery was carried down and all those in the building at the time were buried under the mass of brick and iron.

◆

AN EXPLOSION OF GAS in the United States Capitol at Washington, D. C., on Nov. 6, wrecked the Supreme Court room and several adjacent rooms, doing in all about $20,000 worth of damage to that portion of the building. First reports stated that a portion of the foundation of the building was badly damaged, and that the valuable law library was largely destroyed. It now appears that the destruction was limited to the interior of the rooms, furniture, fittings and a number of valuable records. The accident is attributed to a leaky gas meter, which permitted a large volume of gas to escape into the rooms composing the damaged section. In some way this was ignited and the explosion followed.

◆

THE "CROATAN," a Clyde Line steamer, was burned at sea on Nov. 1 while about 18 miles north of Cape Charles and 5 out of the 27 persons on board were drowned. The "Croatan" sailed on Oct. 31, south bound, and when 24 hours from port was discovered to be on fire. The flames spread so rapidly that, notwithstanding a smooth sea, it was impossible to launch the life boats, and the passengers and crew had to jump into the sea. They were rescued by a passing schooner.

◆

THE INVESTIGATION OF THE CORNWALL BRIDGE failure on Sept. 6, in which two spans of the new New York & Ottawa R. R. bridge across the St. Lawrence River, at Cornwall, Ont., were precipitated into the water by the failure of the masonry pier between them (Eng. News, Sept. 15, 1898), has disclosed the cause of the accident, according to press dispatches. The diamond drill borings which are being made into the foundation bed of the collapsed pier have shown that the pier was founded on a bed of hard pan barely 2 ft. thick, below which was a muddy deposit into which the drill sank 14 ft. without striking hard bottom. Further borings are being made to determine the conditions more exactly.

◆

AN UMBRELLA LIFT, for the Paris Exposition, is proposed by Mr. R. E. Sherman, of Chicago. It is to be a rival to the Ferris wheel already erected, and the design has been worked out by Mr. H. R. Hinchcliff, an engineer of Chicago. The plan calls for a steel structure 350 ft. high and 250 ft. in diameter when the "umbrella" is spread. There would be a central cylindrical framed stem, serving as a guide for a lower platform supporting ten braced ribs. At the ends of each rib would be a car with a capacity of 50 passengers. Steel cables run from the ends of the ribs to the top of the stem, and the hydraulic lifting power is applied from the moving platform at the bottom of the ribs. There would also be a rotary motion electrically controlled. Application for a site on the Champ de Mars is said to be under favorable consideration. The cars are supposed to make three trips per hour, with an average of 350 passengers per trip.

◆

A SEWAGE FARM OR FILTRATION AREA for the St. Denis Ward of Montreal is under consideration. It is said that plans and a bid for the construction of the work have been submitted to the city authorities by Mr. C. Janin, C. E., and referred to the City Surveyor, Mr. P. W. St. George.

◆

THE FIVE-YEAR GARBAGE CONTRACT at Chicago has again been declared illegal, this time by the State Supreme Court, on appeal by the city. The contract was for the removal and disposal of garbage. The city has been doing the work, pending the decision. Future action will depend, it is supposed, on the conclusions of a garbage commission, composed of the mayor, commissioner of public works and others. The ground for the decision is that the city cannot make a contract payable from yearly appropriations for a period of more than one year.

◆

A MUNICIPAL LIGHTING PLANT is under consideration by the city of Santa Barbara, Cal. The local private company, which has had a monopoly for 12 years, formerly received $156 per lamp per year for about a 5-hour service on a moonlight schedule. The present rate is $108 per lamp per year for 60 lamps for the same service. It is proposed in the design of a municipal plant to use the city water supply, which comes from the mountain under a heavy pressure, to operate turbines and the necessary electrical apparatus.

◆

ANOTHER THAMES TUNNEL, for foot passengers only, is to be built and the London City Council is asking for proposals. The tunnel would have a vertical shaft and stairway at each end and cross between the Poplar and Greenwich sides of the river.

◆

COMMERCIAL EDUCATION was recently discussed by the New York Chamber of Commerce, and it was generally admitted that present educational facilities for those contemplating a business career were inadequate. A special committee of five was appointed to prepare a plan for the establishment and development of a sounder system of education of this sort in the secondary and higher schools. It was pointed out that other nations, and especially Germany, are rapidly developing satisfactory systems of commercial training for young men and reaping marked benefits therefrom.

◆

THE PACKING OF THE AMERICAN COTTON BALE is again causing trouble abroad, regardless of the repeated warning of American consuls on this head. Reports from Liverpool say that English companies are refusing to insure against loss from "wet and mud damage" due to loose and badly packed bales of American cotton. It is estimated that the claims arising from cotton thus damaged and delivered at Liverpool during the last season will aggregate $500.000. The English insurance companies sent an agent to the United States to investigate the cause, and the blame is placed partly upon the producer and partly upon the transportation companies. A closer and better woven covering is urged; but the chief requisite seems to be greater care in both packing and transport, and some decrease in the belief that foreign nations must take our cotton "any how." Indian and Egyptian cotton is an active competitor and the splendid condition in which cotton from these countries arrives in England is in very sharp contrast with our own.

◆

ELECTRIC TRACTION ON NEW YORK STREET railways is rapidly growing. According to a late article in the "Street Railway Journal," nearly four-tenths of the entire Metropolitan system of lines was operated by electricity on Sept. 30, 1898. In the year ending June 30, 1898, about 34¼% of these lines employed cable traction, 20¼% underground electricity, and 45½% horse-power. Reducing the earnings and expenses to the mile basis the following comparison per car-mile is made:

	Gross earnings.	Total expenses.	Net earnings.
Cable lines, cts........	34.42	16.42	18.00
Electric lines, cts......	27.	10.25	16.75
Horse traction, cts......	27.35	17.87	9.50

While the electric lines thus show a less total expense for operation and maintenance than either cable or horse-car, the writer says that this statement may be somewhat misleading, owing to the fact that the electric lines are practically new, and cost for maintenance is only ⅛-ct. per car-mile, as compared with 3½ cts. on the cable lines and ¾-ct. on the horse-car lines. But the article also claims that the experience in New York demonstrates that the underground electric is better than cables in the large cities when traffic is dense and weather conditions favorable.

TWO RECENT MELAN ARCH BRIDGES.

The illustrations presented herewith show two Melan arch bridges erected for Mr. Frederick W. Vanderbilt on his private estate at Hyde-Park-on-the-Hudson, eight miles north of Poughkeepsie. They both cross Crum Elbow Creek, and while only 600 yds. apart, the scenery at the two locations required very different artistic treatment to harmonize the structures with their surroundings.

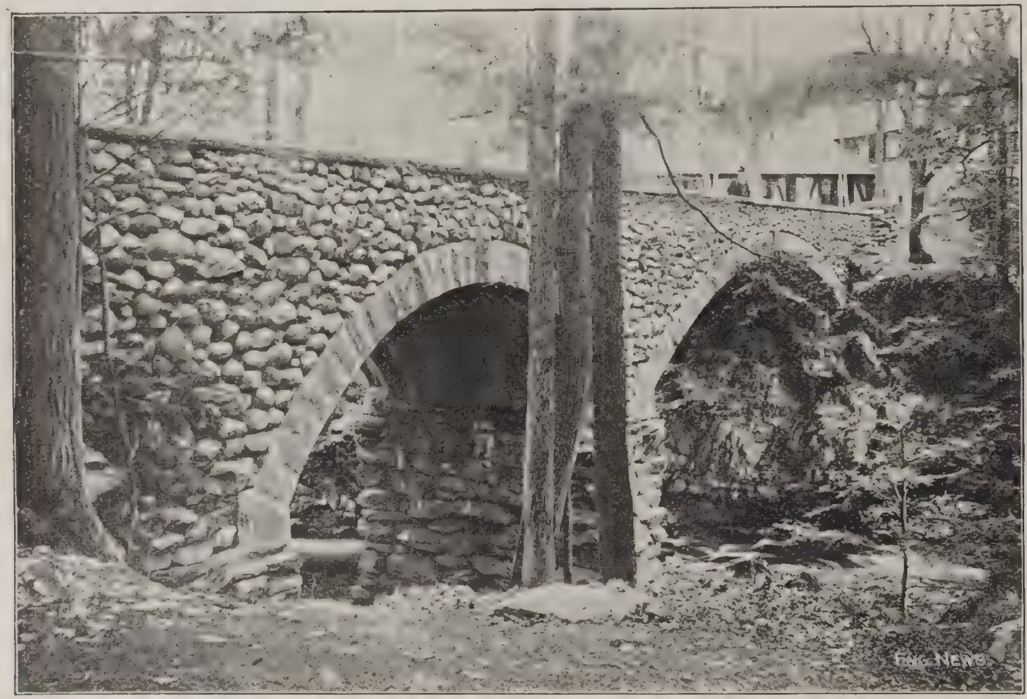

FIG. 1.—MELAN CONCRETE ARCH, WITH FIELD STONE FACING, ON GROUNDS OF FREDERICK W. VANDERBILT, HYDE-PARK-ON-HUDSON, N. Y.

Mr. Vanderbilt, after extended investigation, finally selected the Melan system of concrete-steel arch construction, not only on account of its lower cost with equal permanence as compared with voussoir stone arches, but also because of the ready adaptation of this style of construction to the varying architectural treatment required in different locations.

The structure shown in Fig. 1 with natural surroundings, was faced with unhewn field stone and boulders. It consists of two spans, 53 ft. and 26 ft. in the clear, respectively, and each 7.5 ft. rise, and is 17 ft. wide. The longer arch springs from the rock cliff to the pier and its concrete ring is 10 ins. thick at the crown, and 30 ins. near the springing line, and at right angles to the intrados, embedding five 7-in. steel I-beams bent to the curve of the arch. The shorter span springs from the pier to an abutment founded on a hard strata of gravel and clay. Its concrete ring is 8 ins. thick at the crown and 20 ins. near the springing lines, at right angles to the intrados, with five 5-in. steel I-beams, bent to the curve of the arch, embedded therein. The centers for this bridge were designed to suit the local circumstances.

The bridge shown in Fig. 2, being in a more improved part of the grounds, was given a more elaborate architectural treatment, all exposed surfaces being molded in Portland cement mortar. It has a clear span of 75 ft., with a rise of 14 ft. 8 ins., and a clear roadway of 16 ft., the total width of arch being 20 ft. The intrados is a curve of five centers. The wing walls on the four corners are curved outwards to give better approaches to the bridge and more easy and graceful connections with the driveways. The concrete arch ring is 15 ins. thick at the crown, increasing slowly towards the springing lines to a thickness of 21 ins. at a point 22.5 ft. from the center, and more rapidly from there to the abutments. Embedded in the arch ring are seven 9-in. steel I-beams characteristic of the Melan system, as shown in plan and sections.

One abutment is founded on solid rock, the other on reasonably hard strata of clay and gravel. The concrete in the abutments, spandrel and wing walls was proportioned 1 part Portland cement, 3 parts sand and 6 parts broken stone; near the springing lines of the arch the proportions were gradually changed to those used in the arch ring, which were 1 Portland cement, 2 sand and 4 broken stone. After the completion of the abutments the concreting of the arch was started simultaneously from both sides to the full width of the bridge, and work was continued day and night until the arch ring was completed and the spandrel walls carried up to the copings and expansion joints, in order to make the work monolithic and to avoid all signs of demarkation in connecting old with new concrete. Each of the four wing walls were then carried up as continuous work for the same reason, and expansion joints were provided between spandrel and wing walls to facilitate the free action of the arch under varying temperatures. The entire face finish is in concrete, as is also the balustrade. In all exposed faces, for a thickness of about 1½-in., mortar was used without the broken stone, but in all cases deposited at the same time as the concrete backing. In order to get a very fine finish, the lagging of the centers and all molds for spandrel and wing walls were neatly covered on the inside with a thin coat of plaster, which was oiled before any concrete was deposited.

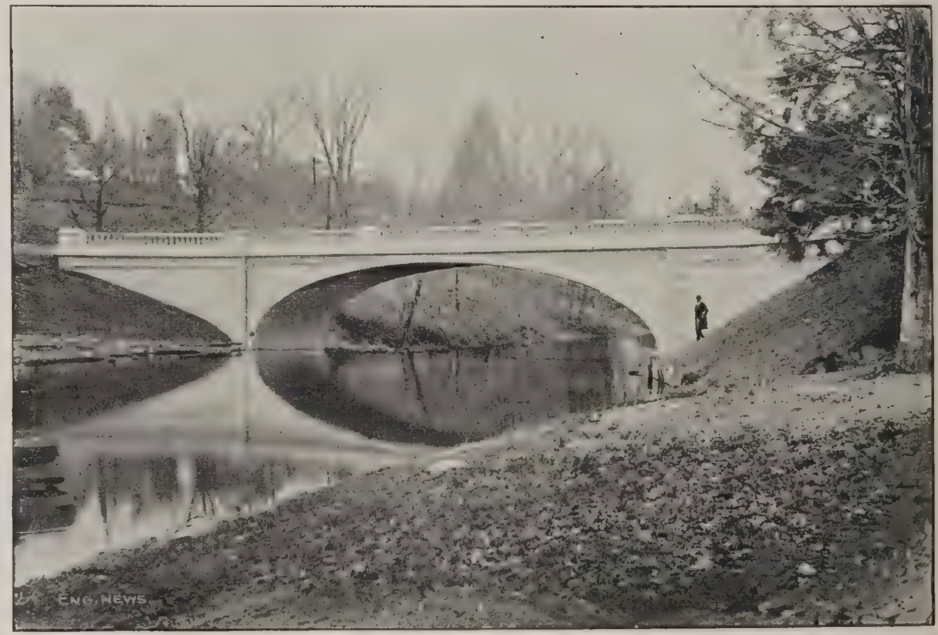

FIG. 2.—MELAN CONCRETE ARCH, WITH MOLDED CONCRETE FINISH, ON F. W. VANDERBILT'S GROUNDS, HYDE-PARK-ON-HUDSON.

The centers for this bridge were constructed to rest on two old piers, which were afterwards removed. The base of the balustrades and the posts were molded in place, but the balusters and top rails were molded or cast in iron or wooden forms, and afterwards set in place exactly as would be done with cut stone. In all parts of the balustrades, concrete, 1 to 2½ to 5, was used, except near the faces where the mortar was without stone.

Mannheimer Portland cement was employed in the two-span bridge, and in the abutments of the single span bridge; and Germania Portland cement for all the remainder of the latter, including the railing. Both bridges were designed and superintended during erection by the Melan Arch Construction Co., 35 Nassau St., New York city, who are also the owners of the U. S. patents covering the Melan arch construction.

THE NEW HYDRAULICS: AN ESSAY FOR ADVANCED STUDENTS IN THE ART, AND FOR THOSE WHO LOOK BENEATH THE SURFACE.

By Clemens Herschel,* Hydraulic Engineer.

To the graduate student or practitioner in hydraulics of the present day, there has always been something disappointing in the art. Here is a science which pretends to give rules and formulae for the discharge of water through orifices and over weirs, when in truth it only indicates what these rules should be, and are not. Instead of being a science founded on fact, and deduced theory, as it set out to be, it has degenerated into a prolix schedule of coefficients to be applied in hydraulic cases as they are met with. So numerous have these coefficients become, that their great number has defeated their very purpose. It has been found impossible to match cases as they arise with their appurtenant coefficients, and engineers have been obliged to practically ignore the most of them, and, instead of using them, to confine themselves in their practice to a very few selected simple cases. Instead of practicing under the guidance of a science of hydraulics, the working hydraulician takes for his mentors only a few simple hydraulic experiments, and by repeating with slavish exactness the apparatus used in the experiments to be followed, he manages merely to allow nature to do for him what she did years before for another. Any step, therefore, that will do away with or merely will reduce the range of the multitude of coefficients now found recorded in hydraulic writings for the practice of hydraulics, will benefit that science very much.

Hydraulics, to look at the situation from another point of view, has not hitherto been able to free itself from the apron-strings of its older sister science of hydrostatics. Instead of noting the conditions obtaining strictly for the water in motion which is to be observed, and confining himself to them alone, the modern hydraulician still encumbers his work with measurements based on, or derived from, a water level which belongs in the domain of the hydrostatics of the case in hand, rather than in that of its hydraulics. Such cases are the measurement of the head on a weir, by measuring from the level of still water upstream from the weir; and determining the head on an orifice, from the position of the orifice and the level of still water upstream from it. Inasmuch as this mode of procedure totally eliminates the form and shape of the weir or orifice—takes no account of the same whatever—the measurements thus taken being precisely the same for any and all kinds of weirs and orifices; and inasmuch as these different kinds of orifices do have, nevertheless, very different unit discharges, it becomes necessary to introduce a host of coefficients to cause this method of procedure to produce the numerous called for practical results.

---

*2 Wall St., New York city, Oct. 5, 1898.

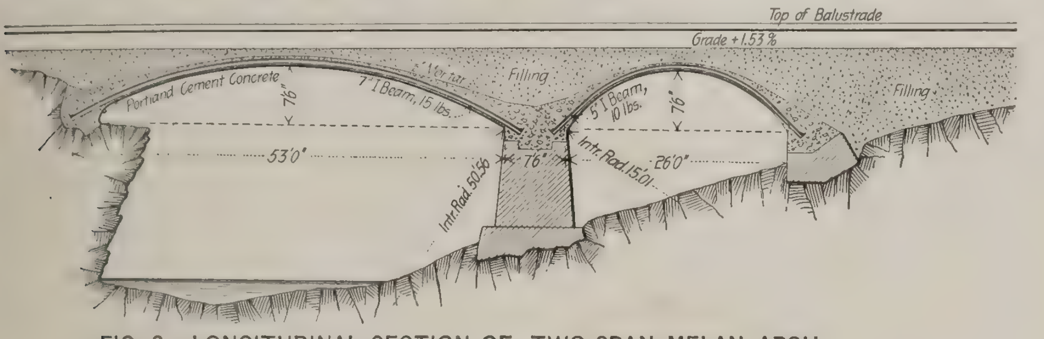

FIG. 3.—LONGITUDINAL SECTION OF TWO-SPAN MELAN ARCH.

But how would it be, were we in these cases to take measurements and observations which would themselves be influenced by the shapes of the orifices and by the velocity of the water passing through them? May we not hope, that the coefficients to be applied to formulae containing data thus obtained, would have a much smaller range and would be much reduced in number, to the manifest benefit of the art and science now spoken of? This has indeed already been shown to be the result of such a method of obtaining data, as will presently appear.

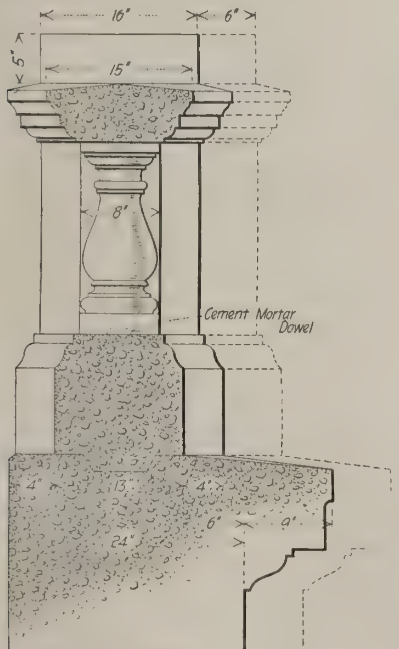

Fig. 5.—Detail Cross-Section of Balustrade for Single-Span Arch.

A method of doing hydraulic work in the manner alluded to must be the next great step to take in the development of practical hydraulics, and there are many signs of the times, plain enough to those who will see them, that point in the stated direction.

Emboldened by what to-day's leading hydraulician, Inspector General H. Bazin, of the Corps des Ponts et Chaussees, says on this point, p. 240, Annales des Ponts et Chaussees, 1898, the writer may claim to have done pioneer work in that direction by the invention of the Venturi water meter in 1886. As many know, this is an instrument whose gaging of a stream of water is based on the observed difference of water level in two piezometers; in which, therefore, static water levels do not appear at all. And it is also known that the range of value of the appurtenant coefficients was found to be surprisingly small. The Venturi water meter has been so often described, that in place of a further description reference is here made to leading articles upon it.*

Another set of experiments made and founded upon the observation of hydraulic heads are those of Mr. John R. Freeman, on the discharge of nozzles,† unhappily named by the author to be experiments made for the purpose of converting the nozzle into a water meter. But a nozzle can never become a water meter, properly speaking. The office of a nozzle is to discharge and waste or throw away water. The office of a water meter is to preserve the water measured, and to treat it as a thing of value. There must always be a large element of incongruity in any attempt to speak of a nozzle as though it were a meter, and much confusion of thought has no doubt followed Mr. Freeman's choice of title. But as an exhibit of the reduction of range, accompanied by an increase of accuracy, in hydraulic coefficients, when based on hydraulic, instead of on hydrostatic observations and measurements, and as a study of piezometer observations, Mr. Freeman's nozzle experiments are of great value.

A third series of such experiments have now been furnished by that Past Master in experimental hydraulics, Inspector General Bazin, in the last number of the Annales des Ponts et Chaussees, 2d trimestre, 1898, in the sixth article of the series describing his experiments on the discharge of weirs. By taking heights on the weir, as measured by means of a pressure tube laid in the body of the crest of the weir, and basing the formulae for the discharge of weirs on such hydraulic heights, instead of on heights derived from still water, which may be called hydrostatic heights, he gets again, as in the experiments above recited, a much smaller range of coefficients for his formulae. M. l'inspecteur general Bazin notes with pleasure that this method of observation and record gives more accurate results than the hydrostatic method, and is to be followed by preference.

Nothing is wanting, then, to enable engineers to use the method of hydraulic coefficients exclusively, except an advocacy and teaching of the practice, and a collection of the new coefficients, derived from experiment.

This article is intended to be an appeal, amongst other things, to engineers and others to begin the collection and publication of such new coefficients. Especially is this appeal addressed to the authorities having in charge the Cornell Hydraulic Laboratory. It has here an opportunity, in the writer's estimation, to practically found for all time a new science, and to make a most able beginning of the many benefits it may in good hands yet confer on mankind.

To illustrate still further the harvest waiting for future laborers in this field, attention may also be called to the conflict between the selected coefficients usually found, and the orifices, weirs, etc., met with in practice. The favorite coefficient is for an orifice or for a weir "in a thin plate"; and with reason; for no others can briefly be described. But the things to which such coefficients are to be applied persist in being almost anything else but holes or notches in "a thin plate."

The most of this contest would at once be done away with by the new hydraulics. It would be developed from experiments on orifices cut in the side walls of vessels of an appreciable thickness, and from choice, of a practical standard form, say a half circle in cross-section; but measuring heads from the indications of pressures at the crown of such a semi-circular edge and the hydraulic water level downstream; not from the static level upstream, to the static level downstream.

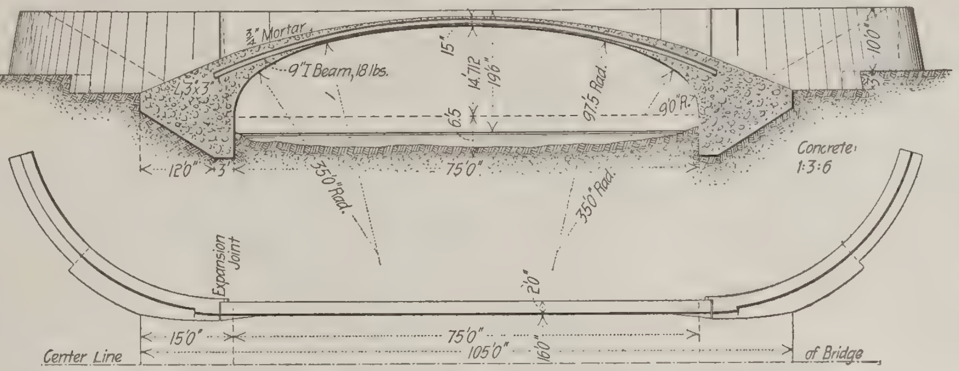

FIG. 4.—LONGITUDINAL SECTION OF SINGLE-SPAN MELAN ARCH.

If these words shall induce future experimental hydraulicians to make a specialty of piezometric observations, and of their application to all forms of discharge measurements, their object will have been attained. That the results will be most useful and beneficial to succeeding generations is the writer's firm conviction.

◆

THE CAPTURED SPANISH CRUISER "MARIA Teresa," raised by the government at Santiago, was abandoned at sea, on Nov. 4, during a storm, while on her way to the United States. The "Maria Teresa" was a 7,000-ton armored cruiser, built at Bilboa, Spain, in 1890; her engines developed 13,758 I. HP., and this gave her a speed of 20.25 knots. After the battle of Santiago, she was raised by the Merritt-Chapman Wrecking Co., under the superintnedence of Naval Constructor Hobson. She was towed into Guantanamo harbor, and after being patched up, she started for Norfolk, Va., under her own steam, on Oct. 29. She was accompanied by the repair ship "Vulcan" and the wrecking tug "Merritt." On Nov. 1, when about 310 miles from the port from which she started, and in 24° N. Lat. and 74.30° W. Long., she encountered a heavy northeast gale and labored heavily; under the strain many new leaks appeared at the butts and seams of plates; the water gradually gained until it came into the firerooms, and the ship was finally abandoned in a sinking condition. The "Merritt" returned to hunt for her after the tow line parted, but could not find her. It is supposed that in addition to the damage to the hull by going on the rocks, the firece fire on board this vessel heated and warped the deck-beams, which later contracted again, and that this action imposed great strains upon the hull of the ship and possibly partly sheared some of the plate-rivets. If this were the case the subsequent leakage at these plates under the strain imposed by the storm would explain the disaster. Later accounts say that she may be still afloat, or stranded on Cat Island, as a vessel answering her description has been reported in that neighborhood.

STEEL HEAD FRAME FOR THE PHILADELPHIA & READING COAL & IRON CO.'S MINES AT GILBERTON, PA.

By W. L. Cowles, M. Am. Soc. C. E.*

Among the latest and most interesting examples of the rapid extension of the use of steel in construction is its employment in the erection of head frames for mine shafts, which were formerly made of heavy timber framing. Several specimens of steel or iron head frames erected in earlier years are to be found in the coal regions of Eastern Pennsylvania, but within the past two years the development of this branch of structural engineering has been rapid, and a number of steel head frames have been erected in the vicinity of Wilkesbarre and Pottsville. The most recent practice in this line is exemplified in a steel head frame completed a short time since for the Philadelphia & Reading Coal & Iron Co. for their new water shaft at Gilberton, Pa., illustrations of which are presented here.

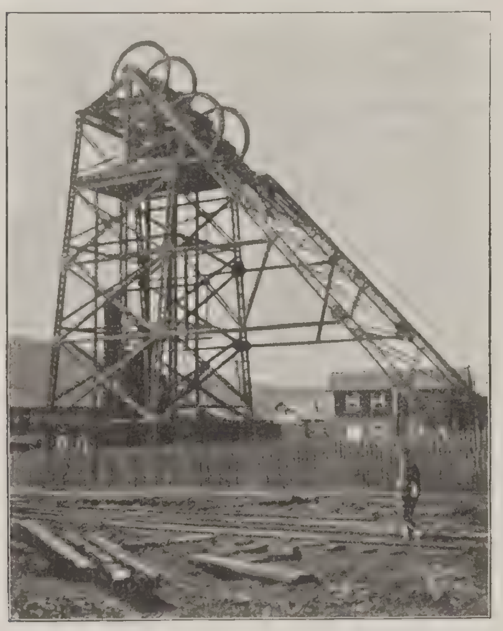

Fig. 1. Perspective View of Steel Head Frame for the Philadelphia & Reading Coal and Iron Mines, at Gilberton, Pa.

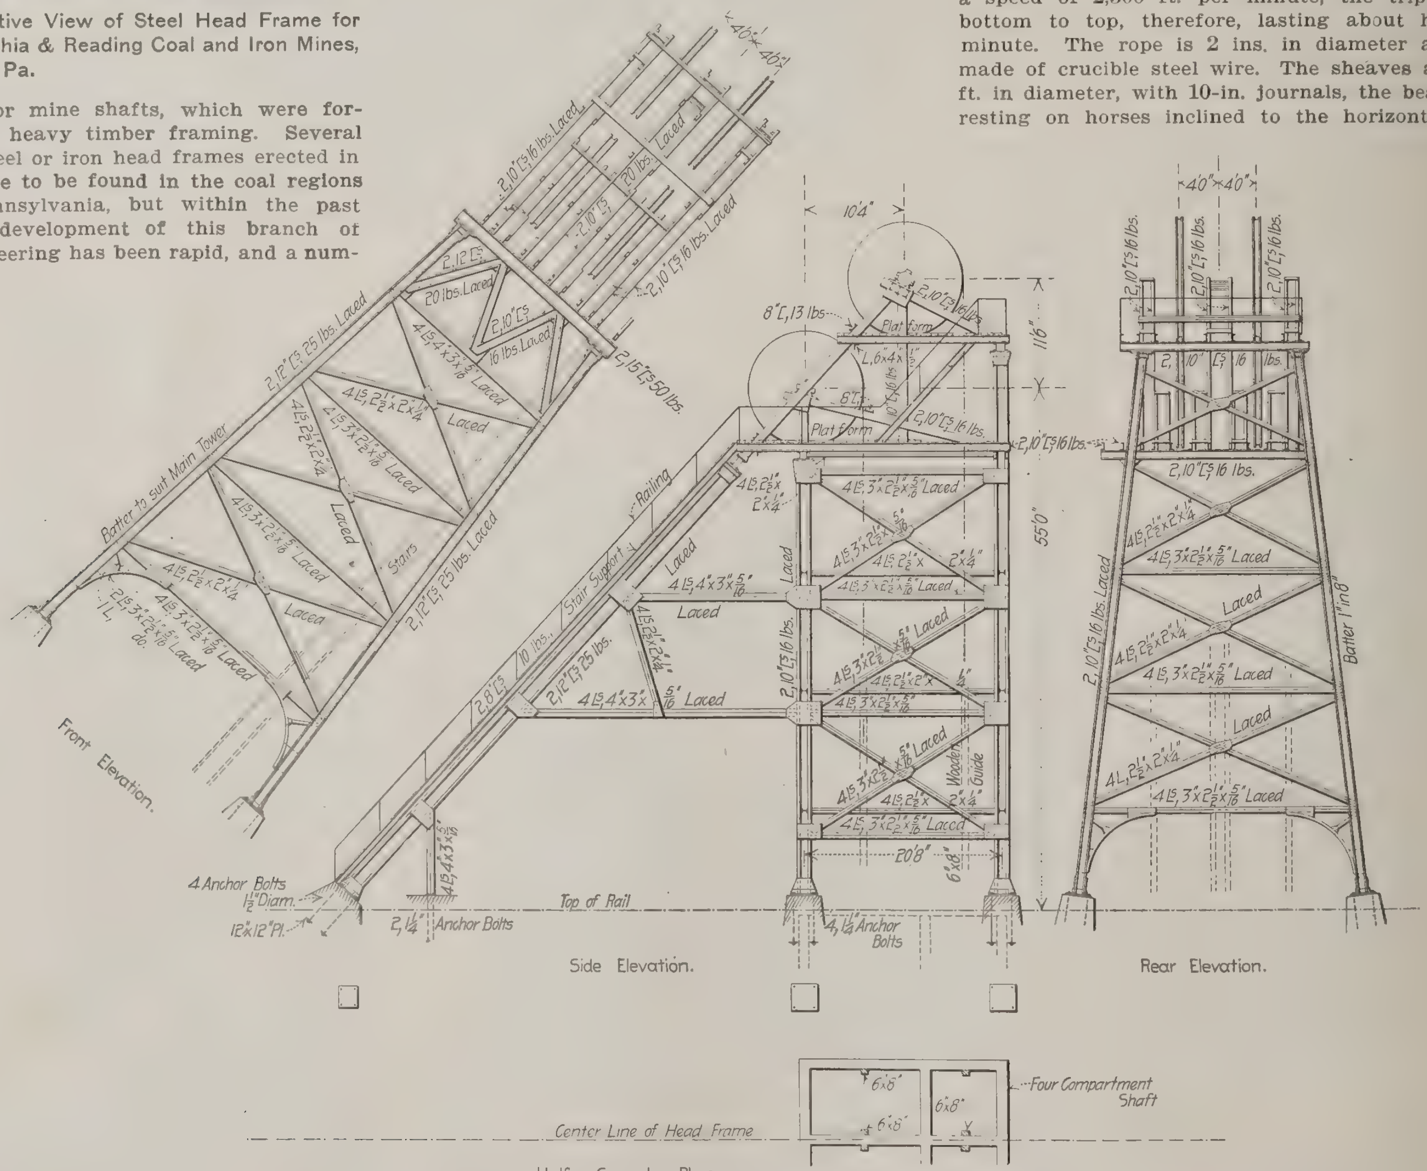

FIG. 2. ELEVATION OF STEEL HEAD FRAME FOR THE PHILADELPHIA & READING COAL AND IRON MINES, AT GILBERTON, PA.

Pottsville Iron & Steel Co., Builders.

Plans had been prepared for erecting this structure in wood, but an investigation of its cost as compared with the cost of a steel structure, taking into consideration the relative life of wood and steel based upon experience in first-class railway bridge work, led the company to accept the proposed plan for a steel head frame. The superior rigidity of the steel frame, being riveted throughout, over the timber framing which, being bolted, is subject to continual readjustment and tightening up on account of shrinkage and racking, also had great weight in deciding the company to adopt the steel construction.

The Gilberton shaft is 1,100 ft. in depth and is divided into four compartments. It is located in a valley between two hills, in each of which are extensive collieries, and is intended to drain all the workings by means of tunnels connecting them with the bottom of the shaft, replacing a large number of independent pumps now operated continuously at great expense.

The two compartments nearest to the engines are used for hoisting water and are served by the engine nearest to the shaft, while the other two are ordinarily used for hoisting coal and rock, although in case of emergency they can also be used for water. The special arrangement of the shaft renders it necessary to place the sheaves serving the two front compartments, or those farthest from the engines, in front of and higher than the sheaves for the two rear compartments, and the engine operating the former must likewise be placed behind and higher than the engine operating the latter.

The center plane of the back brace produced passes through the centers of the two pairs of sheaves, which are so located that the line of resultant pressure produced by the load in the shaft and the pull from the engine falls slightly below this plane, thereby avoiding all overturning moment and throwing nearly all the pressure produced by hoisting directly upon the back brace. The main tower, therefore, carries practically no load except that resulting from its own weight and that of the sheaves and their frames, and its principal office is to provide a substantial and well-braced support for the sheave frames and sheaves and, by means of heavy cross struts, a secure and rigid connection for the tops of the shaft guides. The bracing is stiff throughout, consisting of four angles, laced, in I-section both for horizontal struts and diagonals, and all connections are riveted. The back brace is securely held and stiffened by struts running to the main tower and, together with the feet of the tower, is anchored to the heavy masonry foundation by 1½ in. steel bolts.

From the fact that in operating the shaft one car or bucket of a pair is filled, while the other is light, the back brace is nearly always unsymmetrically loaded, a condition which is provided for by a system of trussing at the top of the back brace, which efficiently distributes the stresses. The frequent reversal of load causes a constant racking of the structure which necessitates the use of heavy and rigid lateral bracing.

Provision is made for a working load of 20 tons in each compartment of the shaft and the engines have a capacity for raising these loads at a speed of 2,300 ft. per minute, the trip from bottom to top, therefore, lasting about half a minute. The rope is 2 ins. in diameter and is made of crucible steel wire. The sheaves are 14 ft. in diameter, with 10-in. journals, the bearings resting on horses inclined to the horizontal, so that the resultant of the live load is nearly normal to them. These horses are thoroughly braced and the frames of which they form a part are so placed that those supporting the lower sheaves are between and in contact with those supporting the upper sheaves and, being well bolted together, the construction becomes quite homogeneous, affording the maximum of rigidity. Access to the sheave platforms for purposes of oiling and inspection is provided by means of a stairway following the slope of the back brace, and consisting of channel iron strings with white pine treads and protected by a substantial gas-pipe railing.

---

*Keystone Bridge Co., Pittsburg, Pa., late Chief Engineer Pottsville Iron & Steel Co.

The head frame was built by the Pottsville Iron & Steel Co. from drawings prepared by their head draftsman, J. S. Branne, C. E.,† after the designs of the writer, who was at the time chief engineer for the company.

◆

AN ELECTRICAL SURVEY IN THE BOROUGH OF MANHATTAN.

It has heretofore been supposed that, inasmuch as New York city had been successful in preventing the building of electric railways operated by overhead trolleys on Manhattan Island, the water pipes, gas mains, etc., were free from the danger of rapid electrolytic corrosion.

In a paper just read before The American Institute of Electrical Engineers, however, the author shows that stray earth currents are to be found on the water and gas pipes in various parts of Manhattan Island, and in the part adjacent to the Harlem River and in the lower portion of the city these currents are sufficiently strong to furnish a possibility of serious injury to underground piping. The author of the paper, Mr. A. A. Knudson, began his investigations to determine whether any current from the conduit electric railway on Lenox Ave. was escaping from the conductors to the ground. It will be remembered that in this system the rails are not relied upon for a return conductor, but both positive and negative conductors are placed within the conduit and insulated. The tests showed that there was no ground current discernible from the conduit electric system; but that an overhead trolley railway in 135th St. was furnishing a very noticeable ground current, amounting in some cases to from 2 to 2¼ volts. In addition to this, a small but steady current flow was found with a potential of 1-30 to 7-30 volt, which was finally determined to proceed from an incandescent lighting system. This last current was found over a large area of the city.

As an illustration of the corrosive action of electric currents escaping from metal, the author gives the following:

Attention is now directed to the east side of this part of the city where another branch of the Union railway is located. Tests made here show even more pronounced results than at the branch running through 135th St. to the west side. It may be stated that the power-station of this road is located on the Bronx river in Westchester county.

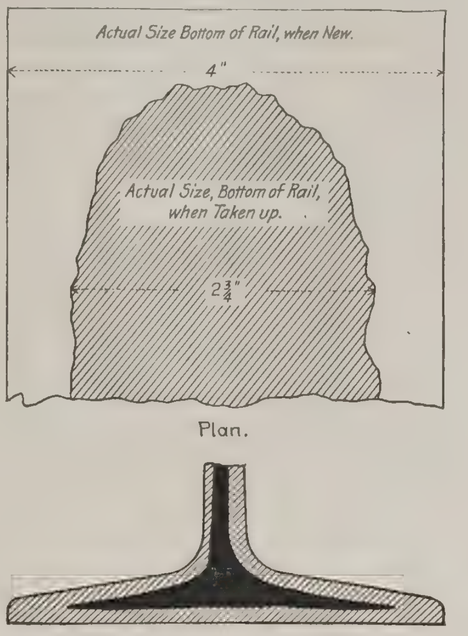
Something more than a year ago when these tests were made, this branch had a terminus at Third Ave and 129th St., immediately in front of the Elevated Ry. station, the cars then passing over the Harlem river at the old wooden bridge, which is now being removed. The cars now pass over the public bridge recently opened, to the new terminal at Lexington Ave.

The maximum reading here was 10 volts, and the average 2 volts. The rails were positive to the elevated railroad pillars and to sewer and gas pipes. Tests on the Harlem bridge showed the same reading. A few days ago this locality was visited with a view of obtaining any further items which might be of interest for this paper, and workmen were found engaged in removing the rails of this very terminal.

Information was therefore obtained as to the results of electrolytic action on these rails (they having been positive). An impression was taken on paper of the exact size and shape of the end of one of the four rails which composed that terminal switch, the ends of the other rails all being in just about the same condition. Fig. 1 shows a comparison of the size and shape of the rail when new and its present condition; the position of the outlines as to each other being about as shown. From the condition of these rails now, it is quite plain that a large amount of metal has been removed from them by electrolysis. The rails were originally 70 lbs. per yd.; furthermore, the bottom sides of all these rails were cut by the current down to knife edges for several feet back from the ends. These edges were irregular in shape and somewhat jagged in appearance.

Another feature of interest is the condition of the crossbars or tie-rods which keep the rails in position. These bars, which were originally 1½ ins. wide by ⅝-in. thick, were nearly all so eaten away that the middle portion was missing, the ends protruding from the rails from 6 ins. to 12 ins.

The concluding portion of Mr. Knudson's paper referred to the stray trolley current of which he found evidences near the lower end of Manhattan Island, and his examinations to determine the effect which such a current might have on the Brooklyn Bridge. We print it, substantially in full as follows:



Actual Size Bottom of Rail, when New.
4"
Actual Size, Bottom of Rail, when Taken up.
2¾"
Plan.
Section.

Fig. 1.—Plan and Section Showing Electrolytic Corrosion of Ends of Rails at Terminal of Union Ry. 3d Ave. and 129th St., New York city.

Just why there should be indications of a trolley current in this part of Manhattan Island was difficult to understand, but after making further tests coming up on the east side, this current was found to come from the Brooklyn bridge. Having pointed out how an overhead trolley, using the water pipes and incidentally the rails as a return, such as is operated on 135th St., can spread its influence, so to speak, for a distance of over 20 blocks in either direction north and south, through various pipes, railway structures, etc., the existence of this current from the bridge permeating underground metals through a large portion of the lower part of the city, is accounted for.

The tests were continued at the New York entrance of the bridge, and at the pillars which stand in the street just west of the Third Ave. cable railway, I found the readings as follows: At one pillar a maximum of 3 volts, average 1½ volts, pillar positive to Third Ave. cable rails. At another practically the same reading. Further up Park Row at the corner of Chambers St., pillar positive to cable rails, 1 volt maximum; water positive to cable rails ½-volt; pillar positive to water ⅓-volt.

All of these tests were made nearly a year and a half ago. A few days ago, tests were made over this same ground, and at places where a difference of potential of 3 volts maximum existed at that time, it is now found to be 3 1-5 volts, pillars positive as before to rails of Third Ave. cable and also to water pipes, showing in all probability that this current has been during all this time actively and unceasingly passing down the pillars which support the "L" station at this place, as well as the bridge crossing the street, and out from their foundations to other metals as stated, with now a fifth of a volt more for good measure.

In the light of present knowledge on this subject the very serious question presents itself to any practical mind here present, in what condition would we expect to find the anchor bolts and iron foundations of these pillars, if excavations were made at their base?

In Mr. Farnham's excellent paper read before this Institute four years ago (Eng. News, May 3, 1894) he showed that but a small fraction of a volt was necessary to establish electrolytic action between metals. What then can be expected from an incessant action of from 1½ to 3 1-5 volts jumping out of these foundations during the past year and a half or perhaps two years?

Further tests at the New York entrance of the bridge at pillars nearest the four loop tracks, show that they are negative to rails of these tracks with maximum voltage of 3¼ and estimated average of 2¼. These tests were made on three different days at different times of the day, the highest maximum reading as above being taken at 4:45 p. m.

The other tests, one made during the so-called rush hour between 5:30 and 6 p. m., where a maximum reading of 2 1-5 volts noted at track 1, did not vary much from the tests made in the afternoon of another day at from 2 to 2:30 p. m. at track 4, where the voltage was found to be 2⅓ maximum. Previous to any use of electricity for operating cars on the bridge it had been known that current were escaping to that structure from trolley lines in Brooklyn, and passing over would find their way through the city by underground pipes, etc., and thence crossing the river arrive back to the power-station in Kent Ave.

The polarity of both of these railway systems now operated on the bridge, indicates that these currents escape from their lines, but it is also quite likely that currents are even now coming over the bridge as they were a year ago. Only an extended investigation would determine these points, even if it were desirable that they should be known.

Let us now take up the investigation made on the bridge to determine if possible the movements of straying trolley currents and their possible effect on the cable terminals. In view of the importance of this matter I regret not being able to make it more thorough than here stated, as it would involve not only a fortnight's work at least, but the shutting down of the bridge plant for a time, which could hardly be expected under the circumstances. Such facts are represented, however, as it was practicable to obtain.

In regard to the construction of the cable terminals; as most of us know, the main cables are made up of eighteen strands, or smaller cables, which are practically continuous, the wire running back and forth from New York to Brooklyn, passing through the holes at the ends of heavy steel bars or links at each place, and the ends of the single wire being finally fastened by a rigid screw coupling. These two rows of steel bars of nine each, which are attached to the cable strands, one row placed over the other, pass down with a graceful curve into solid stone masonry to the anchor-plates, and are secured to them by heavy steel bolts passing through the eyes at the ends. The anchor-plates are in shape somewhat longer one way than the other, each being a single piece of cast iron, weighing twenty-three tons.

Coming now to the tests, it will be noticed that there is no possibility of reaching the anchor-plates other than by connection through the cables themselves, and they being firmly attached to the structure, cables and all are practically one conductor; and a connection on the structure would mean connection with the cables, and consequently with the anchor-plates.

This point therefore being settled, the next thing was to obtain a suitable ground, and on the suggestion of Mr. C. B. Martin, the electrician of the bridge, one of the railway cables was used during that portion of the day when it was not in operation for hauling a bridge train. This was a convenient as well as a good ground, the cable surface being polished bright through friction in passing over the pulleys, it was possible to obtain a good contact, and as it passed over the large drums in the engine-room which were on foundations connecting with engines, water-pipes, etc., it was probably the best ground independent of the structure obtainable. The connection to the structure was made by the use of a 2-in. screw-clamp, the wire to the voltmeter being attached to it by the simple means of a screw and washer. Two of these clamps were generally used in nearly all of the previous tests, as they were found very convenient for attaching and detaching quickly to and from hydrants, pillars, etc. The first test under these conditions was made just over the Brooklyn anchorage, where the structure was found to be positive to the ground, with a difference of potential of 2¾ volts maximum, estimated average 1¾ volts.

At the Brooklyn tower another ground connection was made to a water-pipe, which ran down the side of the tower, and is intended for use in case of fire on the bridge. At this point the reading was 3¾ volts maximum, average 2¾, bridge structure was as before positive. At center of span, structure positive at first, with 2¼ volts maximum, but during the readings there were two reversals one of them only remaining long enough to obtain a reading, which was 1¼ volts maximum, structure negative. At the New York tower, structure positive to cable ground, with trolley variations ranging from ¾ths to 3 volts, average 2 volts. At New York anchorage: maximum 2¾ volts, average 2 volts, structure positive to ground.

Other tests were made to determine the polarity of the rails of the bridge trains, and they were found positive to the structure, the same as the rails of the trolley road heretofore tested. Let us now consider the question of the electrolytical conditions of the cable anchorages, as this point appears to be of high importance in this matter, if not the key to the whole situation in determining whether or not electrolytic action is going on. First: These anchorages are composed of solid stone masonry and are put together with the highest quality of cement; there is no brickwork or mortar in their construction.

2. The 23 tons of iron composing the plates are set about 80 feet below the top of the anchorage. The distance from the bottom of the plates to mean high water is 3 ft. 8 ins. at the New York end, 5 ft. at the Brooklyn end; there is no earthly matter, salts or alkalies, such as is found prevalent in the streets which go to make up an electrolyte, so I am informed, in any part of this structure.

I was at first apprehensive that on account of the comparatively short distance between mean high water and the plates at both anchorages there might be opportunity for salt water to reach the plates through seepage or capillary attraction and thereby produce such an electrolyte as to cause corrosion, but have been informed that it is not possible for salt water to reach these terminal plates on account of the distance from the river, the anchorages being over 900 ft. from the towers which stand at each side of the river. Even allowing 100 ft. for the salt water to work back, there is still ample margin as to distance before salt water can reach these plates.

---

†Now Chf. Eng. of Koken Iron Works, St. Louis, Mo.

In view of the tests therefore that have been made showing the structure and the cables to be positive at both ends, it is quite possible that a portion of the currents straying from the trolley lines, and possibly from the bridge service, find their way out of the anchor plates through the dampness of the stone-work of these anchorages. The construction of these anchorages, however, is such, as I have endeavored to set forth, that it seems reasonable from the general construction of these piers that the mass of stone and concrete surrounding these plates will not constitute an electrolyte such as would favor electrolysis, and thereby cause corrosive action on them.

The damages already done and threatened to public works in England by electrolysis has led to the establishment of regulations to prevent such action in the future, and similar legislation may be expected in this country should these conditions be allowed to continue. One of the provisions in the regulations prescribed by the British Board of Trade may be of interest just here. It is to the effect that if the pipe is negative to the rails the potential difference shall not exceed 4.5 volts, and if the pipe is positive to the rails the potential difference shall not exceed 1.5 volts. This appears to be very liberal for the railways, in view of the experience in cities on this side of the water; it is probable, however, they will be made more stringent as future experience in this direction dictates.

I have purposely avoided elaborating any particular scheme for preventing damage by stray railway currents in this paper, for the reason that methods are perfectly well known to railway companies for confining currents to their proper conductors, such as efficient bonding, and providing a return that will leave no inducement for the current to seek underground pipes, in preference to a legitimate conductor. It is simply a question of additional expense. Referring to the incandescent light current which was found prevailing everywhere in this part of the city from the Harlem river to the Battery, passing between all kinds of underground metals, and some on the surface, I do not consider these currents as particularly dangerous at the moment on account of their low voltage, but as before stated, it having been established that a fraction of a volt difference of potential will cause electrolytic action, it then comes down simply to a question of time, when those straying incandescent currents will have to be seriously considered.

In conclusion, I wish to say that these remarks regarding possible damage to public structures through the action of electrolysis, have been made with no desire on my part to appear as an alarmist, but to present simple facts as found in these investigations. I believe that too little attention has heretofore been paid to this matter by any of us; perhaps for the reason that electrolytic action being invisible, as well as noiseless, it has thus escaped attention, and its baneful effects not fully appreciated. It is my opinion, however, that ordinary caution would suggest that periodical tests should be made in every city by competent parties where a trolley road using a ground return is in operation, and the reports placed before those having authority to deal with the matter. In this way threatened damage by electrolysis to water and other pipes, as well as bridges, might be arrested and finally controlled.

ANNUAL REPORT OF THE BUREAU OF STEAM ENGINEERING, U. S. N.

The annual report of Commodore Melville, Chief of the Bureau of Steam Engineering, to the Secretary of the Navy, covers a period of most unusual activity, and the report shows that this bureau has well met the extraordinary emergency demands placed upon it.

Including the $430,613, alloted from the national defense fund, the appropriations for steam machinery in the last fiscal year aggregated $6,665,613; but of this amount only $1,922,054 had been actually expended up to Sept. 1, 1898. The work immediately necessary on the breaking out of the war was not so much extensive repairs to ships in commission as the fitting out of every available ship in ordinary, with the view of getting some service out of each in an emergency. In three of the old monitors at League Island worn-out boilers were replaced by new ones in 30 days, by the Babcock & Wilcox Co.; and this was done without cutting the decks, the boiler sections being passed through the smoke-pipe openings. The greatest amount of labor was expended in fitting out 110 vessels of the auxiliary navy, purchased, chartered or transferred to the government. Few of these vessels were provided with evaporators or distillers, and they all required outfits of stores and tools. After leaving the yards a number of these ships were partially disabled, as a result of the novelty of the machinery to the crews and the emergency of war which made it necessary to start them out before the men were familiar with this new machinery. One result of this experience is the demonstration of the importance of modernizing and stocking the naval station at Key West, the least accessible of all our stations. Liberal appropriations should also be made at once for correcting faults developed at the various navy-yards and stations, both in building and machine tools.

The greatest amount of repair and outfitting work was done at the New York Navy Yard; and of the 86 vessels repaired there during the fiscal year, 73 were handled in 90 days. At the Norfolk Navy Yard 72 vessels were repaired and fitted out in the year; of which 46 came within the 90-day limit. At Key West repairs were made to 64 vessels in the last year, and to 37 more in July of the present fiscal year.

The report deals in detail with the condition of the machinery of our naval vessels completed and authorized prior to March 2, 1883, and in nearly every case engines and boilers are rated as "good." A similar report of conditions and progress is given of vessels completed or building during the year ending Aug. 1, 1898.

Under the head of material it is noted that nickel-steel engine forgings have been brought to a high degree of perfection; and seamless drawn steel boiler tubes have been made of a degree of excellence undreamed of a few years ago. These seamless drawn steel tubes, with wrought steel flanges welded on, are now substituted for the copper and brass steam and feed pipes on destroyers and torpedo-boats. Owing to the temperature corresponding to the high pressures carried on these boats the copper and brass pipes formerly used lost a large percentage of their strength. The change in the machinery of the new battleships of the "Alabama" class, without hull changes, necessitates the reduction of the thickness of the shell plates for cylindrical boilers. In the "Alabama" class this thickness had reached 1 7-16 in. in material, having a tensile strength of over 65,000 lbs., an elastic limit of over 35,000 lbs. and an elongation of 24% in 8 ins. Experiments have been made on a higher carbon steel, oil-tempered and annealed, which has a tensile strength of over 74,000 lbs., an elastic limit of over 40,000 lbs., an elongation of over 21% and a very satisfactory cold-bending test. With the higher pressures called for in the new battleships this steel would allow a slight reduction in thickness. With this high-grade boiler plate, nickel-steel bracing and rivets will be used.

The use of water-tube boilers is increasing in all foreign navies, and the experience of the last year would warrant us in using boilers of this type in all our ships, says Commodore Melville. That contracts for the new battleships were awarded on the basis of cylindrical boilers is explained as follows: The Bureau designed and was anxious to use water tube boilers; but, as it was decided that these ships should be practically identical with the "Alabama" class, without change in hulls, the use of the water-tube boilers would have involved a readjustment of hull weights to maintain the trim. But in the Department circular of July 26, asking for designs for higher speeds and greater endurance, builders were encouraged to use the water-tube boilers, as the easiest way to secure the desired rsults. The bids received on Sept. 1 justify this idea and it is practically certain that the new type of boiler will be used, and all machinery will be of the most modern type. The present demand upon the naval engineer for great power on small weight, to secure the higher speed deemed necessary, practically rules out the cylindrical boiler, on account of its weight and its inability to carry the high pressure needed. The tactical importance of water-tube boilers was demonstrated by the conditions existing at Santiago previous to and upon July 3. It was necessary for a long period that all the ships should be ready to develop maximum power in a few minutes. With cylindrical boilers this involved keeping all the boilers under steam, with heavily banked fires and the attendant large consumption of coal. Proper water-tube boilers, admitting of the rapid raising of steam with safety, remove this difficulty and place the fighting machine under better control. Another great advantage is that water-tube boilers can be replaced, or practically rebuilt, without disturbing the decks.

The experiments with liquid fuel, on the torpedo-boat "Stiletto," were very satisfactory, though the economy over coal was not high, owing to the fact that the machinery was not specially adapted to oil fuel. The oil used had a specific gravity of 0.85 to 0.87, a flash point of about 315°F. and a burning point of about 350°F. As a bunch of burning waste was extinguished when plunged into this oil, there can be no doubt of its perfect safety for use on board ship.

Uniformity in machinery in naval vessels, as divided into classes, is an especially important feature; as it permits a reduction in the number of spare parts, facilitates repairs and enables a transfer of crew to another vessel of the same class, ready to at once get the best work out of familiar machinery.

The repair ship "Vulcan," fitted out during this war, did invaluable service. This ship arrived at Guantanamo on July 1, and by the end of August she had made repairs on 63 ships and had furnished supplies to 60 ships. The "'Vulcan" was fitted with machine tools, cupola, forges, brass furnaces, etc., and carried a crew of 100 skilled mechanics. The usefulness of distilling ships was also proven in the war, though the two vessels thus equipped were not completed before active operations were over. It was shown that a multiple-effect evaporating machine could be made which would give 20 lbs. of fresh water for every pound of coal burned in the boilers; and such a vessel could supply 50,000 to 60,000 gallons of water per day and carry 3,000 tons of coal, supplying a large number of tank vessels and serving as a collier in case coal was more useful than water. The Bureau deems a distilling ship of vital necessity for a fleet of any size; and the cost of thus supplying fresh water is very much less than the purchase of water under any except the most favorable circumstances. Moreover, fresh water is absolutely necessary for the integrity of water-tube boilers.

The report deals briefly with the performance of the battleship "Oregon." Between March 6 and May 24 this ship steamed over 14,500 miles, stopping only for coal and not being delayed anywhere an hour through any derangement of the machinery. She stopped at Key West only for coal and at once joined the blockading fleet ready for service. While this is an unparalled record, the "Oregon" surpassed herself in the great battle of July 3. Always ready for service, she, on that day, speedily attained a power greater than that developed on her trial, and notwithstanding her greater displacement and foul bottom she reached a speed only slightly less than was then recorded. Had it not been for this wonderful speed, one, and possibly two of the Spanish ships might have escaped. Commodore Melville ascribes the credit for the performance partly to her builders, the Union Iron Works, for excellence of material and workmanship, but chiefly to the engineer department of the "Oregon" as organized and led by Chief Engineer Robert W. Milligan.

The performance of the two 1,000-ton gunboats, "Annapolis" and "Marietta," is also most favorably commented upon. Both of these ships have water-tube boilers, made by the Babcock & Wilcox Co., and both were commissioned in 1897 and have been over one year in service. The "Marietta" covered 13,000 miles at an average speed of 9.2 knots, and for several periods of about a week each the average was 10 knots. Yet, in both of these vessels the boilers are now in excellent condition and ready for any service; and at the end of her long voyage from the Pacific the "Marietta" only needed a few fire-brick, and the "Annapolis," after steaming thousands of miles, needed nothing.

The lessons of the war, for the steam engineering department are summed up as follows: The necessity of frequent tests under working conditions of the machinery of all vessels in reserve. All naval stations should be in positions of strategic value, and be properly fitted for repairs and provided with adequate quantities of non-perishable stores. Key West is such a station. Fresh water is almost as important as coal and distilling ships are a necessity. Every fleet should have a repair-ship. With more than two main engines, there should be three engines driving three screws, and not two main engines on each shaft. At Santiago the "New York" and "Brooklyn" had their forward engines disconnected on July 3 and could not stop to couple them. An accident to any part of either of the two engines on a shaft disables half the power; in the three-screw ship this fraction would be only one-third. There should be frequent trials under forced draft to keep the blowers in good condition and make the men familiar with working under maximum conditions. Until the day of the Santiago fight some of the ships had never been under forced draft since ther trial trips. The position ot these blowers is important, and they should not be put in pockets or corners in the fire-rooms to make space for other equipment. In the "Cincinnati," temperatures as high as 205°F. were noted in the fire-rooms. The personnel must be regulated by the class of the ship, and there must be a reserve of trained men and officers; a war of long duration would have greatly embarrased the government owing to the difficulty of supplying the places of disabled or invalided men. Volunteers, however, well trained in other ways, can not replace the regular officers. Finally our fighting ships must have the highest practicable speed, and 18 knots is now recognized as a standard in battleship construction.

NOTES ON THE SEWERS AND PAVEMENTS OF DENVER, COLO.

By W. P. Hardesty.*

Both the sewers and pavements of Denver, Colo., are of comparatively recent construction. Nearly all of them have been put down under supervision of the Board of Public Works since the latter was organized in 1889.

The sewers are divided into three distinct classes, as follows:

I. Public Sewers.—Up to May, 1898, 61,129 lineal ft. have been laid, at a total cost of $520,020. Of this there are 17,766 ft. of vitrified sewer pipe 8 to 24 ins. diameter; 15,211 ft. of oval brick, 1 ft. 11 ins. × 2 ft. 10½ ins. to 3 ft. 6 ins. × 5 ft. 3 ins.; 13,805 ft. of circular brick, 24 to 58 ins., and 13,298 ft., 70 to 94 ins.; also 1,049 ft. of 24-in. cast-iron pipe.

II. District Sanitary Sewers.—Work has been done in 20 districts from 1880 to 1897. The total cost has been $1,687,709, and the cost per lot of 25 × 125 ft. varied from $14.80 to $73.61. There is a total length of 1,066,829 ft., or 202.04 miles, divided as follows:

Vitrified pipe.			
Size.	Length, ft.	Size.	Length, ft.
8-in.	775,956	18-in.	17,701
9-in.	102,164	20-in.	5,269
10-in.	25,237	21-in.	9,076
12-in.	72,723	22-in.	1,759
15-in.	43,301	24-in.	7,039
Total pipe			1,060,225

Brick.			
Oval.		Circular.	
23 × 34½ ins.	1,740	21 ins.	6
18 × 30 ins.	1,320	24 ins.	2,639
		30 ins.	1,169
Total	3,060	Total	3,544

There are 67,816 Y's and 3,821 manholes.

III. Storm Sewers.—There are 13 storm sewer districts in which work has been done from 1890 to 1896. There are 19,788 ft. of vitrified pipe 8 to 24 ins.; 2,521 ft. of oval brick sewer, 2 ft. 10 ins. × 4 ft. 3 ins. to 3 ft. × 4 ft. 6 ins.; 10,003 ft. of circular brick 26 to 54 ins. diameter, or 32,312 ft. in all. There are 53 "Y's," 140 manholes and 233 basins. The total cost has been $157,268.

The total length of the three classes of sewers is 223.97 miles. Some sewer construction was done in 1880, but nearly all of it has been done since the beginning of 1890.

The most interesting and most expensive piece of work per foot is the extension of the Delganey St. public sanitary sewer, 8,290 ft. long. It is 94 ins. in diameter for 2,380 ft. when it is bifurcated, a branch or spillway discharging into the Platte River near by. Here the diameter is reduced to 70 and 77 ins. to the end. The grade to the spillway is 0.10, then it is 0.05. The spillway or storm overflow is designed to take care of all the excess of storm waters that enter before it is reached. The storm area drained is 300 acres, from which the estimated maximum flow is 188.4 cu. ft. per sec.; the sanitary area is 10,585 acres and the expected flow is 128.9 cu. ft. per sec. The standard construction of this sewer is of three rings of brick. The storm overflow is 10 ft. wide and is semi-circular. The actual cost of construction of both was $148,628.18, including $9,687.90 for river protection.

Paving.—The first street paving was done in 1890. There was a bitter fight made against the use of asphalt, both by newspapers and parties directly interested, but it was adopted and has proven so satisfactory that nothing else has been used except for the wholesale and manufacturing districts; 2.298 miles of sandstone and 11.761 miles of asphalt had been laid up to May, 1898. The price for the former ranged from $3.47 to $2.39 per sq. yd., and for the latter from $3.23 to $2.595. Asphalt is laid 2½ ins. thick on a 6-in. concrete base, and sandstone in blocks 6 ins. deep on 1½ ins. of sand on 6 ins. of concrete. The streets are 80 ft. wide, leaving 48 ft. for the paving and the gutters. Of this the street car companies have to pave between their rails (3½-ft. gage) and for 2 ft. each side, making 15.8 ft. The average arching of the pavements from the gutters to the center is 6 ins. To obtain sufficient fall for the gutters in many parts of the city, they are raised or lowered so as to make the height of the curb vary all the way from 4 to 10 ins., at the same time reducing or increasing the crown of the pavement. Prices have gradually come down, and last spring 1½ miles of asphalt paving was let to the Colorado Paving Co. at $1.80, including grading. The Denver Paving Co. also took work of the same class at $1.93. On the new 14th St. viaduct 2 ins. of Alcatraz asphalt on 6 ins. of concrete is being laid at $1.45.

AMERICAN NAVAL ORDNANCE AND ARMOR IN THE LATE WAR.

Naval ordnance in the American-Spanish war is reported upon by Capt. Chas. O'Neill, U. S. N., Chief of the Naval Bureau of Ordnance. Contrary to current opinions but little war material for the navy was purchased abroad; a number of minor caliber guns and some ammunition for them and a few torpedoes covered the foreign supply; all else came from the United States. Nevertheless, batteries and ammunition were placed on 107 auxiliary vessels purchased or otherwise acquired, and these vessels mounted an aggregate of 576 guns. Besides these, two new gunboats and twelve new torpedo boats have been armed since January last, bringing the total up to 121 vessels supplied with munitions of war in the emergency.

The main batteries of the U. S. regular naval vessels now number 564 breech-loading rifles, and the secondary batteries of these ships carry 1,023 guns of less than 4-in. caliber. Since the date of the last annual report, 112 guns, of from 4 to 13-in. calibers have been completed at the naval gun factory; or, 16 4-in., 54 5-in., 29 6-in., one 12-in., and 12 13-in.; besides this two 8-in. and 33 6-in. guns were converted into quick-firing rifles. Under contract with private establishments 37 4-in. guns and mounts have been partly completed, and forgings have been ordered for five 8-in., 20 5-in. 26 4-in., and one 3-in. guns. New designs adopted for future guns of all calibers are calculated to insure a much greater muzzle-energy than is now obtained from guns of like caliber.

Guns, mounts and their appurtenances have been severely tested during the war, and their performance has been in general thoroughly satisfactory. Some minor defects in the mounts of guns of small caliber have been, or are being remedied.

As soon as the war became imminent orders were at once given for large quantities of powder, projectiles, fixed ammunition, small arms and small guns for secondary batteries, and these orders were promptly filled. It was proposed by Engineer-in-Chief Melville to utilize bicycle and other machine shops in rapidly building 75 torpedo boats; but this plan was abandoned when Admiral Dewey, in Manila Bay, proved that the Spanish fleets could be defeated without them.

The lessons of the war, as to guns and armor, are covered in the following statement of Capt. O'Neill: While heavy guns in turrets must be regarded as one of the chief characteristics of a battleship, the greatest execution, except against the heaviest armor, may be expected from a number of quick-firing guns of small caliber. The larger guns demand a greater sacrifice of space and weight, to accommodate them and their protection, and are slower and less accurate in fire. Turrets do not protect the hull; the space within them is limited, and so is the field of view from the sighting-hood; the heat in them is intense in warm climates; ventilation is imperfect and elaborate machinery is necessary to operate them. Notwithstanding these drawbacks, heavy guns in turrets are recognized as a necessity; but the question of the maximum caliber to be used in them is now demanding the serious consideration of the Bureau.

The 13-in. gun, of 60½ tons weight and 35 calibers long, has a muzzle velocity of 2,400-ft. seconds with smokeless powder, and a capacity to penetrate, with a capped-projectile, 19 ins of face-hardened armor at a distance of 2,500 yds. This gun has been heretofore considered as the best type of heavy turret gun for our first-class battleships, and all, excepting the "Iowa," with her 12-in. guns, were so equipped. The development of the 12-in., however, has been so great and its power has been so much increased that the Bureau now recommends it as the maximum caliber to be installed on future battleships; and it proposes to supplement these 12-in. guns by a battery of 6-in. quick-firing guns in casements, and with a secondary battery of 6-pdr. and 12-pdr. guns. The present 12-in. gun weighs only 7½ tons less than the present 13-in. gun; but the reduction in size and weight of the turrets, barbettes and ammunition is very great. As to armor, the Bureau believes that 12 ins. is sufficient in view of the recent improvements in manufacture, and the necessity of distributing protection over a greater area than was formerly the practice.

Smokeless powder, made by the Bureau's formula from soluble nitro-cellulose, dissolved in ether alcohol, is successfully made and proven to be uniform in character and to possess good keeping qualities. This powder could have been furnished in considerable quantities during the war; but, owing to lack of time, it was impracticable to furnish complete outfits of this ammunition, and a few guns using brown powder would have nullified the advantages gained by using smokeless powder in other guns. Considerable quantities of smokeless powder are now provided, and hereafter all naval vessels will be supplied exclusively with this powder, excepting only a certain number of brown powder charges for practice work. This will use up the cheaper brown powder on hand. The government is now building a smokeless powder factory at Indian Head.

As showing the amount of work speedily accomplished by the Ordnance Bureau, we find that at the New York Navy Yard alone, 48 vessels were surveyed, transformed for war service, fitted with batteries, ammunition and ordnance outfits; and the guns, ammunition and outfits for 41 of these vessels were prepared and shipped in the ten weeks between April 15 and July 1, 1898. Freight trains loaded with ammunition were rushed to San Francisco and to Tampa on passenger train schedules.

TORPEDO BOAT DESTROYERS OF 35 KNOTS SPEED are being built by the Parsons Steam Turbine Co., of Wallsend-on-Tyne, England. One of these is for England and the other for a foreign country. These destroyers will be twice the length and six times the weight of the original "Turbinia," and there are reasonable expectations of attaining a speed of 40 knots. The advantages claimed for the turbine-type of destroyer, aside from great speed, are economy in coal consumption, which was 15% in the "Turbinia," traveling at ordinary rates; a great saving in engine space and weight; the absence of vibration; and the absolute command over the engine, as the "Turbinia" could be brought to a standstill in 40 seconds, and she could be quickly turned and handled while going at full speed.

SUBSCRIPTION RATES: United States, Canada and Mexico, One Year, $5.00; *6 months,* $2 50; *2 months,* $1.00. *To all other countries in the Postal Union: Regular Edition, One Year,* $7.60 *(31 shillings); Thin Paper Edition, One Year,* $6.31 *(26 shillings). SINGLE COPIES of any number in current year,* 15 *cents.*

In ordering changes of mailing addresses, state BOTH old and new addresses; notice of change should reach us by Tuesday to be effective for the issue of the current week. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number 328 *means that subscription is paid to the* 32d *week (that is the issue of Aug.* 11) *of the year* 1898; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: **20 *cents per line. Want noticees, special rates, see page* 18** *Rates for standing advertisements sent on request. Changes in standing advertisements must be received by Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements by Wednesday noon.*

A new evidence of the passing of the old barge canal as a factor in freight transportation under modern conditions is furnished by the announcement that the Delaware & Hudson Canal Co. is considering the abandonment of the famous old waterway, for the construction of which the corporation was originally organized. The Gravity R. R., completed by the company in 1829, is to be closed to traffic on Jan. 1 next, and it is not likely that the company will continue to maintain and operate the canal. For a number of years the traffic on the canal has been falling off, and it is said that only 250 boats were run last summer, where 1,400 boats once ran during the canal's prosperous days. A large proportion of the coal mined by the Delaware & Hudson Co. has been sent to the New York market over the Erie R. R. for several years; and it is now said that such traffic arrangements have been obtained that all the coal for the New York market from the company's mines will take this route.

It is plainly evident that a few years more will see the entire disappearance of the old-time canal barge as a vehicle for freight transportation. The 60,000-lb. freight car is a competitor which it cannot meet. The only ones of the old-time canals on which even a semblance of their old-time traffic is to be found are such canals as the Erie, where the taxpayers foot the bills for maintaining and operating the canal. Even here, however, the question of who is to carry on the traffic in the near future is a serious one. The profits to the canal boatmen for several years have been so meager that hardly any new boats have been built for some time; the old boats are fast becoming rotten and useless; and with the present uncertainty as to the future policy of the state respecting the canal, no new investments in boats to ply upon it are likely to be made.

◆

The proposition to erect a memorial of some kind to the late Col. George E. Waring, in testimony of the value of his services to the city of New York, and in a broader sense, to the cause of better municipal sanitation, is a project eminently worthy of consideration. By his masterly executive ability and strong personality, Col Waring introduced new methods, and organized on a new system the work of street cleaning and refuse disposal in New York city, and so greatly improved the sanitary conditions that the system which he established is likely to be perpetuated. His services to the city were, indeed, valuable, far beyond the salary which he received, as is indeed often true of the engineer's work. It is well that the value of his services should now be substantially recognized, if for no other purpose than to preserve the memory of an energetic and faithful public servant who intelligently and honestly performed his duty.

That Col. Waring died a poor man speaks much for his honesty in positions of large responsibility; but he leaves a widow practically unprovided for, and, if a memorial fund is to be raised, we heartily commend the method for disposing of this fund suggested by Ex-Mayor William L. Strong. Briefly stated, the project, as thus far outlined, is to raise a fund from among the friends of Col. Waring, and those who appreciate his services to New York, and his later services to the government, to put this fund in trust and to pay the income to Col. Waring's widow during her lifetime. After her death the principal can then be disposed of as may be deemed best; enther in erecting a monument, or, better, in endowing a department of sanitary engineering in some reputable technical institution. Whatever the final disposition of such a fund might be, however, if it is to be raised at all, its first object should evidently be to secure Mrs. Waring from want. Posthumous recognition of valuable public service is better than none at all; but it should at least take the form that will best carry out the wishes of the deceased had he survived.

◆

In our issue of Oct. 27, we noted the displeasure of the City Councils of Philadelphia because the Chief of the Water Department, Mr. John C. Trautwine, M. Am. Soc. C. E., did not complete the plans and specifications for the new George's Hill Reservoir as soon as they desired. Mr. Trautwine has now completed these plans, and in submitting them to the Director of Public Works, he has taken occasion to fully answer the charges of "contumacious conduct," etc., which were made in the Council sessions. He shows that the force of assistants which is allowed him comprises, all told, four draftsmen, at an average yearly salary of less than $1,200, and three rodmen at $2.50 each per day. With this force Mr. Trautwine, during the past summer has had to perform all the routine work of his department, and, in addition, prepare the following plans, estimates and reports: On Aug. 1 he was instructed by his superior officer to carry out a resolution of the city council calling for "plans and drawings and estimated cost of the filtration of all the water used by the city," and he was given just one month in which to do it. On Sept. 12, the site for the new reservoir, mentioned above, was approved, and on Sept. 15, Councils called for detailed plans for the reservoir, to be submitted at its next regular meeting, Oct. 6. About Oct. 20, Mr. Trautwine received a letter from the director of public works transmitting a resolution of the Select Council, calling for a report

> at the earliest possible time as to whether there is, within a radius of one hundred miles from the city, a supply of good water capable of furnishing this city with a sufficient storage quantity for 150 days, and whether the same can be stored and brought down by gravity and deposited in the city reservoirs for distribution. Also, report on the estimated cost of procuring such supply, together with any other information bearing upon the subject.

Mr. Trautwine is by no means the first engineer who has been overwhelmed with work, and then found fault with because he could not perform miracles. In fact, it is one of the greatest difficulties in carrying on work under state or municipal or national control that duties are assigned to public officials without the slightest question as to whether other demands on their time make it possible for them to perform them. In work under direction of a private firm or corporation, when an officer is given additional duties or special work, he is empowered to employ assistants enough to do it. But red tape prevents this, as a rule, in work under municipal or state control, and the man on whom the responsibility is laid has to struggle along as best he can.

◆

LESSONS FROM THE LOUISVILLE EXPERIMENTS ON WATER PURIFICATION.

The value of experimental work, especially when conducted on a sufficiently large scale to make the conditions comparable with those prevailing in practice, is seldom better illustrated than by the results of the Louisville experiments on water purification. From the advance pages of Mr. Fuller's report on this subject, reviewed in Engineering News of Oct. 27, it appears that had the Louisville Water Co. awarded a contract for filters of the current mechanical type at the outset, instead of making, as it did, an exhaustive investigation of their efficiency, the results obtained would have been unsatisfactory, at times, and the expense unnecessarily great. The reason for this is that the companies, whose apparatus was tested, did not, prior to these experiments, fully appreciate the magnitude of the task of purifying a water so variable in character, and so heavily charged with minute particles of suspended matter, as is the Ohio River, at Louisville. In other words, too much reliance was placed, at the start, on coagulation and mechanical filtration and too little upon sedimentation. A number of other points brought out by the investigation were, when taken together, of much practical importancee as regards both the cost of purification and the quality of the water, especially the uniformity of the results obtained.

It may seem surprising that after 10 or 15 years of experience with mechanical filtration, and the installation of a hundred plants, by various companies, it was deemed necessary to undertake an exhaustive series of experiments at Louisville before the water company felt warranted in adopting the system. But the facts are, as we have repeatedly pointed out, that the data were lacking which would enable an engineer to decide upon the capabilities of mechanical filtration. The filter companies themselves did not possess such data, for two reasons: (1) Because they, like most proprietors of patented systems, had such confidence in their filters that they thought much experimental work, outside the laboratory, unnecessary; and (2) because their energies have been concentrated more upon fighting each other in the courts, and in competition for business, than upon learning the limitations of their filters. Public officials and private water companies have done very little in the way of studying mechanical filtration, (1) because the various filters were regarded as proprietary devices, and (2) because of the general apathy that has prevailed, until recently, regarding water purification. This apathy has been remarkable, even on the part of officials having mechanical filters under their care, some of these never having taken the trouble to learn how much wash water they were using, while it is a rare thing to find a filter plant for which periodical water analyses are made.

When the Louisville investigations were begun, the only notable experimental test of mechanical filtration on record was the one conducted at Providence, R. I., in 1893-4, by Mr. Edmund B. Weston, M. Am. Soc. C. E., reviewed at length in Engineering News of April 16, 1896. This test was made on a small scale, and had other limitations besides. In addition, the water treated contained such small amounts of suspended matter, in comparison with the water of the Ohio River, as to throw little light upon this phase of the Louisville problem, where the removal of mud must accompany bacterial purification. Besides this lack of experimental data, there confronted the Louisville officials the fact that a large mechanical filtration plant at New Orleans had been rejected by the water company there, after installation and a long contract trial, on the ground that it did not remove the suspended matter in the Mississippi River water without the use of an excessive amount of coagulant. The courts sustained the contention and the filter company suffered a heavy loss.

In view of the meager data available, and the

sad experience at New Orleans, it is not strange that the Louisville Water Co., and its able Chief Engineer, Mr. Chas. Hermany, M. Am. Soc. C. E., were unwilling to contract with any of the filter companies for a purification plant. Nevertheless, the indications were strongly in the direction of mechanical filtration, as best suited to the conditions at Louisville, because it was felt that a coagulant would be necessary for the removal of the suspended matter. Slow sand filtration alone was out of the question, on account of the rapid clogging of the beds and the vast amount of labor required to clean them, as had been determined experimentally by Mr. Hermany some ten years before the recent tests.

After ten months of experience with the filters of three different companies, each plant having been designed for a capacity of 250,000 gallons a day, the Louisville Water Co. felt the need of still further investigations to settle some questions raised but not answered by the filters tested. Finally, we understand, the company secured sufficient data to enable it to design a system of water purification which it believes will be efficient and economical. The details of this system are not given in the report, but its final conclusion indicates that a modified form of mechanical filter will be adopted, the facilities for sedimentation being greatly increased over those provided in any of the plants installed by the filter companies. Contracts have been let, since the report was written, for portions of the purification plant, but not for the filters proper.

The question naturally arises, have we now sufficient information regarding mechanical filtration to enable an engineer to say whether it is capable of doing the work required in any specific case, or are further investigations necessary? This suggests the broader question, whether water purification as a whole is now on as definite a basis as other branches of water supply engineering, say pumping machinery? We do not think it is, although it seems to be rapidly approaching that state. When the reports on the Pittsburg and Cincinnati experiments are added to the Louisville report and to the mass of valuable information emanating from the Lawrence Experiment Station and from foreign sources, there will certainly be no longer any ground for complaint of a scarcity of data regarding water purification. We have had a fair amount of information regarding some phases of sand filtration for a number of years, most of which has originated at Lawrence or abroad. At present the chief deficiency in American records relating to slow sand filtration is that they throw little light on the treatment of water carrying large quantities of mud, like the Ohio and Mississippi, and other Southern and Western streams. The Pittsburg and Cincinnati experiments will do much towards supplying these wants, as both were instituted largely for this very purpose, but with a realization that sedimentation would be necessary to supplement slow sand filtration. These later experiments, it is to be hoped, will also afford some comparative data regarding mechanical and slow sand filtration, although official statements as to this have not been made. It is known, however, that both systems were tested at Pittsburg, where the experiments were recently completed, Mr. Allen Hazen, Assoc. Am. Soc. C. E., being engineer to the commission on filtration. The Cincinnati tests, like those at Louisville, are being conducted by Mr. Geo. W. Fuller, Chief Chemist and Bacteriologist, under the direction of Mr. L. F. G. Bouscaren, M. Am. Soc. C. E., Chief Engineer of the new water supply. Both reports will probably be published promptly.

With the information outlined available, what we shall mostly need will be the detailed results obtained by full-sized working plants. As already stated, scarcely any regular periodical analyses of filtrates have been made in this country, and fewer yet have been published. The results obtained by the slow sand filtration plant of the city of Lawrence, Mass., are available, but the analyses are not made at very frequent intervals. Examinations of the water from the mechanical filter plant at Davenport, Ia., ware made at fairly frequent intervals, some time ago, for the Davenport Water Co. by Prof. E. G. Smith, of Beloit, Wis., but only portions of the results have ever been published, so far as we know. Prof. Smith also made some analytical studies of the effect of sedimentation of Missouri River water at Omaha and Council Bluffs, a few years back, but these figures, also, have not been made generally available. Valuable studies, extending over several weeks, of the work done and coagulant used by the mechanical filter plant at Lorain, O., were made not long ago, under the direction of Mr. Hazen, as will be seen by referring to Engineering News for Oct. 28, 1897. In our issue of June 4, 1896, there appeared a report by Dr. Thos. M. Drown, President of Lehigh University, on the removal of iron from ground water at Asbury Park, N. J., by means of aeration and mechanical filtration, the tests here also extending over a number of weeks.

When the sedimentation and slow sand filtration plant at Albany, N. Y., described in our issues of Feb. 10 and Oct. 20, 1898, is put in use we may expect to have some valuable figures regarding it, for a chemical and bacteriological laboratory are very wisely being provided as a part of the works. Soon other of the larger cities will have water purification plants in use, and doubtless they also will see the advisability of providing and operating analytical laboratories. The importance of frequent chemical and bacterial analyses in connection with purification plants can hardly be urged too strongly, both as a guarantee of good results and of economical design and operation.

While we are learning and expecting to learn so much about water purification from the various sources already open to us and likely to be open soon, five or ten years, at least, will probably pass before most of our largest and many of our smallest cities can safely install complete systems of water purification without making more or less preliminary experiments. Where large plants are to be constructed, the total expense of such tests need be only a small fraction of the capital charges and operating expenses for one year, and the tests may often more than pay for themselves in a single suggested modification in design. In many cases the only doubtful points may pertain to operation, rather than design, when the tests may be delayed until the plant is in use. In fact, the supreme test is daily use, and that is why any filter plant should be constantly under good engineering, chemical and bacterial supervision.

Reverting now to the specific lessons of the Louisville tests, we have as the most important the great value and necessity of sedimentation in the treatment of all waters high in suspended matter, the process also removing a large percentage of bacteria. But where the sediment is finely divided, or where a high degree of bacterial purification is necessary, sedimentation must be supplemented by filtration. Coagulation would also be necessary at Louisville and is now almost universally recognized as an essential part of mechanical filtration, at the high rates usually employed.

The proper amount of coagulant, or the optimum quantity, as Mr. Fuller terms it, is a subject demanding careful investigation for each water to be treated. At Louisville it was found that the clayey particles in suspension absorbed a large amount of sulphate of alumina, without any effect upon the water. This was at times as high as ¾-grain per gallon. On the other hand, this coagulant in excess of certain quantities may be worse than useless, as has been known for some time, since all in excess of that which the carbonates in the water are able to take up passes into the filtrate. There might be cases where the use of sulphate of alumina, or alum, in sufficient quantities for efficient work, would be objectionable on account of adding to the corroding and incrusting qualities of the water and increasing its hardness. At Louisville this would not be the case, with proper design and operation of the purification works. These possibilities are one of the many reasons for careful analytical studies in connection with each filter plant. Another point about coagulants is that they must be given a proper amount of time to act, depending upon the character of the water and, presumably, the nature of the agent. Uniformity in the rate of admission of coagulants is essential to good results and to economy. Mr. Fuller thinks each of the devices used for this purpose at Louisville in the experimental plants could be improved upon, either by modifications in design or by the substitution of a direct gravity feed, instead of some form of pump. Reliance upon passing a stream of water through a receptacle containing the coagulant is wrong.

For the Ohio River water, sulphate of alumina was found to be the best and cheapest coagulant available, after an exhaustive study of the whole range of possible agents. This coincides pretty generally with experience elsewhere, although there might be waters for which some other agent was better suited.

Another confirmation of the opinions commonly held by disinterested scientists who have given the matter sufficient attention to warrant sound conclusions is that the direct treatment of water by electrical currents is of little value. There were, however, such apparently good grounds for hoping that a coagulant might be produced by electrolytical, in preference to chemical, methods, that extended studies of the subject were made. Nearly all of the so-called electrical systems of water and sewage purification, it may be stated here, are such only in the electrolytical production of a coagulant at the purification works, and for immediate use, instead of buying it from a manufacturing chemist. The Louisville experiments showed that the cost of the electrolytical production of aluminum hydrate was not only excessive, but that this method was unreliable "on account of the very low and irregular formation of the hydrate." An iron hydrate could be produced much more advantageously than an aluminum, and would be somewhat cheaper, apparently, than commercial sulphate of alumina, but it could not be safely employed at Louisville because the water there at times is too low in dissolved oxygen to oxidize more iron than an equivalent of three grains of sulphate of alumina per gallon, which would be insufficient. If more iron were used, it would appear in the effluent. Iron and aluminum, the report states, are the only metals available for the electrolytical production of coagulants. Neither of these hydrates, when thus produced, increases the hardness, corroding or incrusting qualities of the water, as does the commercial sulphate of alumina.

LETTERS TO THE EDITOR.

Formulas for the Volume Enclosed by the Intersection of Two Cylinders.

Sir: From a careful examination of the various formulas for the volume enclosed by two intersecting cylinders, published in your issue of Oct. 6, it is apparent that five of the ten mathematical formulas given are identical. For, if in those submitted by Messrs. Baldwin, Comstock, Talbot, and Dean, we retain only the first three terms of the series, represent $\frac{a}{r}$ by P, give to π its numerical value and reduce, we shall obtain in each case the expression

$$0.3927\ a^3\ P \left\{1 + \frac{P^2}{8} + \frac{5\ P^4}{128}\right\},$$

Volume Enclosed by Two Right Cylinders Whose Axes sect at Right Angles.

r = larger radius; $P = \frac{a}{r}.$

a = smaller radius;

Values of the volume in terms of r obtained by retaining only the first three terms of each series and substituting different values for $P = \frac{a}{r}$ in the formulas submitted by

Value of P substituted.	True value.	Mr. Sherman.	Mr. Peterson.	Mr. Serviss.	Mr. Frescoln.	Mr. Thomas.	Messrs. Baldwin, Comstock, Talbot & Dean.
P = 1.0........	$0.475\ r^3$	$0.8\ r^3$	$2.6804\ r^3$	$0.4748\ r^3$	$0.4749\ r^3$	$0.466\ r^3$	$0.457\ r^3$
P = 0.8........	...	$0.2048\ r^3$	$1.833\ r^3$	$0.1504\ r^3$	$0.1586\ r^3$	$0.350\ r^3$	$0.344\ r^3$
P = 0.5........	...	$0.0268\ r^3$	$0.76\ r^3$	$-0.00625\ r^3$	$+0.0078\ r^3$	$0.2067\ r^3$	$0.203\ r^3$
P = 0.3........	...	$0.0033\ r^3$	$0.2795\ r^3$	$-0.01185\ r^3$	$-0.0044\ r^3$	$0.1214\ r^3$	$0.11916\ r^3$
P = 0.2........	...	$0.000646\ r^3$	$0.125\ r^3$	$-0.0066\ r^3$	$-0.0029\ r^3$	$0.0804\ r^3$	$0.0789\ r^3$
P = 0.1........	...	$0.0004\ r^3$	$0.031\ r^3$	$-0.00185\ r^3$	$-0.00087\ r^3$	$0.04\ r^3$	$0.0393\ r^3$

which is exactly the value from which my approximate formula was obtained by using 0.4 in place of the coefficient 0.3927.

Since five of the formulas agree so exactly, while the others are all dissimilar, it seems fair to assume that these five are correct solutions of the problem.

I desire to take exception to your published statement that formulas 4, 5 and 6 agree quite closely.

Having tested them carefully, I submit herewith a table showing results obtained by substituting various values for the ration $\frac{a}{r}$ in the nine principal formulas given:

From an inspection of the above table it will be seen that the last five formulas give practically identical results. Those of Messrs. Serviss and Frescoln give correct values only when $P = 1$ or $a = r$, and they agree with each other pretty closely when $P = 0.8$; but they both give negative values for the smaller values of P. Mr. Peterson's formula seems to come nowhere near the mark except when $P = 0.1$, and Mr. Sherman's is not "in it" at all.

Yours truly, Frederick M. Thomas.

Skaneateles, N. Y., Oct. 17, 1898.

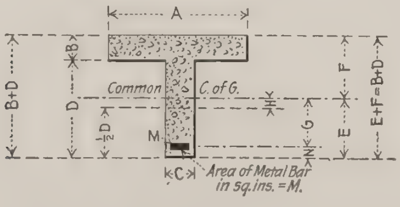
◆

A New Formula for Determining the Fiber Stresses in Concrete and Steel Beams.

Sir: The analysis of concrete beams reinforced by iron or steel, arranged in several ways, has been the subject of considerable discussion, and, although several formulas have been given in the columns of Engineering News (Eng. News. Jan. 3, 1895, and Oct. 21, 1897), some of them undoubtedly correct, the following, which, I believe, has not appeared in print, may be found to have some advantages. No originality is claimed for the analysis, but the formulas are arranged with a view to simplifying their practical application.

One method of analysis has aimed at determining the stresses after the concrete has cracked (failed in tension), because this occurs with "one-third the load required to develop the compressive strength of the concrete or elastic limit of the steel." To accomplish this the depth of the cracks is "assumed," the result therefore being true only for that depth. In a material like concrete it would be hardly safe to assume that repetitions of the load that first caused the crack would not extend it indefinitely, possibly up to the constantly changing neutral axis. This point can be determined and should be used for the depth of the crack. But the author of this method himself says "the factor of safety used in practice would always keep the working load well inside of this limit." To this, I think, all will agree. Therefore, the rational formula to use in proportioning concrete-steel beams, is one giving the working stresses. With these formulas the proper working unit stresses may be selected by the designer to suit each case. Ordinarily the unit tensile stress allowed for the concrete may safely be 75% of the ultimate tensile strength of the concrete when seven days old, or about 50% when 28 days old, and a decreasing percentage of the ultimate strength as the concrete ages.

In the examples given below I believe the ultimate breaking load would be from ten to twelve times the safe loads used. The only assumption made is of the value of the modulus of elasticity of concrete. This I have taken at 750,000, the result obtained by Professor Boek, in the Vienna experiments. This, however, can be determined for any given concrete when required.



Let I_s = moment in inertia of steel about the common center of gravity (area steel × 40).
" I_c = moment of inertia of concrete about the common center of gravity (area of steel × 40).
" E_s = modulus of elasticity of steel, = 30,000,000.
" E_c = modulus of elasticity of concrete, = 750,000.
" L_c = load on concrete.
" L_s = load on steel.
" c = proportion of total load sustained by concrete.
" s = proportion of total load sustained by steel.

Test, No.	Width, ins.	Thickness, ins.	Area, sq.in. Concrete.	Area, sq.in. Steel.	Common c. of g., above under side, ins.	I_c = for concrete, ins.	I_s = for steel, ins. Then

$$\frac{L_c}{L_s} = \frac{E_c\ I_c}{E_s\ I_s} = Y = \frac{I_c}{40\ I_s}.$$

and

$$c = \frac{Y}{1+Y}, \text{ and } s = \frac{1}{1+Y}.$$

If M = bending moment in inch-pounds, tension in concrete will be $= \left[\frac{M\ E}{I_c}\right] \times c.$

Compression in concrete will be $= \left[\frac{M\ F}{I_c}\right]$ c.

Tension in steel will be $= \left[\frac{M\ G}{I_s}\right]$ s.

The letters E, F and G refer to the figure, although the formulas are perfectly general. This figure represents one element of a floor, the beam and floor being built at the same time and monolithic. A is equal to the distance from center to center of beams. The values for seven different sections are tabulated below.

There have now been made a number of tests of concrete-steel beams, and it is quite likely that a careful and rational analysis of the results would suggest the use of other unit stresses than I have used in these examples. But as the formulas are general it is very easy to substitute other unit stresses whenever, in the opinion of the designing engineer, the state of knowledge on the subject indicates it. Mr. George Hill has presented in tabulated form 56 tests of concrete-steel slabs, in which the steel was in the form of "expanded metal." The concrete was of several different kinds, both as to ingredients and proportions. The "load producing first crack," as well as the "load at which metal broke," are given, and in the calculations given below I have used the smaller of the two, which is generally, but not always, the first mentioned.

The slabs made of cinder concrete are neglected because the modulus of elasticity for that is not at hand.

The modulus of elasticity of the stone and gravel concrete has been taken at one-fortieth that of steel.

The slabs for which the distance of the metal from the surface of the concrete at the center of the span was not clearly given, have of necessity been omitted.

This table shows the stresses developed in concrete and steel, for the load-producing rupture, on the tension side of the beam or slab, by the formulas

$$T_s = \frac{M\ G\ s}{I_s}, \text{ and } T_c = \frac{M\ E\ c}{I_c}.$$

Many tests of concrete beams have shown that they develop a tensile stress in the extreme fiber, by formula, about twice that of the tension tests. The above seem to correspond with those results very closely, but as no tension tests were given for the concrete in the slabs, they cannot be directly compared. The compression tests given are not applicable, since the ratio of tensile to compressive tests of concrete are very variable. (Tensile strength of concrete indicated, average = 230 lbs. per sq. in.) The low stress at which the metal broke may be attributed to tearing, due to its form, and to punishment by shearing and bending in its manufacture.

Albert W. Buel.

150 Broadway, New York city, Sept. 27, 1898.

Table Giving Dimensions, Moments of Inertia, Loads, Capacity in Bending Moments, Safe Span, and Quantities of Material Required for Concrete-Steel Beams.

Note.—Allowed tension on concrete, = 100 lbs. per sq. in.; allowed compression on concrete = 500 lbs. per sq. in.; allowed tension on steel, equals 16,000 lbs. per sq. in. Safe spans given are for dead load of 150 lbs. and live load of 200 lbs. per sq. ft.

RECENT TYPES OF EUROPEAN AND AMERICAN LOCOMOTIVES.

(With full-page plate.)

The fact has been frequently noted that locomotive design in this country for the past quarter century has been tending more and more towards uniformity, and the half dozen or more standard types of locomotives which are in use in this country vary little in their design on different roads except in minor details. In Europe, however, notwithstanding the smaller mileage of railways and the fact that they are spread over a much smaller territory, the greatest diversity in design continues to exist. This fact is very well shown in a plate published in a recent issue of our German contemporary, "Der Praktische Maschinen-Constructeur," showing 63 locomotives in use on various European and American railways, all drawn to a uniform scale. We have reproduced this plate and the article accompanying it has been translated for us by Mr. Geo. L. Fowler, M. Am. Soc. M. E., and is printed below.

In considering the causes for the greater uniformity in locomotive design in this country, we are inclined to assign a first place to the work of such organizations as the Master Mechanics' Association, the various railway clubs and the various railway technical journals. Of course the political and social barriers between different countries in Europe has operated to hinder any such full and free interchange of experience between the mechanical officers of different railways as prevails in this country. It is also true, we think, without doubt, that variations from standard practice are easier to introduce on the other side, and especially on the continent, than in this country. The inventors who want to improve the locomotive are classed in the same category with beggars, peddlers and book agents, by the average American Master Mechanic. Anything in the way of complication is his especial abhorrence; while on the Continent, if we may judge from the looks of the locomotives, each new designer of complicated valve motions and similar mechanical curiosities is greeted with open arms.

It is a little curious, however, how steadfastly every railway on the other side refuses to accept two distinctive American features of locomotive design, the pilot and the headlight, and how every American railway as steadfastly persists in their use. Our English friends, who still persist in calling the pilot the "cowcatcher" used to gravely explain that it was necessary in America because the railways there were not fenced and the cattle and other wild animals roamed at large on the tracks; but though we have now a considerable mileage of track protected from trespass of this sort, nobody proposes to take the pilot off road locomotives and is not likely to. About the same thing is true of the headlight. Its value as a safety appliance is so well established that nobody in this country would think of discarding it. On the other side, however, they argue that they have always got along very well without pilots and headlights and have fewer accidents in proportion to the traffic than American roads. Hence they see no reason for using them.

Taking up now the article in our contemporary, we may remark that it gives credit for the greater portion of the drawings and data to a treatise on "Railway Technics of the Present Time," by Messrs. Blum, Von Borries and Barkhausen, which has just been published by C. W. Kreidel, of Wiesbaden. In denoting the type of a locomotive a fraction is used in each case, the numerator denoting the number of driving axles coupled and the denominator the total number of axles. Mr. Fowler's translation follows:

I.—Passenger and Express Locomotives.

Up to the year 1880, the majority of the locomotives on European railways were of the 2/3 coupled type. In the decade between 1880 and 1890, the 2/4 coupled locomotive was introduced, which ran more smoothly at high speed and put less strain on the tracks. In these new locomotives a four-wheeled bogie truck was placed beneath the smokebox; the driving axle was in front of the firebox and the coupled axle beneath or back of the same. Engines with three and four axles with only a single pair of driving wheels are still used principally in England; while in America, locomotives with three axles coupled are in common use.

Fig. 1 is a 2/4 coupled express locomotive of the State Ry. of Saxony. In common with many German engines, these locomotives have two outside cylinders, Heusinger valve motion, inside frames and fireboxes held by radial stays. The springs of the two driving axles are connected by equalizing levers; the bogie truck is fitted with four springs that are independent of each other and a ball-and-socket center bearing on a spring bolster so that the locomotive is carried on three points. By means of his system of intercepting valves von Borries can admit live steam into his large cylinder and thus increase the tractive power of the locomotive.

Fig. 2 is a 2/4 coupled express locomotive of the Wurtemberg State Ry. In order to secure a deeper firebox, there is no driving axle placed beneath it; the locomotive is carried by trailing wheels at the front and back with the two pairs of driving wheels set between them. The engine has three cylinders of the same diameter, whose cranks are placed at an angle of 120° with each other. The inside cylinder is the high-pressure cylinder, but live steam may be admitted to all three, so that a wide variation in the tractive force may be exerted. The trailing axles are connected with the tender from their center, so that curves of 500 ft. radius can be readily traversed by these locomotives. The steam pressure is 180 lbs. per sq. in.; the heating surface, 1,581 sq. ft. and the grate area, 21.3 sq. ft.

Fig. 3 is a 2/4 coupled Austrian passenger locomotive. The firebox is of the Belpaire type. The boiler is fitted with two domes, which are connected by an outside steam pipe. An outside pipe also runs from the forward dome to the steam chest. The tubes are of steel.

Fig. 4 is a 2/4 coupled express locomotive of the Pfälz Ry. The arrangement of the wheels is the same as in Fig. 2, but a Krauss truck is used, by means of which the forward axle will be set radially to a curve by the side movement of the front driving axle. Owing to the better arrangement of the cylinders, the running is smoother than in the preceding design. The steam pressure is 180 lbs. per sq. in.; the heating surface, 1,215 sq. ft., and the grate area, 19.4 sq. ft.

Fig. 5 is a 2/4 coupled locomotive of the Belgian St. Ry. In this locomotive all of the peculiarities which characterize the Belpaire system are to be found, namely: outside frames, cylinders with the Heusinger valve motion inside the frames, a large firebox spreading out to the back of the rear wheel and an inclined grate. The front truck axle is movable, and the cylinders are set at the extreme front end, an arrangement that is very detrimental to the stability of the engine. In order that fine coal may be burned the grate has a large area, namely, 51.6 sq. ft., but the heating surface is small, being but 1,204 sq. ft. The steam pressure is 150 lbs. per sq. in.

Fig. 6 is a 2/4 coupled express locomotive of the Austrian State Ry. It is a two-cylinder compound engine and is used in heavy express traffic on the main line. It is built upon the Gölsdorf plan, which provides for the admission of live steam to either end of the low-pressure cylinder. This is accomplished by means of two holes drilled in the valve seat, which are kept closed under ordinary conditions of valve travel, but which are opened when the point of cut-off is later than from 50 to 60% of the stroke. The wheelbase of the truck is very great, being 8 ft. 10¼ ins., and it is also set so far to the rear that it carries a large portion of the weight of the boiler, since an axle loading of 14½ tons must not be exceeded. The grate area is comparatively large (31.2 sq. ft.) because fine coal of a medium quality must be burned. This engine also has two domes connected by an outside pipe. The steam pressure is 195 lbs. per sq. in., and the heating surface 1,489 sq. ft., and the grate area 31.2 sq. ft.

Fig. 7 is a 2/4 coupled express locomotive of the Holland Ry. Co. This new Dutch locomotive resembles the English patterns and differs from them only in the use of inclined grates and Belpaire firebox.

Fig. 8 is a 2/4 coupled express and passenger locomotive of the Manchester, Sheffield & Lincolnshire Ry. The principal English lines have, in recent years, built a large number of locomotives with four wheels coupled and a bogie truck in front, and this is becoming typical of English practice. Owing to the good fuel which is available on most of the English roads, the boiler may be made comparatively small. The cylinders are inside and have one steam chest in common; the frames are also inside, and the springs are independent. The firebox is fitted with a long fire-arch and the crown is held by crown-bars.

Fig. 9 is a 2/4 coupled express locomotive of the London & Northwestern Ry. This locomotive is of the well-known Webb three-cylinder compound type. The two high-pressure cylinders are on the outside and are back of the forward wheels. The pistons of the outside cylinders turn the back driving axles and that of the low-pressure cylinder, which is beneath the smokebox, drives the forward axle. The driving axles are not coupled together. The steam distribution in the high-pressure cylinder is accomplished by means of a piston valve driven by the Stephenson link-motion; that of the low-pressure by a slipping eccentric. The tubes start from a combustion chamber in front of the firebox. The steam pressure is 180 lbs.; the heating surface is 1,413 sq.ft., and the grate area, 20.4 sq.ft.

Fig. 10 is a 2/4 coupled four-cylinder, compound express locomotive of the Northern Ry. of France. The same type is also used by some of the other great French companies. The two outside high-pressure cylinders are located back of the truck, and their connecting rods take hold of the crank-pins of the back driving wheels, while the low-pressure cylinders are set beneath the smokebox and their connecting rods take hold of the cranks of the forward driving axle. The cranks stand at an angle of 120° with each other in order to relieve the working parts to as great an extent as possible. The two pairs of cylinders can be worked perfectly independently of each other, which is a valuable quality in case of accident. The steam distribution is effected by means of the Heusinger valve motion. Live steam can be admitted to all of the cylinders in starting.

Fig. 11 is a 2/4 coupled compound locomotive of the Paris, Lyons & Mediterranean Ry. In size and general arrangement it is very siimlar to Fig. 10, as just described, but in the details of its construction it is very different. The boiler, for instance, is much shorter, the Serve ribbed tubes are only 9.8 ft., instead of 12.8 ft. long. The smokebox is 5 ft. 9 ins. long. In the firebox there is an arch of firebrick. The truck has a side play. The frames are carried on a wedge-shaped surface by means of which they can be brought back to their original position. All parts of the machine which present a resisting surface to the wind, are protected by wedge-shaped shields. By this means the resistance of the air is said to be decreased about 22* tons at a speed of 62 miles (100 km.) per hour.

Fig. 12 is a 2/4 coupled locomotive of the Eastern Ry. of France. For express service these locomotives are fitted with the double boiler of the Flaman type. The lower boiler, which is entirely filled with tubes, is really the water space, while the upper one forms the steam chamber. This boiler has 304 tubes, each 14.1 ft. long, giving it a heating surface of 1,809 sq. ft. As the firebox is formed of corrugated steel plates, it needs no further staying. The cylinders are outside and their pistons turn the back driving axles. The engine weighs 57 tons. In order to relieve the driving axles of a portion of the load that they would otherwise carry, the truck is set somewhat back, in spite of which the loading amounts to 33.4 tons, or practically 17 tons per axle.

Fig. 13 is a 2/4 coupled passenger locomotive of the Left Bank of the Rhine Ry. The characteristic feature of this locomotive is the boiler, which is of the Lentz type with a corrugated flue firebox. The boiler consists of three divisions, namely, two conical end pieces at the ends and a cylindrical connection between the two in the center. The sheets are welded together without any riveted joints. At the front end the boiler rests with the smokebox on the frames, at the back it is carried by two side stays. In front of the horizontal grate there is a space that serves as a combustion chamber.

Fig. 14 is a 2/4 coupled compound locomotive of the Southwestern Ry. of Russia. The engine has four cylinders, which are placed above the truck. On account of their lesser weight, the high-pressure cylinders are placed at the front. The steam first enters the small cylinder and then passes out through a large tube, which serves as a receiver, into the large cylinder upon the other side of the engine. This pipe passes through the smokebox. The steam distribution is effected by the Stephenson link-motion. Live steam can be admitted to the low-pressure cylinder through a small pipe on starting. The driving axles are loaded with but 13 tons.

Fig. 15 is a 2/4 coupled passenger locomotive of the Chicago, Burlington & Quincy R. R. The principal characteristics of the American machine are as follows: The main frames are formed of bars of iron or cast steel. The firebox is always made of steel, and, in case of the example given, the crownsheet is flat and is stayed on the Belpaire system. The cylinders are outside and above the truck. The valve seats are on top of the cylinders and the steam distribution is effected by means of the Stephenson link-motion with open links. The wheels are made of cast iron with steel tires. In order to prevent the throwing of sparks, the cylindrical smokebox is made very large and is fitted with spark arresters. A bell is used instead of a whistle. (So in the original.—Ed.) The steam pressure is 165 lbs. per sq. in.; the heating surface, 1,280 sq. ft., and the grate area, 24.7 sq. ft.

Fig. 16 is a 2/4 coupled express locomotive of the New York Central & Hudson River R. R. The large dimensions of the boiler make this engine still stronger than the preceding. The weight on the driving axles rises to what in European practice would be the unprecedented amount of 19 tons. These locomotives are used to haul the fastest train in the world between New York and Buffalo. The steam pressure is 200 lbs. per sq. in., the heating surface is 1,742 sq. ft. and the grate area is 30.1 sq. ft.

Fig. 17 is a 2/4 coupled express locomotive built by the Baldwin Locomotive Works, of Philadelphia, on the Vauclain system. The engine has four cylinders. Upon each side there is a small cylinder above a large one, the two are cast in one piece, and the steam is distributed in both by a single piston valve. The two piston-rods of each group take hold of a single crosshead, so that the steam works after the manner of a Woolf compound engine. In contradistinction to other American locomotives, these engines are not fitted with a bogie truck. The steam pressure is 190 lbs. per sq. in., the heating surface is 1,333 sq. ft., and the grate area is 24.7 sq. ft. (This is the "Columbia" locomotive, as most of our readers will recognize.—Ed.)

Fig. 18 is a 1/4 coupled compound locomotive of the Philadelphia & Reading R. R. This engine is also built on the Vauclain system. The driving axle is placed in front of the firebox, and carries the enormous weight of 21.6 tons. The firebox is placed above the back pair of wheels and occupies about one-half of the whole length of the locomotive. The grate is separated from the tubesheet by a firebrick bridge, so that a combustion chamber is formed in which the gases from the fire are mingled with the air, and these, with the particles of coal carried with them, are thus perfectly burned. The grates are slightly inclined and are formed of water-tubes, between each alternate one of which there is a bar of hard cast iron. The closed ashpan is opened from the rear. The position of the engineer is separated from that of the fireman.

Fig. 19 is a 2/3 coupled compound locomotive of the Prussian State Ry. The cylinders are back of the leading axle, and it is the rear wheel that serves as the main driver. The valve motion is of the Heusinger type; the receiver pipe is laid around the shell of the boiler. The steam pressure is 180 lbs. per sq. in., the heating surface is 1,110 sq. ft., and the grate area 20.1 sq. ft.

Fig. 20 is a 2/3 coupled express locomotive of the Great Eastern Ry. For a long time this type of locomotive was the principal one used for express service in England. The cylinders are inside. The frames are outside. The springs are perfectly independent of each other. The steam pressure is 180 lbs. per sq. in., the heating surface is 1,290 sq. ft., and the grate area 18.3 sq. ft.

Fig. 21 is a 1/4 coupled express locomotive of the Great Northern Ry. of England. The driving axle of this engine carries 18 tons, so as to obtain the necessary adhesive weight for starting. Such an exceptional loading as this is only allowable upon an exceedingly well built permanent way. In spite of the small dimensions of the boiler, the engine is comparatively heavy, 74,400 lbs. The cylinders are outside, and the driving wheels, with a diameter of 8 ft. 2 ins.. are the largest in the world. The steam pressure is 170 lbs., the heating surface is 1,025 sq. ft., and the grate area 17,7 sq. ft.

Fig. 23 is a 2/3 coupled passenger locomotive of the Prussian State Ry. This type of engine is still extensively used upon the railroads of Continental Europe. The cylinders are upon the outside and the frames and steam chests on the inside. This very simple construction labors under the disadvantage that, on account of the location of the heavy cylinders at the front end, the running of the machine is unsafe and the track must necessarily be very rigid. The valve-motion is of the Allen type. The crown of the firebox is held by radial stays. The steam pressure is 180 lbs. per sq. in., the heating surface is 1,107 sq. ft., and the grate area is 19.4 sq. ft.

Fig. 24 is a 2/2 coupled locomotive for mixed service on the Oldenburg State Ry. Owing to their lack of stability and their small tractive power, these engines are but little used. The steam pressure is 180 lbs. per sq. in., the heating surface is 1,007 sq. ft., and the grate area is 10.1 sq. ft.

Fig. 26 is a 3/4 coupled compound passenger locomotive of the Jura-Simpton Ry. The several Swiss railway companies make a very frequent adaption of that American type of locomotive known as the mogul, since it is very well fitted to work on lines with heavy gradients. It has three axles coupled, and one located in front ahead of the cylinders. The steam works in two cylinders only; and, by means of an automatic starting valve of the von Borries type, live steam may be admitted direct to the low-pressure cylinder. The cylinders and their steam chests are upon the outside. The springs of the first and second wheels are connected by a longitudinal and a cross equalizing lever; while those of the third and fourth axles are connected by equalizers at the sides. The steam pressure is 180 lbs. per sq. in., the heating surface is 1,209 sq. ft., and the grate area is 16.1 sq. ft.

Fig. 27 is a 3/4 coupled passenger locomotive of the Belgian State Ry. The engine is remarkable for its weight. and is used for hauling heavy express trains upon difficult stretches of track. The very wide and very shallow firebox lies above the back axle, and has a firebrick bridge in front of the tubesheet, which is rendered necessary by the high grate. The Heusinger valve-motion is used. The cylinders are inside the frames and inclined. The support is from four points. These engines are capable of hauling 100 tons up a grade of 1 in 60 at a speed of 40 miles an hour.

---

*This was probably intended for 2.2 tons.—Ed.

Fig. 28 is a 3/5 coupled four-cylinder, compound, express locomotive of the Baden State Ry. It is used for work on the long grades in the Black Forest. Here a locomotive of the "ten-wheeled type" was chosen, which is distinguished from the mogul by having a four-wheeled truck in front. The steam works in two high and two low pressure cylinders, as in the French compound locomotives. These locomotives were built by the Société Alsacienne, with the French engine as a pattern. The steam pressure is 180 lbs. per sq. in., the heating surface is 1,204 sq. ft., and the grate area is 22.6 sq. ft.

Fig. 29 is a 3/5 coupled express locomotive of the Canadian Pacific Ry. This engine is a sample of the "ten-wheeled" type. All of the details are the same as those given for Fig. 15, with the exception that the crownsheet of the firebox is carried by crown bars. The steam pressure is 190 lbs. per sq. in., the heating surface is 1,344 sq. ft., and the grate area is 25.8 sq. ft.

Fig. 30 is a 4/6 coupled express locomotive of the Chicago, Milwaukee & St. Paul Ry. In order that the weight on the driving wheels might not be excessive, a third trailing axle is placed at the rear. This engine, which is the most powerful express locomotive that has up to this time been put into service, carries a steam pressure of 210 lbs. per sq. in., has a heating surface of 1,774 sq. ft., and a grate area of 33.3 sq. ft.

Fig. 32 is a 3/5 coupled locomotive of the Mediterranean Ry., of Italy. This engine was built as a ten-wheeler in order to climb the steep grades of the Apennines. The frames are inside and the cylinders and the steam chests outside.

Fig. 34 is a 3/5 coupled express locomotive of the Hungarian State Ry. This engine was built for the same service as the preceding, but with a compound action. The frames are outside and the boxes of the cranks play in them. The steam pressure is 195 lbs. per sq. in., the heating surface 1,530 sq. in., and the grate area 32.3 sq. ft.

II.—Freight Locomotives.

In order to utilize the whole weight of the locomotive for tractive purposes it is customary in Europe to couple together all of the wheels of their freight locomotives; in America, on the other hand, it is the practice to place a pair of leading wheels or a bogie truck in front, whereby the running of the engine is made much smoother and the motion on sharp curves easier. The number of coupled axles varies from three to five. Upon European roads with heavy grades, 3/3 or 4/4 coupled engines prevail, the latter being the ruling type for steep gradients in Austria, France and Russia. In England the Northwestern is the only road having 4/4 coupled locomotives, the other companies using the 3/3 coupled. In Germany and France they have now made some headway in the introduction of the 3/5 coupled locomotives, with a bogie truck at the front, in imitation of the practice of the United States. In America there are two types in use: the 4/5 coupled locomotives, known as the "consolidation" type, and the "mastodon" type, having five axles coupled. By the use of two sets of working parts with three axles coupled, as in the Meyer, Fairlie and Mallet systems, a still higher tractive power is obtained. The Hagan system has a strong and flexible mechanism.

Fig. 22 is a 3/3 coupled freight locomotive of the Lancashire & Yorkshire Ry. The noteworthy peculiarities of this locomotive are the shortness of the boiler, the long wheel-base, and the position of the cylinders inside the frames. The valves are placed on top of the cylinders and are driven by the Joy valve motion. There are no overhanging weights and, in spite of the long wheel-base, the engine rides very easily. The steam pressure is 170 lbs. per sq. in., the heating surface is 1,099 sq. ft., and the grate area 18.3 sq. ft.

Fig. 31 is a 3/3 coupled compound freight locomotive of the Austrian State Ry. For a number of years the 3/3 coupled freight locomotive was the only one used on the moderately heavy grades. Now they are only used on branch lines, since their short wheel-base and overhanging weights unfit them for speeds of more than from 28 to 30 miles an hour. The locomotive shown has a high tractive power; the starting apparatus is of the Golsdorf type, with valves driven by an outside Heusinger motion. The steam pressure is 180 lbs. per sq. in., the heating surface 1,290 sq. ft., and the grate area 12.9 sq. ft.

Fig. 33 is a 3/3 coupled locomotive built by the Schenectady Locomotive Works. This locomotive is used in America for switching purposes in railway yards, and is provided with a tender having a sloping tank at the back.

Fig. 35 is a 3/4 coupled compound freight locomotive of the Prussian State Ry. Like the mogul type of engines on the American roads, these engines have a single pair of wheels in front of the cylinder, and, on account of their weight, they are especially fitted for the hauling of fast freight as well as passenger trains on steep grades. The boiler, with its heating surface of 1,481 sq. ft., is very large, and the firebox is placed above the back axle. Both cylinders are on the outside; the steam pressure is 180 lbs. per sq. in., and the grate area is 24.7 sq. ft.

Fig. 36 is a 3/4 coupled freight locomotive of the Great Northern Ry. These locomotives resemble other American passenger locomotives in their construction, so that what has already been said of them need not here be repeated. Their steam pressure is 190 lbs. per sq. in., the heating surface is 1,236 sq. ft., and the grate area 21.3 sq. ft.

Fig. 37 is a 4/6 coupled freight locomotive of the Duluth & Iron Range R. R. The tractive power of this locomotive is very great, and the use of a four-wheeled truck causes it to take curves very easily. It is used for hauling iron ore in the Lake Superior region. The steam pressure is 190 lbs. per sq. in., the heating surface is 2,171 sq. ft., and the grate area 34.4 sq. ft.

Fig. 38 is a 4/5 coupled freight locomotive of the Prussian State Rys. In the 4/4 coupled Prussian locomotives the distribution of the weight is not particularly favorable, a fifth axle running in a truck has, therefore, been added. The cylinders are outside and slightly inclined. The valves are driven by an Allan motion placed inside the frames. The springs of the driving wheels are connected in pairs by equalizers. The steam pressure is 180 lbs. per sq. in., the heating surface is 1,484 sq. ft., and the grate area is 24.6 sq. ft.

Fig. 39 is a 4/4 coupled freight locomotive of the Austrian State Rys. Although belonging to an old system, this engine is still extensively used in Austria. The steam pressure is 165 lbs. per sq. in., the heating surface is 1,769 sq. ft., and the grate area is 24.6 sq. ft.

Fig. 40 is a 4/4 coupled, compound, freight locomotive of the Paris, Lyons & Mediterranean Ry. The engine has four cylinders, arranged with the low pressure cylinders (diameter 23.2 ins.) outside and the high pressure (diameter 14.2 ins.) inside. The Serve tubes have inner ribs, an outside diameter of 2.46 ins., and a length of but 9 ft. 10 ins. The driving wheels have a diameter of 59 ins., which is larger than that usually employed on freight locomotives. As a consequence of the use of the Serve tubes, the heating surface is comparatively large, 1,656 sq. ft., the grate area is 27.8 sq. ft., and, in all of the new locomotives of this company, the steam pressure is 225 lbs. per sq. in.

Fig. 41 is a 4/5 coupled compound locomotive of the Mohawk & Malone R. R. The arrangement of the axles is similar to that of the Prussian locomotive, Fig. 38. The locomotive is a characteristic example of the consolidation type. The steam pressure is 190 lbs. per sq. in., the heating surface is 1,838 sq. ft., and the grate area 32.3 sq. ft.

Fig. 42 is a 4/4 coupled compound locomotive of the Prussian State Rys. The first locomotive in Prussia with four axles coupled and intended for heavy freight service on steep grades was built in 1894. The frames are inside and the firebox is placed over the rear axle. The engine is fitted with the Allen valve motion, and, for starting or the exertion of the maximum tractive force, it is fitted with a von Borries intercepting valve. The cylinders have a diameter of 20.87 ins., and 29.53 ins., with a stroke of 24.8 ins. The other measurements are the same as in Fig. 38.

Fig. 43 is a 5/5 coupled compound freight locomotive for the Wurtemberg State Ry. The peculiarity of this locomotive consists in the fact that the two end axles can move into a radial position with reference to a curve, and, yet, are coupled together. This result was obtained by the use of the Klose system. The steam works in the three cylinders either with single expansion or on the compound principle. The steam pressure is 180 lbs. per sq. in., the heating surface is 2,129 sq. ft., and the grate area is 23.7 sq. ft.

Fig. 44 is a 5/6 coupled, compound, freight locomotive of the Erie R. R. This enormous engine was built by the Baldwin Locomotive Works, and it is intended for the Pennsylvania coal traffic. It is built on the Vauclain system, with one cylinder over the other. The diameter of the high pressure cylinders are 16 ins., diameter of the low-pressure cylinders 28 ins., and stroke of the piston 27 ins. The number of coupled axles and the weight put upon them (16 tons per axle) do not indicate good design. The firebox is very large and very long, is of the Wootten type, and is adapted to the burning of anthracite culm. As a result of their great length the engineer is stationed alongside the boiler, and there is another cab for the firemen at the back. The separation of the two men is a great disadvantage.

Fig. 45 is a 2/2 coupled compound freight locomotive of the Prussian State Ry. The frames are carried on two swivel trucks. The forward truck carries the low-pressure and the back the high-pressure cylinders. The parts of the engine proper are entirely separated from each other. The springs of each truck are connected by equalizing levers, so that the weight on the individual axles remains unchanged and the locomotive is carried on four points. This engine possesses great tractive power and flexibility. The steam pressure is 180 lbs. per sq. in.; the heating surface is 1,559 sq. ft., and the grate area is 20.4 sq. ft.

III.—Tank Locomotives.

The arrangement and proportions of tank locomotives vary according to the service for which they are intended. Tank locomotives are built either with ordinary frames or on the Krauss system whereby the frames are so arranged as to form the water tank. This portion of the review will be divided into two heads, in the first of which those tank locomotives intended for main line traffic will be described, and in the second those designed for branch lines.

(a).—Main Line Locomotives.

Fig. 46 is a 2/3 coupled passenger, tank locomotive of the Prussian State Ry. These engines, with ordinary plate frames and side water tanks, are used in passenger traffic on lines where the grades are light. The ease of running is injured by the weight of the overhang. The steam pressure is 180 lbs. per sq. in.; the heating surface is 968 sq. ft., and the grate area is 17.2 sq. ft.

Fig. 47 is a 2/3 coupled passenger tank locomotive of the Hanoverian Rys. The arrangement of the cylinders back of the leading axles in connection with the long wheelbase insures a very easy motion for the engine. The water tanks form a portion of the frames. The steam pressure is 180 lbs. per sq. in.; the heating surface is 897 sq. ft., and the grate area is 15 sq. ft.

Fig. 49 is a 2/4 coupled, compound passenger tank locomotive of the Central Ry. of Switzerland. The application of the bogie truck to tank locomotives has also been made in England, and the north of France, as well as in Switzerland. The engine shown here has ordinary frames with side water tanks. The steam pressure is 180 lbs. per sq. in.; the heating surface is 1,043 sq. ft., and the grate area, 17.2 sq. ft.

Fig. 50 is a 2/4 coupled passenger locomotive of the South Eastern Ry. The passenger traffic within the city limits of London requires a rapid acceleration, and the locomotive here shown is intended to do this. The tractive power is 10,230 lbs.; the steam pressure, 170 lbs. per sq. in.; the heating surface, 714 sq. ft. and the grate area, 15 sq. ft.

Fig. 51 is a 2/4 coupled freight locomotive of the London City Ry. A long wheelbase is obtained by placing the axles at either end of the firebox, which is 6½ ft. long. The cylinders are outside and inclined. When running through the tunnel the steam is exhausted into the feed-water, whence it naturally follows that the boiler must be fed by pumps. Since the running is done for the most part in tunnel, no shelter is provided for the engineer.

Fig. 52 is a 2/5 coupled freight locomotive of the London, Tilbury & South End Ry. It is designed for special freight traffic on lines with light rails. It runs in either direction with equal facility and readily passes around curves of short radius. The front end of the engine is carried by a bogie truck, and the back end by a single axle, which is held in position by springs. The steam pressure is 170 lbs. per sq. in.; the heating surface, 919 sq. ft., and the grate area, 15 sq. ft.

Fig. 53 is a 3/3 coupled passenger tank locomotive of the Western Ry. of France. The constructive proportions of the engine are good; it resembles the English types in size and appearance. Its three coupled axles enables it to work successfully upon steep grades. The steam pressure is 150 lbs. per sq. in.; the heating surface is 968 sq. ft., and the grate area is 14 sq. ft.

Fig. 54 is a 3/7 coupled passenger tank locomotive of the Chicago & Northern Pacific R. R. The engine is of the Forney type, and is used for suburban traffic out of Chicago. The weight in working order is 71 tons. Similar engines are now extensively used in the suburban traffic about other large American cities. The steam pressure is 190 lbs. per sq. in.; the heating surface is 1,462 sq. ft., and the grate area is 22.6 sq. ft.

Fig. 55 is a 3/4 coupled compound freight locomotive of the Prussian State Ry. The engine was designed to meet the requirements of a fast freight service and heavy passenger traffic upon steep grades. The boiler has a heating surface of 1,481 sq. ft.; a grate area of 24.7 sq. ft., and carries a pressure of 180 lbs. per sq. in. The forward axle is carried in a curved box in such a way that it has some side play.

Fig. 56 is a double 2/2 coupled freight locomotive of the Central Ry. of Switzerland. It is built on the Mallet system. The engine has a tractive power of 20,550 lbs. It is used on the line between Basle and Olten.

Fig. 57 is a double 3/3 coupled freight locomotive of the St. Gothard Ry. On the St. Gothard Ry. there are long grades of 1.4% and over, with curves of 1,000 ft. radius. Until recently two 3/3 coupled locomotives were always used for working trains over these grades, but they have now been supplanted by the locomotive here shown, which is a Mallet compound engine. The total wheelbase is 26 ft. 8 ins. The tractive power reaches the remarkable figure of 22,000 lbs. As the result of its great adhesive weight, it can haul a train of 220 gross tons up a 1.37% grade.

(b).—Tank Locomotives for Narrow Gage Lines.

Fig. 48 is a 1/2 coupled compound locomotive of the Hanoverian Ry. The engine has box frames, Heusinger valve motion, and the von Borries automatic intercepting valve. The steam pressure is 180 lbs. per sq. in.; the heating surface, 371 sq. ft., and the grate area, 8.6 sq. ft.

Fig. 58 is a 4/4 coupled tank locomotive of the Hagans type. It is designed for a gage of 2 ft. 11.4 ins., and to work on grades of 1.4%, and around curves of 130 ft. radius where it can haul 114 tons. The two forward axles are set in the main frames, while the two back ones are in a swivel truck. The Heusinger valve motion is used; the water tanks and coal bunkers are on the side next to the boiler, which carries a steam pressure of 180 lbs. per sq. in.; has a heating surface of 548 sq. ft., and a grate area of 9.1 sq. ft.

Fig. 59 is 2/2 coupled tank locomotive of the Emmenthal Ry. This system has been extensively introduced into Switzerland on account of its great simplicity. The engine works with a steam pressure of 150 lbs. per sq. in.; has a heating surface of 408 sq. ft., and a grate area of 7.5 sq.ft.

Fig. 60 is a 2/3 coupled locomotive of the Prussian State Ry. It is designed for work on branch lines at speeds of 18 miles an hour and over. The engine has a boiler that carries a pressure of 180 lbs. per sq. in.; has a heating surface of 817 sq. ft., and a grate area of 15 sq. ft.

Fig. 61 is a 3/3 coupled locomotive of the Northern Ry. of Austria. In spite of its light weight (28 gross tons) it has a tractive power of 8,800 lbs. The steam pressure is 165 lbs. per sq. in.; the heating surface, 580 sq. ft., and the grate area, 10.75 sq. ft.

Fig. 62 is a 3/4 coupled locomotive of the Prussian State Ry. On the line between Wiesbaden and Langenschwalbach there are grades of 1 in 30. These strong engines were built for such steep grades. The back axle runs in curved boxes and has some side-play. The engine is usually built with plated frames, side water tank, an outside Allan valve motion, and the air brake. The steam pressure is 180 lbs. per sq. in.; the heating surface is very large, being 1,450 sq. ft., and the grate area is 18.3 sq. ft.

Fig. 63 is a double 2/2 coupled compound locomotive of the State Ry. of Saxony. The Meyer system, upon which this engine is built, differs from the Mallet system in that each steam truck is free to turn over a center plate having a smooth upper surface. The engine, therefore, runs more easily over sharp curves, but it requires more joints in the steam pipes. The steam pressure is 180 lbs. per sq. in.; the heating surface is 925 sq. ft., and the grate area, 15, sq. ft.

THE ADOPTION OF A STANDARD KNUCKLE FOR M. C. B. COUPLERS.*

By P. H. Peck.†

I will give the Club facts and figures, gathered by close observation during the past seven years in heavy interchange of cars, to show why a standard knuckle should be adopted by the M. C. B. Association. If it were not for the interchange of cars by railways, the Interstate Commerce Commission and M. C. B. rules or standards would not be necessary. The more cars interchanged, the more standards are required in order that the cost of repairs may be kept at a minimum, and switching and delay to traffic avoided. As the volume of interchange has increased, new difficulties and dangers have arisen, and the M. C. B. Association was organized to devise means for overcoming these difficulties and dangers and the annoyances occasioned thereby. Rules governing the interchange were framed and standards adopted, and the adoption by the Association was followed by legislation on the part of both the state and national governments to compel the use of the standards.

We have standards for many parts of trucks, and standard drawbars, but the latter ends at the contour lines, leaving the most essential feature, the knuckle, not standard. The knuckle receives the shock first and is, therefore, most likely to be injured, and for this reason, if for no other, it should be interchangeable. Delays of several hours are frequently caused by having to set a car on the repair track to change the bar, because there may be no knuckle at hand which will fit the coupler head. With the link and pin bar such delays would not occur.

During the last few months I have endeavored to secure the names of the different knuckles in use at the present time and the numbers of different designs furnished by each coupler company. The result was a surprise to me. The following statement represents the result of my efforts in the direction referred to:*

M. C. B. Couplers and Knuckles in Use.

Weight of knckls, lbs.	Name of coupler.	Number of knuckles.	Weight of knckls, lbs.	Name of coupler.	Number of knuckles.
46	American	2	51	Erie	1
	Ajax	1	41	Elliott	1
49	Barfield	1		Foster	1
	Barnes	1	49	Forsyth	1
	Brown	1		Fox	1
54	Burns	1	38	Gould	1
46	Buckeye	3	38	Gallager	1
	Cowell	1		Gifford	1
48	Columbia	1		Gelston	1
51	Chicago	2	51	Hinson	2
35	California	1	41	Hinson	0
40	Champion	1	38	Hien	2
	Deetz	1		Imperial	1
64	Dowling	2	40	Interstate	1
57	Dowling	0	37	Janney	1
60	Drexel	2	37	Johnson	1
45	Detroit	1		Kling	1
43	Diamond	1		Laburt	1
52	Excelsior	1	61	Ludlow	1
	Edwards	1	50	Lone Star ...	1
36	Empire	1	50	Little Delaw're	1
42	Eureka	1	49	Mo. Pacific ...	2
37	Mather	1	54	St. Louis	2
48	Murphy	1	47	Smith	1
	Marks	1	66	Stand. improvd	1
53	New York	1	53	Smilie	2
43	National	1	51	S. H. & H.....	1
	Price	1	51	Safety	1
38	Pooley	1	50	Talbot	1
49	Perfected	1	50	Trojan	1
	Paragon	1	53	Tower	2
39	Peerless	1	50	Thurmond	2
	Pacific	1	46	Taylor	1
	Rickison	1		Timms	1
55	Standard	1		Union	1
49½	Solid	1	50	Vandorston ...	1
	Shomaker	1	34	Williams	3
	Saams	1	40	Williams	0
	Springer	1	45	Williams	0
	Simplex	1		Walker	1
			50	Washburn	1

This is a total of 77 bars and 83 knuckles; 9 bars having 2, and 2 bars having 3 knuckles each, and in only one instance will the knuckles interchange with each other. The average weight of the 56 knuckles, the weight of which is known, is 48 lbs.; the heaviest being the Standard, 66 lbs.; the lightest, the Williams, 34 lbs.

In order to have, in way cars or at interchange points, knuckles (one of each kind) averaging 48 lbs., it would require 4,464 lbs., which, at 3½ cts. per lb., would cost $156.24. To furnish one knuckle of each of the above kinds, at 16 different points and for 20 way cars, it would require 160,704 lbs., representing a value of $5,624.64.

I find, from the records kept in my office for the past 6½ years, that as the number of M. C. B. bars handled increased, the percentage of broken bars and of broken knuckles decreased, as shown by the following table:

		No. cars to				No. cars. to	
Year.	M.C.B. bars.	1 bar broken.	Knuckles broken.	Year.	M.C.B. bars.	1 bar broken.	Knuckles broken.
1892...	8%	377	2,476	1896...	42%	996	2,345
1893...	15%	385	1,684	1897...	48%	1,240	2,573
1894...	20%	424	1,609	1898...	59%	1,872	3,047
1895...	28%	620	1,663				

A large proportion of the breakage of knuckles occurs when an M. C. B. coupler is coupled with a link and pin bar, such breakages being most likely to occur in heavy trains. In some cases the coupling is made by the pin being placed through only the top hole of the knuckle and into the link; this either breaks the top lug off or breaks out the pin hole; in other cases the knuckles may be broken when two cars strike together and both knuckles are closed. Very few M. C. B. bars are broken when two of these bars are coupled together. Included in our own equipment we have 88 cars and 22 locomotives equipped with M. C. B. couplers; 32 cars equipped last year and the locomotives equipped within the last eight months. As yet we have had but one knuckle broken (that on a car) and that was caused by an accident. One of the engines equipped in this manner is double-crewed most of the time for service both night and day. This serves to illustrate that fact that the proportion of breakage to M. C. B. couplers on switching roads is much less than many believe to be the case.

I do not find, in actual practice, the trouble anticipated by Mr. P. Leeds, in his paper before the Central Association of Railroad Officers, as published in the "Railroad Gazette," of Aug. 12, 1898, viz.: Flange wear or crowding the flanges against the rail, or that the bar is not strong enough for our modern 80,000 and 90,000-lb. capacity cars. We handle hundreds of these cars and the number of breakages of couplers is no greater than with other cars. We do find, however, that when these heavy cars strike very hard, the load shifts, in some instances forcing the end out of the car, but not breaking the bar. I have seen cases of rear-end collisions and trains breaking in two, and have found that in such accidents the damage to M. C. B. bars was not one-fourth as great as that to link and pin bars. Cars are not as liable to telescope when equipped with M. C. B. couplers as when equipped with link and pin drawbars.

In regard to the handling of passenger equipment, we have five roads for whom we do the switching at Dearborn St. station, four of which use the M. C. B. bars, the fifth the Miller hook bar. It is possible to couple the M. C. B. couplers on short curves where the same is impossible with the Miller hooks. We have two engines equipped with the M. C. B. couplers in this service and we are able to couple the engine to M. C. B. bars at points where it is impossible to couple the Miller, with link and pin.

Finally, the trucks, draft rigging, drawbar stops, uncoupling levers and knuckle should be standard and interchangeable. The knuckle, most important of all, should receive immediate attention by the M. C. B. Association, and either the patent rights of a knuckle should be purchased by the Association, or six or seven of the best knuckles at present on the market should be adopted as standard; there are, at least, six or seven which are first-class. If something like this is not done before the law goes into effect, we will soon be in worse trouble in interchanging cars than we were in with the link and pin. A cored or hollow knuckle should not be considered; such knuckles are of no value whatever. It is only 14 months to the time the law takes effect, and something along the lines indicated in the foregoing should be done without delay.

Discussion.

Mr. Ira C. Hubbell (K. C., P. & Gulf Ry.).—I hope that the Western Railway Club will voice itself unanimously in favor of a standard knuckle, and also demand a reasonable, uniform price to all lines on all M. C. B. couplers.

Mr. Gustav Giroux (C., B. & Q. R. R.).—A point that ought to receive some attention soon, is the amount of play that can be allowed around the contour line before the coupler becomes unsafe. There is an M. C. B. gage that gives a minimum and maximum limit to this play, and its use is required by a few roads when buying new couplers; but is there no limit to this play after the coupler is put in service? There are hundreds of couplers in service which do not pass or meet the requirements of the M. C. B. gage.

It will pay to get couplers fitted together in a better manner and with as little lost motion as possible, because we all know a coupler wears loose too soon. Require that the contact parts of the coupler be smooth and clean, free from sand, grit or scale, and the coupler will work easier. I think that it would be much better for all roads to request the manufactureres not to paint couplers, but to put the cost of painting into producing smoother and cleaner castings and fitting the same together with more care; this would enable us to see who are turning out the best castings.

I hope that a standard diameter and length of pivot pin will be adopted; we now have pins 1¼, 1⅜, 1½ ins. diameter and find couplers made for 1½-in. pivot pin repaired with pins 1⅜ or 1½ ins. in diameter. Again, if a cotter or split key is put through the lower end of the pivot pin, I think we would not hear of so many pivot pins working out of place. I have seen a round coupling pin used for a pivot pin; also a knuckle of a certain coupler put in a bar of a different make; I have known repairs similar to the latter to cause breaks in the train three times in a distance of 38 miles.

I hope that the M. C. B. Association will get out very soon a standard specification, specifying not only what kind of a test couplers shall stand, but also specifying the length of guard arm, amount of play around contour lines (not only for new couplers but also for couplers in service), diameter and length of pivot pin and diameter of hole, thickness of knuckle through pivot-pin hole. and distance between lugs of bar, and that all parts shall be plainly marked at a specified place in such a manner as to enable ordering parts for repair.

Mr. A. M. Waitt (L. S. & M. S. Ry.).—I think no one will question the desirability of having a standard knuckle for couplers, but I think many will question the probability that we shall ever enjoy such good fortune. Mr. Peck has shown, in the table given in his paper, the great variety of knuckles, and, excepting two, none are interchangeable with those of other makes. On this account it seems to me that we are a long distance from anything like uniformity. I think that it would not be practicable to attempt voting into existence anything in the way of a standard coupler or a standard knuckle. It seems to me that uniformity in the M. C. B. couplers, or in the knuckles, can be accomplished only gradually and by educating people to appreciate what is the best. I believe we can, however, go a great way toward eliminating the poorer class of couplers and knuckles, either by bringing about the survival of the fittest, or in some other way reduce to a few the number of couplers in the market. That can only be done, I believe, by adopting a specification of some kind.

Mr. Peter H. Peck (C. & W. I. R. R.).—The solution that Mr. Waitt offers is one I have had in view, namely, accepting five or six couplers as standard. In the present state of affairs, roads that are using good couplers pay for the bad couplers. Mr. Waitt might, as he thinks, be using the best coupler, and Mr. Mackenzie might be using another best coupler; but if their cars get on a road which has a cheap coupler that was removed on account of a broken knuckle, the inspector will get rid of the bad coupler by replacing it with a good one, and the road using the good coupler has to pay for the bad one.

Mr. John Mackenzie (N. Y., C. & St. L. Ry.).—I think the larger roads are adopting what we may call a fairly good coupler. When an undesirable coupler is broken, a second-hand good coupler may be used in replacement and the undesirable ones will be driven out gradually, and it will be possible to carry less stock for repair.

Mr. Clement F. Street ("Railway and Engineering Review").—A few years ago a number of public tests were made by committees from this club and from the Master Car Builders' Association, which brought out weak points in some of the couplers submitted. Immediately after the tests several manufacturers started their pattern makers and engineers to work making changes which were beneficial not only to themselves, but also to the railway companies. These tests have undoubtedly aided in driving from the market a number of undesirable couplers, and it would seem to me that the revival of this practice would eliminate some of the poor couplers which are being used.

Mr. F. A. Delano (C., B. & Q. Ry.).—I agree with what has been said in regard to the impracticability of adopting even five or six standard knuckles. The Interstate Commerce Commission is flattering itself that it is compelling the use of an automatic coupler; and yet, if you talk to trainmen and switchmen, you will find that they do not regard the M. C. B. coupler as an automatic coupler. They will tell you that they have to ride the cars, both to couple and uncouple them, and to hang on by their eye-teeth to hold up the pin and to insure that the cars will uncouple while in motion. Surely, that is not the kind of coupler that the Interstate Commerce Commission thinks it is compelling the roads to put on. I would suggest the appointment of a committee to look into the whole question of better standards for couplers.

---

*Abstract of a paper read at the October meeting of the Western Railway Club.

†Master Mechanic, Chicago & Western Indiana R. R., Chicago, Ill.

*We believe that some of the couplers included in this table are not of the M. C. B. type.—Ed. Eng. News.

Mr. H. R. Curtis (Latrobe Steel & Coupler Co.).—I think a great deal of the fault found with automatic coupler equipment is not due to the non-education of the Interstate Commerce Commission, but to the fact that a great many railways have followed the practice of buying and applying the cheapest coupler on the market. If the railways of the country had adopted and adhered to a standard test, they would not have had one-third of the many makes of automatic couplers that are now in service.

After further discussion the President was instructed to appoint a committee to investigate the general subject of standards for M. C. B. couplers. The committee appointed was composed of Messrs. Delano, Peck, Barr, Mackenzie and Fildes.

CONCRETE AND STEEL FLOORS FOR THE PETIT PALAIS DES BEAUX ARTS, PARIS EXPOSITION OE 1900.

This smaller palace of the fine arts occupies part of the site of the old Palais l'Industrie on the right bank of the Seine, in Paris. The basement and lower floors of this structure are interesting as examples of the Hennebicque system of floor construction in "armed-beton," or concrete and steel. The advantages claimed are that—with equal weights imposed, it has superior resisting qualities over floors made of iron and brick; and it is also expected to last longer than these because the iron employed is protected against rust by being completely embedded in beton. As described in "Le Genie Civil" these floors are of several types differing with their span.

For the smaller arches of 20-ft. span (Fig. 1) the beton mass presents a flat extrados, and an intrados that, with a rise of 9 ins., has a thickness of 3½ ins. at the crown and 12½ ins. at the springing point. For the larger spans of 24.11 ft. (Figs. 3 and 4) a series of armed-beton beams are used, 1.08 ft. wide by 1.41 ft. high, placed 7.6 ft. apart on centers; these beams support a floor of armed-beton of a constant thickness of 4 ins. The beams and floor are built separately, but form one mass.

The loads which these floors should carry are estimated as follows:

For the arched floor:	
Free load	1,540 lbs.
Flagging	220 "
Total per sq. meter.	1,760 lbs.
Total per sq. ft.	163.6"
For the floors with beams:	
Free load	2,200 lbs.
Flagging	220 "
Total per sq. meter	2,420 lbs.
Total per sq. ft.	225 "

These floors are to be tested by proof loads equaling one and one-half times these values; the rise must not exceed 1-800th of the span. A test of one of the floors with beams was made by loading it with 90,200 lbs. per beam, the equivalent of about 494 lbs. per sq. ft., and the maximum deflection at the crown was .9 mm.

As shown in Fig. 1 the armor in the arched type of floor is made of a series of beams placed at right angles to the axis of the arch and spaced one meter, or 3.28 ft. apart. Each of these beams is formed of two round iron rods, 17 mm. or .67-in. diameter; one of these rods is horizontal and only a few millimeters below the surface of the floor, and is built into the supporting walls. The other rod takes the curve of the arch, it is buried very near the surface of the intrados of the arch, and its ends are also built into the wall. The beam is then completed by adding a series of flat iron lattices, 30 × 2 mm., uniting the two round rods and tying them into the mass of beton, as shown. Upon the curved member of the beam, or arch truss, at intervals of about 8 ins., are placed a series of iron rods, 6 mm. or 0.24-in. diameter, running parallel with the axis of the arch. These latter rods are 25.6 ft. long, and at their extremities they pass the adjoining rods for a distance of about 2.3 ft., so as to avoid all danger from any lack of continuity perpendicular to the axis of the arch. Upon these longitudinal rods other rods of the same diameter, and spaced 13 ins. apart, are laid perpendicular to the first, so as to form a kind of network.

In the beam type of floor (Fig. 2) there are two systems of arming; one applied to the beams and the other to the floor. In the beams the armor takes the form of three longitudinal beams, or trusses, arranged somewhat like those in a suspension truss. In each there are two round iron rods, about 1 in. diameter; with one located horizontally and near the lower surface of the beam, and the other lying almost upon the first at the middle of the span and then rising at each end to the upper surface of the floor. These two rods are anchored in the supporting walls and are united to each other and to the beton mass by a series of flat bars, as shown.

The armor in the floor portion is made up of a series of round rods, 0.47-in. diameter, placed perpendicular to the direction of the beam and spaced about 8 ins. apart. These rods, alternately, are straight and running near the bottom of the floor, and bent so as to pass from the bottom of the floor span to the top surface of this span.

The beton employed in this work was made of 550 lbs. Portland cement to 400 litres, or 422.4 quarts of sand and 898 quarts of gravel. This beton was made on the spot, and was then spread upon a wooden falsework, which forms the mold for the intrados of the arch, and was rammed against the iron armor placed in position in advance. When the arch was completed the beton was allowed to set for eight days, when its resistance was sufficient to allow the centers to be removed. At the end of 30 days the set was complete, and the floor was then ready to be subjected to the prescribed test load.

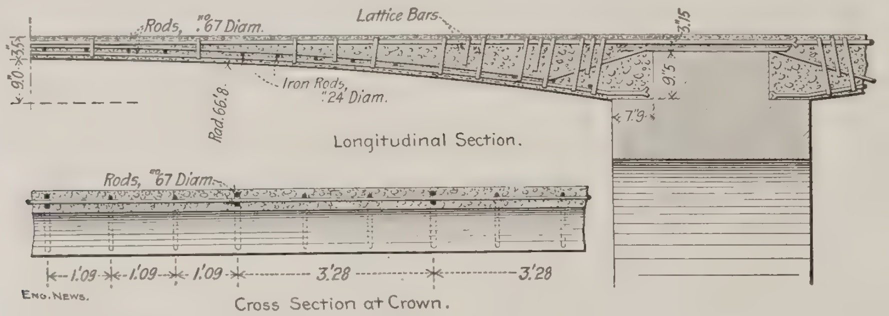

FIG. 1.—HENNEBICQUE ARCH SYSTEM OF STEEL AND CONCRETE FLOOR CONSTRUCTION FOR THE PETIT PALAIS DES BEAUX-ARTS FOR THE PARIS EXPOSITION OF 1900.

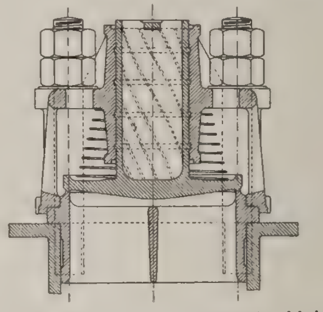
COMPOUND BLOWING ENGINE BUILT FOR THE HERNADTHALER IRON WORKS, KROMPACH, HUNGARY.

(With full-page plate.)

We show on our inset sheet this week an interesting horizontal blast furnace blowing engine built by the firm of Bolzano, Tedesco & Co., of Schlan, Bohemia, for the Hernadthaler Iron Works, at Krompach, Hungary. We have reproduced the engravings on our inset sheet, and those shown herewith from the "Zeitschrift des Vereines Deutscher Ingenieure," and the following description has been translated from the same journal by Mr. Geo. L. Fowler, M. Am. Soc. M. E.:

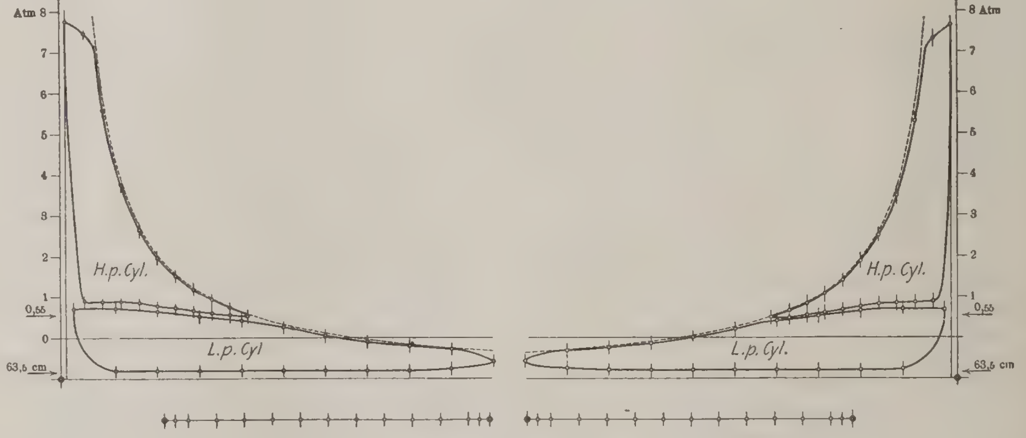


Vertical Section of Automatic Valve.

The specifications prepared by the purchasers of this engine required the valve-motion of the high-pressure cylinder to be controlled by a governor so that steam could be cut off up to half the stroke, or could follow the piston full stroke in starting the machine. Positive-moved valves were required on the air cylinders and they were to have a capacity of 28,250 cu. ft. of air per minute with the engine making 52½ revolutions, and a capacity of 26,840 cu. ft. per minute at 50 revolutions, and a maximum air pressure of about 10 lbs. per sq. in., the initial steam pressure being 112 lbs. and the steam expanding 8 to 1. The fly-wheel was to be so proportioned that the engine should run evenly and smoothly at 26 revolutions per minute, with steam of 82½ lbs. per sq. in., expanding 7 to 1, and the air pressure about 6.4 lbs. per sq. in.

As shown on the inset sheet, the engine is of the horizontal, cross-compound duplex type, and is fitted with Corliss valve-gear throughout. The cylinders are 35.43, 54.33 and 76.77 ins. diameter, with a common stroke of 55.12 ins. The piston rod of the air cylinder extends through the back head, and its weight and the weight of the piston is carried on slides in the front and rear of the air cylinder. The steam cylinders are jacketed, and the jacket is a riveted steel shell made in halves and secured to the cylinder, a special design of the builders. A reheating receiver is placed between the high and low pressure cylinders.

The valve gear is operated by three eccentrics, one driving the steam exhaust valves, one the steam admission valves, and the third the air valves. The valve motion is controlled by means of the Proell weight governor, which has two sliding weights. By changing position of these weights the speed of the engine may be varied about 10 revolutions per minute while the engine is in motion. By changing the driving wheel of the regu-



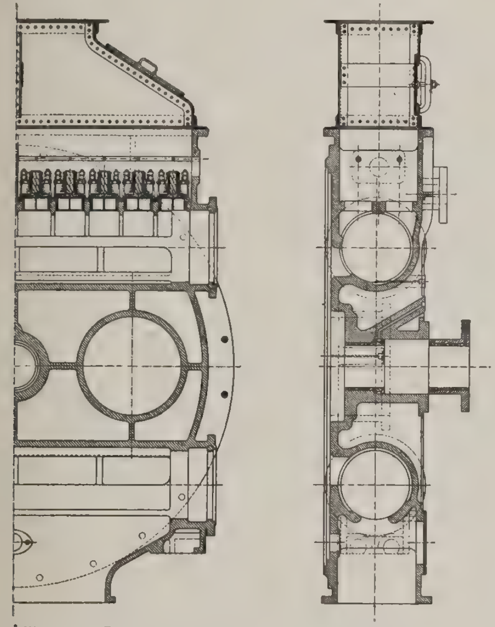
INDICATOR DIAGRAMS FROM STEAM CYLINDERS.

lator while the engine is at rest a still further change in the speed is possible, and a total range of speeds of 33 to 53 revolutions per minute thus provided for. The low-pressure admission valves have a fixed point of cut-off.

A most interesting feature of the engine is the arrangement of the air valves. As already stated, these are driven by a valve-gear of the Corliss type. The air enters through ducts in the masonry foundation, passes up through the inlet valves at the bottom of the cylinders, and is expelled through exit valves at the top. Besides the positive moved valves, automatic spring-actuated valves are placed on top of the cylinder. There are 20 of these at each end of the cylinder. These valves are rotated as they rise and fall by helical guides in the casings in which they work. The sectional area of the air passages at different points are as follows:

	Passages		Check
	Inlet.	Outlet.	valves.
Total area, sq. ins.	325.6	279.0	379.8
Ratio to net cross-section air-cyl.	1 to 14	1 to 16.4	1 to 12
Vel. air at 33 revs., ft. per min.	70.8	83.0	60.7
Do. at 53 revs., ft. per min.	113.5	132.8	97.1

It may be noted that the above engine speeds correspond to piston speeds of 300 to 486 ft. per minute.



½ Transv. Section. Long. Section.

Sections Through Air Cylinder.

Tests of the engine were made before its acceptance by the purchasers, and the results are summarized as follows:

Date of test, Aug. 20, 1897. Duration, 9 h. 55 mins.

M. E. P., high-pressure cylinder, lbs. per sq. in.	29.1
M. E. P., low-pressure cylinder, lbs. per sq. in.	7.7
M. E. P., air cylinder, lbs. per sq. in.	5.6
Revolutions, per minute.	37.5
Power developed, high-pressure cylinder, HP.	304.9
" " low-pressure cylinder, HP.	333.0
" " total HP.	637.9
Work done in air cylinder, HP.	547.1
Efficiency, %.	85.75
Steam consumption, lbs. HP. hr., inc. jacket & recvr	15.25
Excluding jacket and receiver	13.93

The steam diagrams are herewith reproduced. The vacuum in the condensers amounted to only 25 ins. on account of the temperature of the injection water, which ranged from 64° to 68° F.* The temperature of the air above the pressure valves was 132.8° F.

The suction lines of the left-hand diagram from the air cylinder on the inset sheet show some irregularity, which investigation proved to be due to a temporary change in the inlet passage, which caused eddies in the air current. The reservoir into which the air cylinder discharged was also so small that the pressure in the air cylinder rose considerably during the period of delivery. When the machine was put into actual use, however, both these defects no longer existed, and the card taken from the air cylinder as run in actual service (the right-hand diagram in the inset) shows excellent work in both the intake and discharge of the air.

RAILROAD SURVEYING IN TROPICAL FORESTS.

In a recent paper read before the Institution of Civil Engineers Mr. Frederic Shelford, Assoc. M. Inst. C. E., describes "Railway Surveying in Tropical Forests." This paper refers to rapid work performed in the location of railways in Africa, British Honduras and British Guiana. He divides the work to be done as follows: (1) The ride or march over several routes to determine the general route. (2) A reconnoissance survey, for approximate location on the route selected. (3) The location of the center line; with cross-sections of adjoining grounds. (4) The final staking-out.

The first rough survey is to gain general information concerning villages and towns, rivers and small water courses, notes on the geology of the country, a general idea of population, healthfulness of the country and general topography. A prismatic compass and aneroid are used, with distances estimated by noting the time of walking or riding. Rapid work is the essential point aimed at; but a trained observer can secure much valuable information in this way.

With the general route decided upon, a base is required to start the line. This is usually an existing path, road, timber pass or trade route; and the trade route or traveled path established by the natives, after long years of trial and the cutting of corners, is usually found to be the best for permanent location. As timber cutting is costly and occupies much time, it is to be avoided as much as possible. The instruments used were the miners' dial or compass, mounted on a stout tripod, with a plumb-bob and a ball-and-socket joint. This instrument costs only $30, so several may be taken along; it is light, and will stand rough treatment that would use up a more delicate instrument. The author says he never found a prismatic compass satisfactory; in hot, damp countries it becomes foul and slow in action and is apt to give false readings by the dial touching the top glass, when read several hundred times a day.

The chain used is a steel band tape, ⅝-in. wide, with the 1-10 meters marked by brass studs. This chain has no projections and will drag easily, but it must be constantly oiled to prevent rust. It is not very durable, but the author has used one tape in measuring 70 miles of railway.

The method of procedure is for one engineer to run the compass, and a reliable native is sent ahead as far as possible with a pole, other natives cut a pathway towards this pole until it can be seen from the compass. Trees are blazed and marked with a chalk at each turning. In bush country, 3 miles, 60 chains is a good day's work, as there is a long walk to camp and the work must be plotted in the evening. Distances are sometimes measured by a measuring wheel, though owing to rough and crooked paths this is not very accurate. Leveling is done by a dumpy level and two rodmen, with levels taken at every station and bench marks established. This leveling is done at about two-thirds the speed of running the line, and this gives the compassman one day in three for plotting work, etc. Cross-section lines are often surveyed by a pocket compass, fixed on top of a sharpened stick; and here an aneroid barometer is at its best for obtaining levels, as the whole line is measured in 20 or 30 minutes, and the atmospheric pressure has little time to vary.

Plotting the surveys, final location and staking-out for work, differ little from ordinary methods. The author reckons the cost of such surveys per mile, as follows, including instruments and equipment, but without traveling expenses to point of commencing work:

	Per mile.
Rapid reconnoissance survey of 200 to 400 miles; with a rough location of the railway, approximate estimate, statistics, etc.	$40.00
Cutting path through unknown forest, without roads or paths of any kind; with rough railway location.	70.00
Reconnoissance survey along trade routes; with numerous cross sections; careful location and leveling of line; close approximate estimate, etc.	80.00
Accurate reconnoissance survey; exact location of line; clearing the same, staking out, leveling, cross sections and complete working survey.	$600.00 to 650.00.

These results are deduced from actual surveys made in very hilly countries, where railway location is troublesome.

An ingenious method of permanently marking stations was used in British Honduras, the chief object being to reduce the material transported to the smallest bulk. It should be understood that pencil or paint marks cannot be put upon a freshly cut and bleeding blaze on a young tree, so as to last any time. The plan adopted enabled the station marks to be found after the lapse of two or three years.

The marking was done with copper nails about 1½ in. long. These nails were driven in about halfway and then bent over in various directions, to indicate the numerals from 1 to 9 inclusive, according to an arbitary code. A blaze was first cut on the tree in the form of a cross. A nail in the center of the cross indicated units; one in the right hand upper arm, tens; left hand upper arm, hundreds; bottom left hand arm, thousands, and bottom right hand arm, tens of thousands. The bending of the nails to indicate numerals may be on any convenient system. In that used by the author, a nail bent up and to the right at an angle of 45° with the vertical represented 1; horizontally to the right, 2; bent down and to the right at 45°, 3; bent down on the vertical, 4; down to the left of the vertical and at an angle of 45°, 5; to the left, horizontal, 6; to the left and up at 45°, 7; up on vertical, 8; driven in straight, 9. For zero the nail was omitted. For example, the number 1,385 only required four nails; and as the full number was only marked at every tenth station, about 10 lbs. of copper nails were sufficient to mark 70 miles of line. For a reconnoissance survey by a party of two engineers not less than 30 men and 9 mules were required; or, if no mules were available, 57 men; 3 men being taken as the equivalent of one mule. For a staking-out survey, with numerous side lines to be cut and heavy clearing to be done, 80 men can be easily employed. In a rapid survey where the camp is moved about every third day, carriers are wanted in addition to the above. About 12 natives will be sufficient for shifting camp every third day. The march down country to Lagos, after finishing the survey, required 250 natives to carry five Europeans, three sick men and all stores, tools and camp equipment.

For a party of two engineers the following instruments were found suitable and sufficient for these surveys. Two miners' compasses on solid legs and of the plainest pattern; two 12-in. levels; two 16-ft. leveling rods; three steel tapes, ⅝-in. wide, on reels; three sets of steel pins; two pocket compasses; two paceometers; one measuring wheel; 36 ranging poles, 10 ft. long, and two 3-in. aneroids. For plotting work, they carried: Scales, set-squares, one protractor, one parallel ruler, two drawing-boards, sets of drawing instruments, etc. The cost of the equipment, for instruments only, was about $450.

Great care must be taken in selecting the equipment, as no useless articles should be carried; but to fail to bring some essential article may mean the failure of the whole expedition and the waste of much money. The equipment must be packed into loads according to means of transport. For a mule, this load must not exceed 30 × 15 × 12 ins., in dimensions, and weigh from 200 lbs. to 300 lbs. in a rough country. With native carriers the weight is more important than the bulk; and this weight should not exceed 50 lbs. for a long march, and 80 to 100 lbs. for a march of a few hours. Engineers for such expeditions need some medical and surgical knowledge, as accidents are frequent when timber is being felled.

BOOK REVIEWS.

ENGINEERING CONTRACTS AND SPECIFICATIONS.—A Brief Synopsis of the Law of Contracts and Illustrative Examples of the General and Technical Clauses of Various Kinds of Engineering Specifications. By Prof. J. B. Johnson, M. Inst. C. E., M. Am. Soc. C. E., M. Am. Soc. M. E., etc. Second edition. New York, N. Y.: Engineering News Publishing Co. Cloth; 6 × 9 ins.; pp. 452; $3.50.

The first edition of this now well-known work was reviewed at length in Engineering News of Aug. 15, 1895, and about all that is called for here is a brief mention of the additions and revisions which have been made in the present edition. These comprise for the most part a very complete set of specifications for the machinery, track and overhead construction of electric railways for both cities and country towns, these having been drawn by two of the leading engineers of the country in this class of work. The book has been improved in size and appearance, and taken altogether, as we said of the first edition, it should find a large field of usefulness among engineers and contractors.

---

*This would not account for the low vacuum. A temperature of 70° corresponds to a vacuum of 29.2 ins. A temperature of 126° corresponds to a vacuum of 25.85 ins.—Ed. Eng. News.

THE UNIVERSAL DIRECTORY OF RAILWAY OFFICIALS. Compiled from official sources by S. Richardson Blundstone, Editor of "The Railway Engineer." London: The Directory Pub. Co., 8 Catherine St., Strand, W. C. 8vo.; cloth; pp. 475; 10 shillings.

This is the fourth annual issue of this directory and it contains about 25 pages more in the directory than last year. It is stated that with the exception of the African-German colonies, it is believed that information respecting every railway in Africa is now included in the Directory. We are compelled to judge the book, however, by its treatment of United States railways, and on these the editor appears to have drawn the line at about 250 miles. Companies controlling less mileage than this are generally not included. This omission must, of course, be intentional, as the publishers undoubtedly have access to the many excellent and complete directories of American railways which are published, and we suspect no better reason exists for it than disinclination to increase the size and cost of the book. To be really honest, the publishers should frankly state that railways of less than a certain size are not included, or else refrain from calling their work "The Universal Directory."

WATER SUPPLY AND IRRIGATION PAPERS OF THE U. S. GEOLOGICAL SURVEY.—No. 12, Underground Waters of a Portion of Southeastern Nebraska, by Nelson Horatio Darton; No. 13, Irrigation Systems in Texas, by William Ferguson Hutson. Department of the Interior, Washington, D. C. Paper; 9 × 6 ins.; pp. 56 and 68, respectively.

These two separate pamphlets are issued by Mr. F. H. Newell, Hydrogapher in Chicago, in advance of the regular report, and for the convenience of those desiring to use their contents. No. 12 relates to a tier of counties, covering about 6,700 sq. miles of Southeastern Nebraska, and largely situated along the Platte River. In this region the annual rainfall is not large enough to always insure full crops, and the report treats of the geological formation and the water-bearing deposits which underlie nearly all of this area, at depths varying from 10 to 300 ft. No. 13 discusses, for the State of Texas, legislative enactments and the history of irrigation, the distribution of rainfall, and finally describes the irrigation, works and projects in that state. Both of these pamphlets are well illustrated by colored maps, half-tone photographs, plans and diagrams.

CALCULATIONS IN HYDRAULIC ENGINEERING.—A Practical Text-Book for the Use of Students, Draftsmen and Engineers. With numerous Illustrations and Examples. By T. Claxton Fidler, M. Inst. C. E., Professor of Engineering, University College, Dublin, Ireland. Part I. Fluid Pressure, and the Calculation of its Effects in Engineering Structures. Longmans, Green & Co., London, New York and Bombay. Cloth; 8vo.; pp. 153. $2.50.

The purpose and scope of this book are shown in the following quotations from the preface:

> This little book does not profess to be a treatise on hydraulics, but relates to those calculations which have to be made—many of them very frequently, and others perhaps more rarely, in connection with works of hydraulic engineering. . . . . It has been written in the language of practical men rather than in that of the schools or of the mathematician. In all cases, it has been the author's desire to discuss the rational groundwork of these problems in the simplest and plainest terms; and the student who happens to be accustomed to a more rapid mathematical treatment may perhaps find these preliminary discussions unnecessary; but they may nevertheless be acceptable to other students, whose training has been of a more practical kind, and whose ideas have been cast in a somewhat different mould.
>
> In dealing with the effects of fluid pressure, a good many of the calculations which have to be made are too simple to need any extended illustration in this book; and for that reason a great part of its contents is devoted to those problems which are not so simple, or to those which seem to have received but little consideration at the hands of other writers. Among these matters may be mentioned the forces which result from the axial fluid stress in a curved or in a straight pipe.
>
> The stability of floating bodies is treated with especial reference to engineering structures, such as floating docks, pontoons, and the caissons which are sometimes used for bridge foundations. . . . Some experimental measurements of the displacing forces, in the fluid arch and in the fluid column, are described in detail in the appendix, which also contains a short series of experiments upon the direct tensile strength of various forms of socket joints.

The author has made a valuable contribution to the literature of one branch of hydraulic engineering. The field he covers is a limited one, relating to hydrostatics only, and he by no means covers the whole of this subject, but the work as far as it goes is well done. Many of the problems in the book are rare and difficult, and the author's method of treating them is as clear and simple as the subject permits. The chapter headings are as follows: Practical Conception of Elementary Principles. The Action of Fluid Pressure of Uniform Intensity, Cylinders, Pipes and Bends under Uniform Pressure. The Buckling Tendency in Straight Pipes under Pressure. Fluid Arches. The Stability of a Line of Pipe. Hydrostatic Pressure of Varying Intensity. Floating Vessels. Bending Stresses in Floating Pontoons. The typography, illustrations and press work are excellent. We would suggest to the publishers that the leaves of the book should be trimmed. The use of uncut edges is carried too far when they are applied to engineering text-books.

U. S. GEOLOGICAL SURVEY.—18th Annual Report to the Secretary of the Interior, 1896-97. Charles D. Walcott, Director. In five parts. Part IV.—Hydrography. Washington, D. C.: Government Printing Office. Cloth, 11¼ × 7½ ins.; 756 pp.; maps, photographs and plans.

This is a full and very interesting report upon the following hydrographical heads: Progress report on stream measurements, by Mr. Arthur P. Davis; water supply of Indiana and the greater part of Ohio, by Mr. Frank Leverett; continuation of report on artesian waters of a portion of the Dakotas, by Mr. N. H. Darton, and storage reservoirs in the West, by Mr. James D. Schuyler. The book itself is the ninth annual report upon what has been known as the Irrigation Survey, authorized by Congress for the purpose of ascertaining the best means of utilizing the water resources of the arid and semi-arid sections of the United States. This Irrigation Survey was organized under the provisions of the Act of Congress of Oct. 2, 1888, and, under the title of "Water Supply and Irrigation Papers," a series of distinct bulletins has already been issued. Those published cover the following heads: Report of 1888-89, detail of organization and plans adopted; Report of 1889-90, a discussion of the hydrography and of the engineering surveys for canals and reservoirs, and a report upon the topography; Report of 1890-91, location and survey of reservoir sites, hydrography of the arid region, and discussion of irrigation in India; Report of 1891-92, water supply for irrigation, American irrigation engineering, engineering results of irrigation survey, and location of reservoir sites during year; Report of 1892-93, results of stream measurements, potable waters of Eastern United States, and natural mineral waters of the United States; Report of 1893-94, field work; Report of 1894-95, public lands and their water supply, and water resources of a portion of the great plains; Report of 1895-96, report of progress in the Division of Hydrography, underground waters of the Arkansas Valley in Eastern Colorado, water resources of Illinois, and artesian waters of a portion of the Dakotas. This list of subjects sufficiently outlines the scope of the survey and the general progress made.

The report of Mr. A. P. Davis, in the present volume, gives the discharge measurement of streams in nearly 20 states, as obtained by special resident skilled hydrographers. In these detailed reports we find the area of section, mean velocity discharge per second, drainage areas, run-off, etc., for rivers and their tributaries. While the list is by no means complete, a good beginning has been made in what will be of the greatest value to the hydraulic engineer. The territory covered is mainly west of the Mississippi River; though Georgia, Alabama, North and South Carolina, Virginia and West Virginia are included. In the report upon the Water Resources of Indiana and Ohio, by Mr. Leverett, we have a general statement of the physical conditions, with a contour map; a geological map and sections; a discussion of glacial ridges, and a map showing the Pleistocene Deposits on this territory, and the main drainage systems, separately treated. Underground waters and wells are studied in relation to the drift deposits; analyses of water are given, and the report continues with detailed observations on the water supply of cities and towns in Indiana and Ohio, as obtained from the latest authorities. Considerable space is given to rainfall data.

Irrigation by artesian well water in Eastern South Dakota is the substance of the report of Mr. Darton. He tells of the progress made, by counties; both in well-sinking and in irrigation. These South Dakota artesian wells are remarkable for their pressure; many of them showing pressures of 150 lbs. or more per sq. in.; or, the equivalent of a head of 350 to 400 ft. In a well sunk in 1896, at the Cheyenne Agency, the pressure is said to equal 205 lbs. per sq. in. The temperature of the waters of these wells reaches 94.9° F., as a maximum, with 70° to 80° as a common temperature. Though carefully studied, no satisfactory explanation has yet been found of the thermal conditions in the Dakota artesian basins. Chemical analysis shows that in the majority of the basins the waters have the character of surface water, and this would seem to prove that they are derived from local beds of sand and gravel in the drift formations, as some suppose. The volume of flow of the deep wells varies, with different diameters of tubing and local conditions causing partial clogging at the bottom. As shown on a map, the flow in gallons per minute for a 4½-in. outlet ranges from 10 to 2,000 gallons and more.

The paper of Mr. James D. Schuyler, M. Am. Soc. C. E., on "Reservoirs for Irrigation," is treated as we would expect it to be by an engineer of his ability and wide experience. He handles his subject under the main heads of rock-fill dams, hydraulic dam construction, masonry dams, earthen dams and projected reservoirs; and illustrates his paper with a large number of photographic views of completed work and work in progress, accompanied by plans and sections. In the case of many of the completed dams, Mr. Schuyler goes into the details of construction and cost, and the paper, in itself, forms an exceedingly valuable treatise on dam building and flume construction, under varied and difficult conditions. Many of these dams, however, have already been illustrated in this journal, and we shall later give more space than can be spared here to the illustration of several others that are worthy of especial mention.

ANNUAL MEETING OF THE AMERICAN INSTITUTE OF ARCHITECTS.

The 32d annual convention of this association was held at the Arlington Hotel, Washington, D. C., on Nov. 1-3.

The morning of the first day was devoted to the customary routine business attending the opening of a convention, which included a welcoming address by District Commissioner John B. Wight and the annual address by President George B. Post. Mr. Post expanded upon the advantages of selecting designs for government buildings by competition. In speaking of the work done in the past by the supervising architect's office, he said:

> Unfortunately these buildings are built with extravagant excellence and will stand for ages a travesty upon the art of the country, a reproach to the intelligence of those in power who have refused to listen to the urgent and repeated opinions of those qualified by education and experience to give advice, and have persistently neglected to use the means always at their hands to procure designs which should at least represent the average skill and economy daily shown by the architects of the country in private practice.

The report of the Board of Directors, among other things, called attention to the fact that the Institute in establishing its permanent headquarters in Washington was breaking away from all precedent and conducting what really might be called an experiment. This referred to the leasing of the historic "Octagon House" for a term of five years at an annual rental of $360. The object of this move is best expressed in the report of the committee having the matter in charge.

> That it afforded the broadest field for the institute to obtain national legislation in relation to art and construction; that it could here more efficiently advocate the establishment of a government testing station and a national architectural museum, and would be in a position to make its influence felt in the methods adopted by the government for procuring designs for national buildings.

The second day, Prof. W. C. Sabine, of Harvard University. read a paper entitled "Acoustics," in which he stated that the problem of securing an acoustically satisfactory auditorium depended upon three points. The first of these was the proper arrangement of reflecting surfaces, i. e., the walls and ceilings; the second, the avoidance of "interference;" the third, the prevention of the prolongation of the sound, which is due to improperly inclined walls, and an inadequate use of absorbent materials in the construction and furnishing of the halls. Relative to this latter point a chart was exhibited, which indicated the absorption power of different materials as follows:

Hair cushions on seats, per square yard, 2.03; heavy oriental rugs on floor, per square yard, .56; chenille draped as curtains, per square yard, 1.32; cretonne, hanging flat, per square yard, .33; canvas, hanging flat, per square yard, .71; hair felt against wall—half inch thick, per square yard, 1.00; one inch thick, per square yard, 1.8; two inches thick, per square yard, 2.4. Audience, per person, 1.3; individual man, sitting clear, 1.8; individual woman, sitting clear, 2.2.

The secretary read a paper by Adolph Cluss which emphasized the points brought out by Prof. Sabine.

The next paper, by Prof. G. P. Merrill, of the National Museum, "Remarks on Some Little-known American Ornamental Stones." was a review of the history of stone as a construction material and a description of a number of kinds of American stone suitable for building and ornamentation. The last paper of this session, "Peculiarities of Wood," by Prof. B. E. Fernow, Cornell University, was read by Mr. J. C. Hornblower.

The afternoon was devoted to an excursion to Cabin Johns bridge and vicinity, and in the evening papers were read on "The Place to Be Assigned to Jewish People in Architectural History," by Dr. Cyrus Adler, and "General Practice in Regard to the Employment of Electric, Heating and Ventilating Engineers," by H. G. Bradlee.

The latter paper advocated the employment of the engineer by the architect and not by the owner, and that the minimum commission should be 5% on all work costing over $10,000. The work of the architect is no longer confined to the design of a building which is architecturally beautiful, carefully planned and substantially constructed, but to-day he must equip the building with a complicated system of mechanical and electrical apparatus and must design and provide for a network of pipes, flues and wires running through all parts of the building. The architect of the modern building must be an engineer and must be familiar with mechanical, electrical and sanitary engineering in all its branches.

Pittsburg, Pa., was selected as the place of meeting for 1899, and the following officers were elected for the ensuing year: Pres., Henry Van Brunt; First Vice-Pres., W. L. B. Jenney; Second Vice-Pres., J. W. McLaughlin; Secy. and Treas., Glenn Brown; Directors, Frank Miles Day, Joseph C. Hornblower, T. D. Evans; for two years, Robert W. Gibson, Levi T. Scofield, W. M. Poindexter; for three years, Arthur G. Everett, of Boston; W. C. Smith, of Nashville; George B. Post.

The session of the last day was given over to a discussion of the By-Laws of the Institute and the consideration of reports.

The Advantages of Blower Systems for Drying Materials——Automatic Couplers for Air Brake Hose ——The Engineers' Work in the Santiago Campaign——Notes and Queries.

THE JAPANESE BATTLESHIP "SHIKISHIMA" was launched by the Thames Iron Works & Shipbuilding Co. on Nov. 1. This will be one of the most powerful warships afloat when completed. Her dimensions are: Length, over all, 438 ft.; length between perpendiculars, 400 ft.; extreme beam, 75 ft. 6 ins.; depth, 45 ft. 2½ ins.; draft on 14,750 tons displacement, 27 ft. 3 ins. She will have a complete water-line belt of Harveyized nickel-steel armor 8 ft. 2 ins. deep and tapering in thickness from 9 ins. amidships to 4 ins. at the ends; above this is a 6-in. belt between the barbettes, extending to the main deck. The barbettes are 14 ins. thick, and the cross bulkheads, 12 ins. The engines are to develop 14,500 I. HP., and drive the ship at a speed of 18½ knots. As armament she will carry four 12-in. guns in two barbettes; 14 6-in. rapid-fire guns; 20 12-pdr. rapid-fires; 8 3-pdr. rapid-fires; 4 2½-pdr. rapid-fires; 8 Maxim guns, and 5 18-in. torpedo tubes, 4 of the latter under water. Her coal capacity, however, is only given as 700 tons.

◆

THE CRUISER "MARIA TERESA," abandoned in a storm on her way from Cuba to Norfolk, is now aground on Cat Island, in the Bahamas. The water is up to her between-decks, she has a list towards the damaged side, and is dismantled. Meanwhile the wrecking company's boats have gone to inspect her, and a court of inquiry is to be held to determine if her abandonment was justifiable. Later information gives little hope of her final rescue. The hull is badly strained and the engines and boilers seem to be immovably fixed upon the rocks of the reef.

◆

THE DESIGNS FOR THE FOUR NEW MONITORS for which Congress appropriated $5,000,000 at its last session are to be materially changed as the result of recent action by the Navy Department. The prices at which the contracts for the vessels were awarded left so large a margin that it has been decided to build bigger and better vessels. The principal features of the old and new designs are compared as follows:

	Old.	New.
Displacement, tons	2,700	4,000
Coal capacity, tons	200	400
Main battery	2 12-in.	4 10-in.
Horse-power	2,400	3,200
Draft	12 ft. 6 ins.	14 ft. 6 ins.

The speed in the new designs will be 12 knots, as in the old.

◆

THE LIFE OF MODERN NAVAL GUNS is commented upon by Com. Charles O'Neil, Chief of the Bureau of Ordnance in the Navy Department. The popular idea was that a heavy naval gun was out of service and dangerous after 100 rounds had been fired from it with service ammunition. As a matter of fact, in the war with Spain, some of our 12 and 13-in. guns have been fired 300 times, and are yet as sound as when they left the factory, and are free from serious impairment by erosion by gases. Of the smaller pieces, some have been fired 600 and 900 times, and they are still perfectly sound and are not eroded to any extent. The use of cordite hastens the erosion of the gun, but in the British Navy the gun is built with a core, which can be bored out and replaced when too much worn. Commodore O'Neil says that most of the guns now in use in our navy will only be withdrawn when they become obsolete; he thinks there is little danger of their being worn out in service.

◆

MACHINE GUNS, says General Joseph Wheeler, proved their efficiency and value in the San Juan fight. The four guns used in the battery commanded by Lieut. John H. Parker, of the 13th U. S. Invantry, were the regulation Gatling model of 1895, firing regulation Krag-Jorgensen cartridges at the rate of 400 shots per minute each. He lost one-third of his men but drove the Spaniards from their trenches; and, at 1,500 yards, drove the gunners from a 6.4-inch Spanish gun which was trained upon them. This is probably the first time in warfare that a field gun of that caliber was silenced by machine gun fire. The Spaniards left their heavy gun loaded and admit a loss of 50 men in trying to fire that last charge. From July 4 to July 11 two Colt rapid-fire guns and a dynamite gun, throwing 4½ lbs. of explosive gelatine, were added to the Gatling battery. The dynamite gun fire had the effect of driving the enemy from his trenches and the machine gun played havoc with the fleeing men. Gen. Wheeler advocates the creation of an individual arm of the service to be known as the Gatling Gun Corps.

◆

THE REPORT OF THE CHIEF OF ORDNANCE, General Flagler, for the last fiscal year, deals lightly with the late war with Spain. The expenditures of the Ordnance Department for the year were $29,858,783. From April to August the Department produced 250,000 sets of infantry equipments and 26,000 sets of horse equipments; and it met all the demands made upon it for small-arm ammunition. In answer to the criticism on the 45-caliber Springfield rifle used by many of our regiments, General Flagler says that while the single-fire Springfield was not so good as the magazine 30-caliber rifle, it was by no means as inferior as asserted. It fully met all the demands of an active campaign; the chief objection being the use of black powder in the cartridges. Smokeless powder is now being supplied for the Springfield rifle. General Flagler points out, as one of the lessons of the war, that 100,000 stands of arms should be procured at once, and the factories at Springfield and Rock Island should be equipped for turning out 2,500 stands per day; field and siege guns and equipments for an army of 500,000 men should also be held in reserve, as six months' time would be thus saved in an emergency.

◆

EXPERIMENTS WITH FLYING MACHINES, for use in war,are to be conducted by the Board of Ordnance and Fortifications, and the sum of $25,000 has been appropriated for this purpose. The experiments will be carried out by General Greely, of the Signal Corps.

◆

THE U. S. ARMY, IN THE WAR WITH SPAIN, reports Adj.-Gen. H. C. Corbin to the Secretary of War, numbered as follows: At the breaking out of the war the regular army consisted of 2,143 officers and 26,040 enlisted men. Under war legislation this number was increased to 2,332 officers and 56,365 enlisted men, including 5,365 men of the hospital corps. Regular army officers, to the number of 387, were appointed to different grades in the volunteer army. At its highest point the volunteer army numbered 8,785 officers and 207,244 enlisted men; in August, 1898. The aggregate strength of the whole army was thus 11,108 officers and 263,609 enlisted men. The casualties of the war were: 23 officers killed, 113 wounded; 257 enlisted men killed, 1,464 wounded. The total deaths from wounds and disease, to Oct. 3, were 107 officers and 2,803 enlisted men; or a little over 9 per 1,000 for the officers and 10 per 1,000 for the enlisted men.

◆

THE MOST SERIOUS RAILWAY ACCIDENT of the week occurred Nov. 15, near Trenton, Ont., on the Grand Trunk Ry., as the result of a misplaced switch. The Montreal express, west bound for Toronto, took the switch and ran head on into an east-bound freight. The accident caused the death of 12 persons and seriously injured as many more.

◆

A SERIOUS RAILWAY ACCIDENT occurred Nov. 10 on the Lehigh Valley R. R., near Wilkesbarre, Pa., as the result of a failure of the brakes. According to accounts the Buffalo express had orders to stop at a siding on the Wilkesbarre mountain to let an express from New York pass. On approaching the switch the brakes of the Buffalo express failed to hold the train, and it ran past the siding and collided with the approaching New York express. Five trainmen were killed and four injured. Newspaper reports state that the failure of the brake was due to an accumulation of wet leaves upon the rails.

◆

A SALT WATER FIRE PROTECTION SERVICE has been established in Boston for a limited area. A line of pipe has been laid to a point near the post-office and a number of hydrants placed on it. Pumping is done by an engine on a fireboat. This, it is hoped, is the beginning of a comprehensive system of independent fire protection for the business district of the city. Such a system has been advocated for a number of years.

CARBIDE OF CALCIUM AND ACETYLENE GAS are not favorably looked upon by the Boston Manufacturers' Mutual Insurance Co. Its circular for October contains a "Caution" from which we extract the following:

> The purpose of this caution is to call upon each and all of our members not to make use either of carbide of calcium or of acetylene gas without full advisement and consultation at the time the proposed application is to be made. It may happen that the uses of these materials may be made safe. At present they are not deemed so. Therefore, the introduction of either, without the consent of the underwriters, would make an alteration in the condition of the risk not contemplated in the original contract.

A new method of lighting by kerosene oil is also mentioned in the circular, without giving its name, "because there are elements of merit in the process," and it is suggested that no new method of lighting be permitted even for experiment, without consultation with the insurance company.

◆

THE COOLGARDIE STEEL PIPE LINE, in Western Australia, will be constructed by G. & C. Hoskins, of Sydney, and Mephan Fergusson, of Melbourne and Perth. There will be 328 miles of 30-in. steel pipe, with longitudinal joints made under patents owned by Mr. Fergusson, presumably after the plan described in our issue of June 9, 1898, as employed on the Adelaide water-works. The total contract price is about $4,990,000, or $350,000 less than the engineer's estimate. The plans for this work, which includes a storage reservoir and a pumping plant to deliver 5,000,000 gallons of water a day through the pipe line, were made by Mr. Chas. G. O'Connor. M. Inst. C. E., Perth, Western Australia. The work was described in our issue of Feb. 10, 1898, and the pipe line was discussed editorially in our issue of Feb. 17 and Oct. 13, 1898.

◆

THE PURCHASE OF THE WATER-WORKS of the eight companies supplying London is recommended by the water committee of the County Council, providing parliamentary authority can be obtained. Early possession is advised, the price to be paid the companies to be determined by arbitration. Authority is also desired to connect the systems of the several companies, in order to prevent a repetition of the recent water famine in East London. The committee also recommends that parliamentary sanction be asked for introducing a new supply from Wales at an estimated cost of some $80,000,000. It states that the drouth of the last season proves that the late Royal Commission on Metropolitan Water Supply over-estimated the yield of the Thames and Lea and therefore were wrong in assuming that those streams would be sufficient to supply the Metropolis until 1931, at least without an unwarranted expense for storage. A second Royal Commission is now investigating the subject of a metropolitan water supply.

◆

THE DAY-LABOR PLAN of carrying out municipal work, practiced of late by the London County Council, is reviewed by an earnest friend of the system, Mr. J. W. Martin, in "Municipal Affairs," for September. The cause leading the council to adopt this system, according to Mr. Martin, was a combination of contractors to maintain high prices in order to break down the wage-rules established by the council. These rules are termed by Mr. John Burns "the Magna Charta of Labor." They provided for trade union wages for all skilled labor and for a minimum of 12 cts. an hour for unskilled labor, whether employed by the council or by contractors. The trade union wages were already paid by many London employers, so in this particular the council merely placed itself in line with numerous private concerns. The rate of 12 cts. an hour for unskilled labor, Mr. Martin says, was above the market rate, but how much above he does not state. A while ago the moderates achieved considerable control in the council, and succeeded in "starving" the works department, but now the progressives are strongly in the ascendency, and Mr. Martin states the department is in danger of being overfed. The London "Contract Journal," we have observed, is opposed to the works department of the council,which has charge of all the work not done by contract.

◆

SEWAGE DISPOSAL in nearly all the coast towns of England is by the discharge of the crude sewage into the tidal water, but generally with some storage during rising tides. Thus, of 36 towns, only 6 have any system of purification, 3 of these employing chemical precipitation, and the other 3 sedimentation, or screening. Of the 25 towns reporting some storage, this is effected in tanks only in 9 cases, the other instances being the use of enlarged sewers near the outlet, or simple backing up of the sewage in the main sewers by the tides. The above information is taken from a paper read at The Sanitary Institute, by Mr. H. Bertram Nichols, Assoc. M. Inst. C. E., and published in the London "Contract Journal."

◆

THE METRIC SYSTEM is being considered by the Danish Diet, with a view of substituting it for the confusing Danish system of weights and measures. The general opinion is that the metric system will be adopted and the law establishing it will at once go into effect.

THE GOODWIN DUMP CAR.

The great amount of work being done by railways in the improvement of their lines, by means of widening banks and cuts, reducing grades, ballasting, filling trestles, etc., which involves the handling and dumping of large quantities of material, has led to the introduction of various types of dump cars, designed to effect facility and economy in the handling and dumping of this material. We have from time to time described a number of these cars, and the work which they perform, and in the present article we describe the most recent type of the Goodwin car, which has been used on some extensive works.

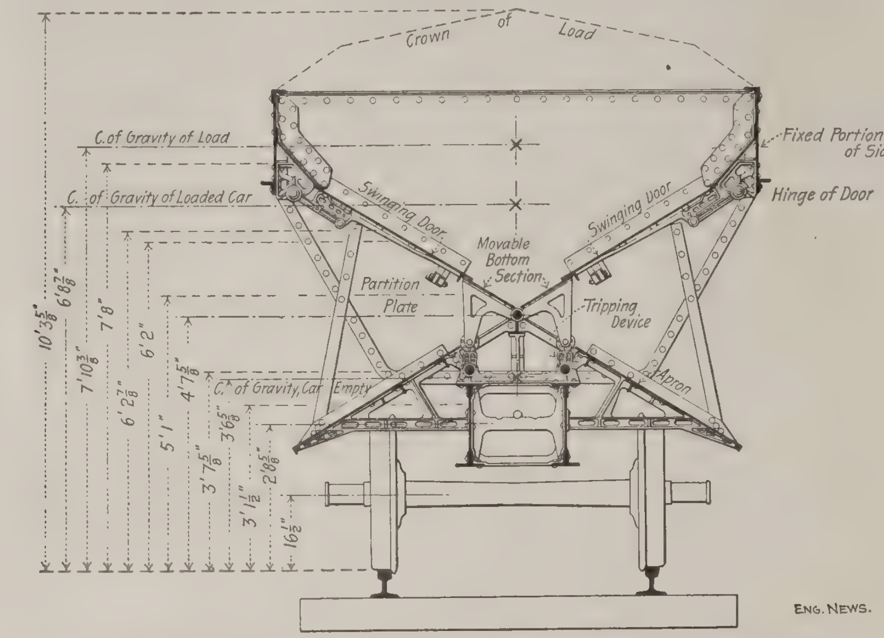

FIG. 1. CROSS SECTION OF GOODWIN DUMP CAR (SIDE DUMP ONLY).

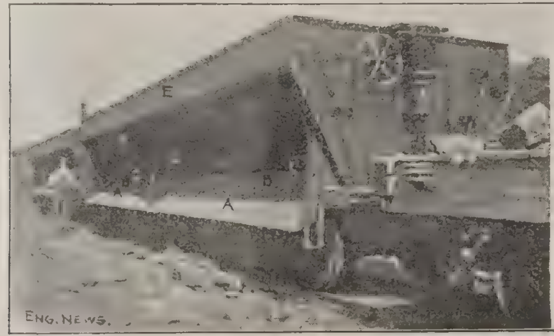

Fig. 2. Car in Running Position.

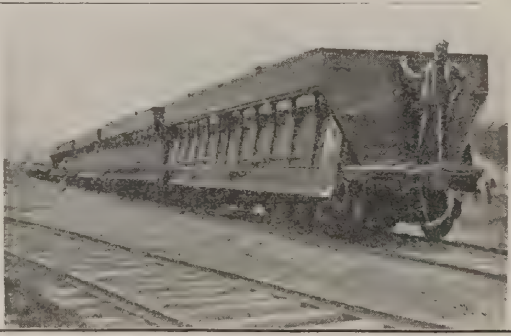

Fig. 3. Cars Dumped at Side.

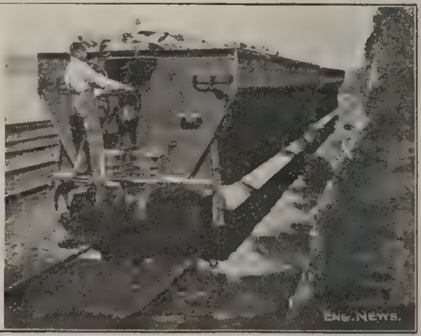

Fig. 4. Ready to Dump by Hand.

THE GOODWIN DUMP CAR. Goodwin Car Co., New York City, Builders.

This car was first patented in 1872 by Mr. John M. Goodwin, and has since been greatly improved on the lines of modern car construction. A four-wheel car of this design, built of iron, and having a capacity of 30,000 lbs., was exhibited at the Columbian Exposition, 1893, and in the past few years new and larger cars have been introduced. These cars are built by the Goodwin Car Co., 96 Fifth Ave., New York (and with a western office at 115 Dearborn St., Chicago), and we are indebted to that company for photographs and particulars of these latest cars.

The Goodwin dump car, as now built, is constructed entirely of steel and malleable iron, and will discharge the whole or a part of its contents between the rails or on either side of the track. There are two plate-girder sills, 21 ins. apart, c. to c., these girders being 18 ins. deep at the middle and 9¼ ins. at the ends. From each sill extends an inclined floor or apron, which serves to deliver the charge clear of the track and of the axle boxes. The space between the sills is left clear for dumping the load between the rails. The ends and end sills are supported by the plate girders, and the ends are connected by top side plates 18 ins. deep. A middle transverse bulkhead divides the car body into two compartments, which can be dumped independently. The bottom of the hopper or body is composed of swinging doors on each side, hinged at the top and inclined inward at a flat angle. These doors do not meet when closed, but rest on two narrow central movable sections on each side of a longitudinal shaft, about 15 ins. above the sills. By turning the shaft, one or other of these narrow sections is made to incline downward towards the apron instead of upwards, thus releasing the door on that side, which will then swing out to a vertical position, while the load slides under it and over the apron. The aprons are hinged on a line nearly over the wheels, and in order to dump between the rails the inner portion is swung up and out, so that when the door is released it strikes against the raised apron, and the contents of the body fall between the sills. Some of the cars, however, are made to dump only at the sides, and these have no movable section to the aprons. The dumping and closing devices may be operated by compressed air or by hand power, and are under control, so that the load may be discharged slowly or rapidly, as desired, and while the train is in motion.

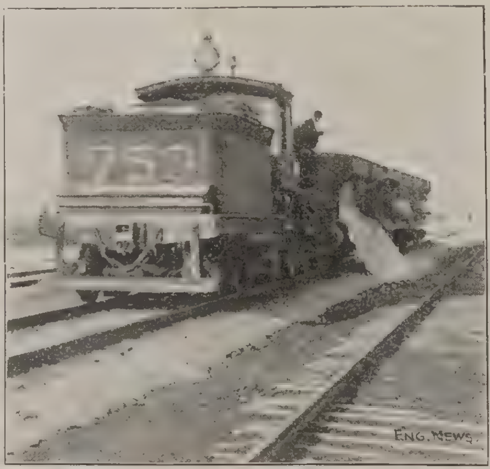

Fig. 5. Dumping Stone Ballast from Goodwin Cars, Illinois Central R. R.

The cars are mainly used for ballasting and filling, but are claimed to be suitable for carrying grain, coal, coke, ore, and other bulk freight. For grain service, an adjustable steel top is fitted, while for carrying coke a steel railing or crate is attached to increase the height of the fixed sides. These cars have been used for ballasting and filling on the New York Central R. R., the Pennsylvania R. R., the Lehigh Valley R. R., and the New York, New Haven & Hartford R. R., and on the lake front work of the Illinois Central R. R., at Chicago. They have been used for trestle filling in New York harbor by the U. S. Government, and on numerous large contracts for filling by different contractors, including the Globe Construction Co., of Cincinnati. Some of them are now in use on the excavation work for the great Jerome Park reservoir for the water supply of New York.

Fig. 1 is a cross-section of a side-dumping car, showing the positions of its center of gravity when loaded and unloaded. Fig. 2 is a view of a side and center-dumping car in position for carrying the load. In this view, A is the fixed portion and B the pivoted portion of the apron, C is the opening for dumping between the sills, D is the middle bulkhead, E the fixed portion of the top, and F F the swinging doors (pivoted below the sides E) which form the bottom. At the end may be seen the horizontal wheel for dumping the car by hand, while to the right of this is the air pipe and cock for dumping the car by air pressure. Fig. 3 shows the car after its load has been dumped from one side, the swinging doors now hanging vertically. Fig. 4 is an end view of the car, with the man ready to dump the load by hand. Fig. 5 shows the car in use for ballasting on the Illinois Central R. R. The broken stone ballast is being dumped while the train is running at a speed of eight miles per hour.

The cars are mounted on diamond-frame trucks of special design, having steel bolsters, and are fitted with hand and air brakes. They have also the Williams M. C. B. couplers, and a special design of draft rigging with double springs.

The principal dimensions of the cars are:

Length over end sills	35 ft. 11 ins.
Width over all	8 " 10 "
Height, rail to top of sill	3 " 6 "
Height, rail to top of car	8 " 6 "
Wheelbase, truck	5 " 0 "
Wheelbase, total	28 " 9 "
Wheels, cast-iron, 600 lbs.	2 " 9 "
Journals	4¼ × 8 ins. or 5 × 9 "
Carrying capacity	80,000 lbs., or 125,000 lbs.
Cubic capacity (with load crowned 10 ins.)	28.8 cu. yds.
Cubic capacity with top crates	37.0 "

◆

STEAM OMNIBUSES OR STAGES for use in London are proposed by the London Steam Omnibus Co., which is now inviting subscriptions for its stock. The De Dion & Bouton system is to be employed, which system has been successful in some of the motor carriage trials in France. Coke or petroleum may be used for fuel. One omnibus has been put in use for experimental service, and is said to show great economy over the two-horse omnibuses which are so extensively used in London. The same company also proposes to operate similar vehicles on country roads and for long suburban routes, using either the De Dion & Bouton, the Panhard & Levassor or the Daimler (petroleum motor) systems. The cost of operation per month, including wages, cleaning, licenses, and all expenses, is estimated at $160 for the horse omnibus, $127 for the steam omnibus, and $99 for the petroleum omnibus; the cost for the two latter being 73% and 62% of that for the former. It seems very doubtful, however, whether the time has yet arrived for a business sufficient to give satisfactory financial returns.

PORTABLE PNEUMATIC RIVETERS IN SHIP-BUILDING.

At the recent New York meeting of the Society of Naval Architects and Marine Engineers, Mr. W. I. Babcock, Manager of the Chicago Shipbuilding Co., read a paper on the above subject. This company is equipped to drive every rivet in a ship by power machines, operated by unskilled labor; and Mr. Babcock gives a history of the development of portable riveting machines in shipbuilding at his company's works.

A beginning was made with a stationary steam riveter, with a horizontal ram and a 5-ft. gap, and it was used for such pieces of work as could be brought to the machine and handled by a chain hoist working on an overhead trolley. This riveter has driven 1,800 rivets in 10 hours, at a cost not exceeding ½ ct. apiece, or a saving of 2¼ cts. over the labor scale rate for driving such rivets by hand.

For the first portable machines, compressed air was used, as it was feared that the severe climate might interfere with hydraulic power. Moreover, the air-power could also be used for calking and chipping hammers and drills or reamers, and an air-compressing plant was a necessity anyhow. Compression bow riveters, such as are used in bridge shops, were first tried; but they were too light for the work and too difficult to handle about a ship. In 1896, some experimental rivets were driven with an ordinary pneumatic calking hammer, at the works of the Lassig Bridge and Iron Co., in Chicago. This was tried in the shipyard and the method was found to be feasible; but the blows of the hammer were so heavy and continuous that it was impossible to "hold-on" the rivets by the ordinary hand hammer, which was fairly jarred off the rivet-heads. A pneumatic "holder-on" was then devised, of simple construction. It was simply a cylinder, into which air was admitted and then forced out a piston with a cup to go over the rivet-head; by screwing a piece of pipe to this device it was easy to obtain a bearing, or resistance for this cylinder among the longitudinals in the double bottom of lake steamers.

The next step was to connect the hammer and holder-on by a horse-shoe frame, as shown in Fig. 1. A variation in the device is to mount the hammer itself as a piston in a cylinder, to which air is admitted to force out the hammer as the point of the rivet is beaten down. A plain die is used on the other side, and this die can be small enough to go into contracted places. As arranged for various depths of gap, these machines weigh as follows: 9 ins., 83 lbs.; 51½ ins., 160 lbs.; 70 ins., 220 lbs. In the larger machines the bow is made of a piece of wrought-iron pipe.

These machines do better work than hand riveting. In the first place, it requires constant watchfulness, in hand work, to prevent the men from knocking the head over at once, instead of striking the first blows exactly in line with the axis of the rivet and properly filling the rivet hole. With the machine, the blows of the hammer are naturally in line and they are so rapid that "plugging" is accomplished before the point is formed. As the machine work is quicker, the driving is completed before the rivet has lost its heat and the contraction afterwards draws everything firmly together and strengthens the joint by friction between its parts. Then in a ship, there are many places where there is not sufficient space to swing a hammer, or where the rivet can only be gotten at from one side. In these places hand riveting is never what it should be; while these considerations do not affect the machine.

In deck, tank and outside shell rivets, with countersunk flush points, a machine with a separate pneumatic holder-on is employed; and three men and a heater-boy will drive from 800 to 1,000 of these rivets in a working day. In the case of bulkhead rivets, with full or button point, the combined hammer and holder-on can be fastened to the end of a beam which slides loosely on a central supporting stud bolted to the bulkhead, with an adjustable stud-bolt at the other end of the beam governing the distance of the hammer-die from the rivet-point; and thus a number of rivets may be reached at one setting. The pneumatic holder-on may be similarly mounted on the other side of the bulkhead. For flush-pointed rivets a very different arrangement is required. As in hand-work, the varying thicknesses of plating, liners, butt-straps, frame flanges, etc., and the amount of countersink in the plate, make it impossible to gage the length of rivet under the head that will exactly fill flush to the plate surface. Here the hand method is practically followed; the rivet is beaten down with surplus metal crowded off to one side; this metal is then chipped off by hand or by a pneumatic chipping chisel, and the rivet is properly finished on the point. To do this, some freedom of motion must be given to the hammer, so that it is possible to incline its axis, to properly crowd the metal to one side and facilitate chipping. For this purpose hammers are mounted on gimbals; or, so mounted in a frame that while the die is held in position against the rivet the lower end may be given a rotary motion; or, the hammer may be mounted on trunnions and the beam carrying it turned on its own axis and moved forward and back longitudinally. Mr. Babcock thinks the second method not so good as gimbals, and he had never tried the third.

Still another method of driving countersunk flush rivets is to fasten the hammer immovably to the end of the beam, as in the bulkhead riveter; and the flat-faced die has a central 3-16-in. hole drilled in it. When the rivet is beaten down some of the hot metal enters the hole and the result is a projectng teat on the rivet-head, with the remainder of the surplus metal flattened out equally on all sides. This surplus metal is removed by a face milling tool, which also has a central hole fitting over the teat and holding the tool in position. The milling tool is driven by a pneumatic drill, and after the point of the rivet is milled down flush with the plate the teat is easily cut off by the blow of a hand hammer or a cold chisel. This rivet is not, however, quite "shipshape" in finish, and it is difficult to get a milling tool of the right shape to properly cut it. In the yard of the Chicago Shipbuilding Co. the first method described is alone used, as the most satisfactory.

For bottom rivets the beam is hung by a bolt through its center, on which it rotates, to a trolley running inside of a slotted pipe bolted to the bottom of the ship; this enables the operator to reach many rivets at one setting.

For side riveting the machine is attached to a counterweighted horizontal pipe, hung from pulleys above inside of flat iron guides bolted to the ship's sides. For the bilges the hammer beam is again a horizontal pipe fastened to a double frame which fits the bilge and travels on trolleys above and below.

Mr. Babcock says that it is the unanimous opinion of the hull inspectors that the machine rivets are first-class in every respect, and make better and tighter work than those driven by hand. Adding cost of air, repairs, etc., the saving is from 1 to 2 cts. per rivet over piece-work prices for hand-riveting, and averages 1¼ cts. This means a saving of from $4,000 to $5,000, over hand-work, in an ordinary 4,000-ton lake steamer. An important advantage is that unskilled labor can, with these riveters, successfully replace skilled labor of a class hitherto regarded as indispensable, and correspondingly troublesome with regard to strikes, etc.

◆

THE FIREPROOFING OF WOOD FOR THE NEW UNITED STATES BATTLESHIPS.

The terrible experience of at least two of the Spanish cruisers in the naval battle off Santiago added to the destruction by fire of the Chinese vessels in the battle of the Yalu River, in the Chinese-Japanese war has, as many of our readers are aware, brought about the decision to construct our new battleships with fireproof or non-inflammable wood. This order applies to the first-class battleships "Maine," "Missouri" and "Ohio," and is a direct reversal of the policy previously determined upon, which was to use the material for interior construction only, as the result of the experience in peace service with the monitor "Miantonomoh" and the gunboats "Helena," "Newport," "Vicksburg," "Wheeling," "Princeton," "Wilmington," "Nashville," "Marietta" and "Annapolis," all of which were finished with fireproof wood at the time of their construction in 1895-7. The objections raised to the use of fireproof wood on these vessels were briefly as follows: Fireproof wood is heavier, much harder to work, and not so strong as the untreated material; the contained chemicals corrode metals, which come into contact with the wood, prevent the wood from taking paint, and injure clothes kept in drawers made of it. These objections were investigated in 1897 by a board of naval officers, which sustained them in a majority report to the Navy Department, and also advised that the use of fireproof wood on war ships should be abandoned. In a minority report, however, Chief Naval Constructor Hichborn, of the Board of Investigation,

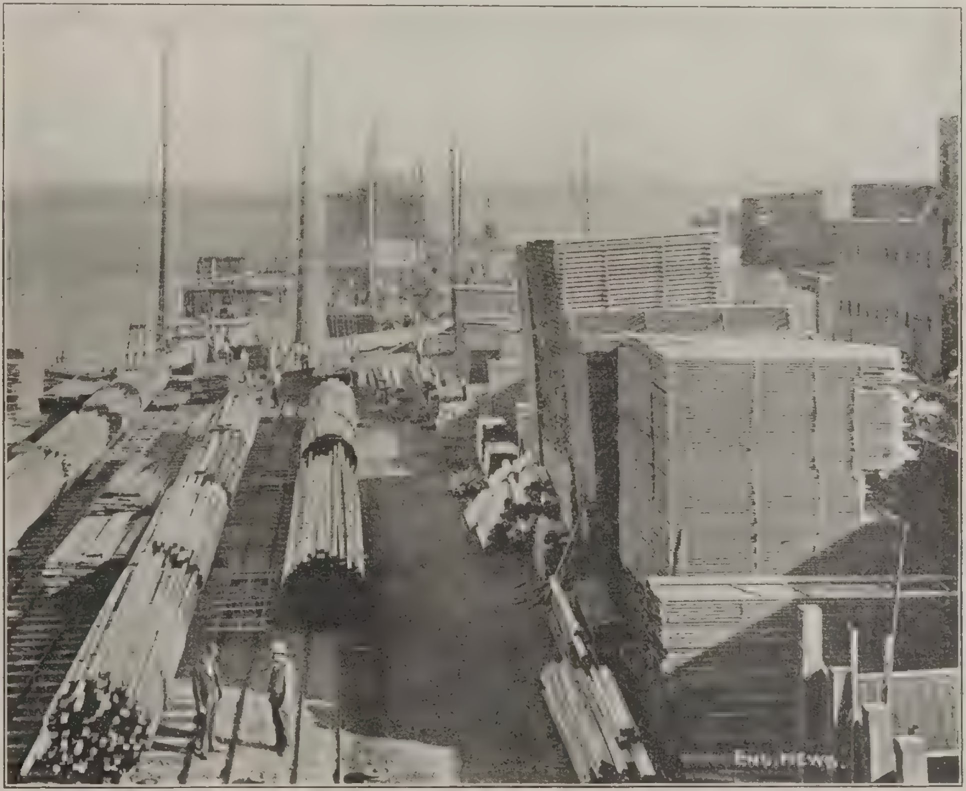

FIG. 1.—YARDS SHOWING LUMBER IN STORAGE AND LOADED ON CARS READY FOR FIRE-PROOFING.
Electric Fireproofing Co., New York, N. Y.

took a contrary position, claiming that the objections raised were not warranted by facts and urging the great value of non-inflammable wood fittings and finishing in time of battle as compared with such minor objections as really existed. The question rested in abeyance until the fight at Santiago showed that if war ships are to resist successfully heavy fire from modern batteries it is of the greatest importance that any woodwork about the superstructure should be made non-inflammable.

The employment of fireproof wood on so extensive scale as is contemplated in the recent orders of the naval authorities is sufficient to make a description of the method of its preparation of interest to engineers, and we have collected from various sources such information of practical interest as is available concerning both the process of fireproofing and the actual fireproofness, durability, strength, etc., of the wood after undergoing this process. It is also apparent that if fireproof wood shall prove to be what it is claimed to be, viz.: non-inflammable, with its strength and durability and the various other qualities of the natural material uninjured, naval construction is evidently only one of many fields of usefulness. In timber construction generally, and in fireproof building construction particularly, the advantages of such a material are many.

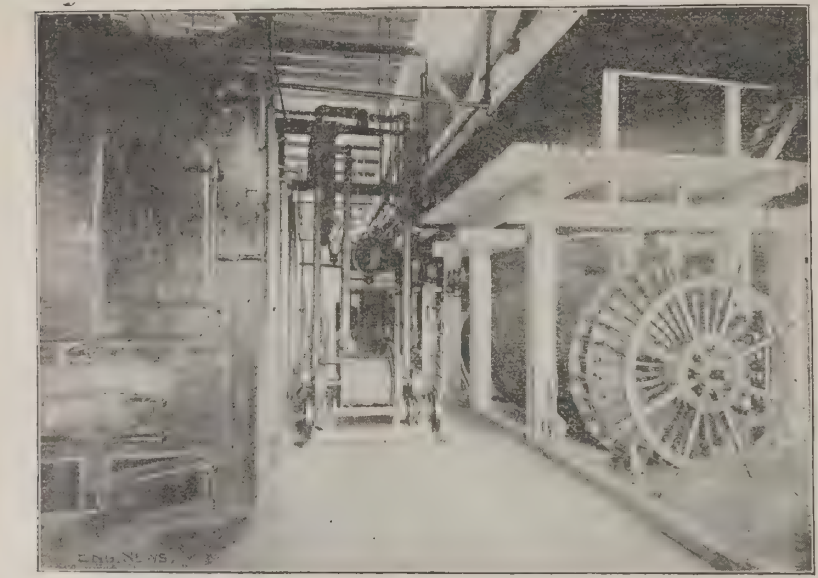

FIG. 2.—INTERIOR OF WOOD FIREPROOFING PLANT, SHOWING CYLINDERS, WITH SOLUTION TANK OVERHEAD, AND THE PIPING SYSTEM.

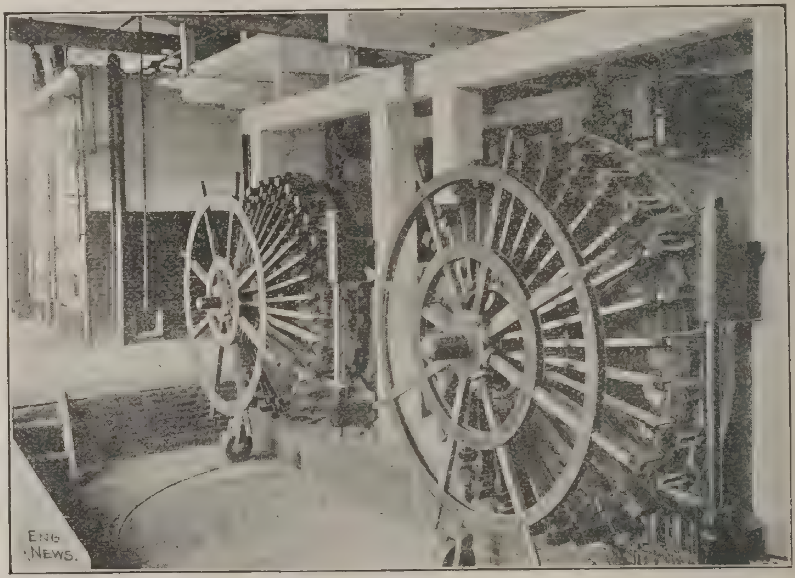

FIG. 3.—INTERIOR OF WOOD FIREPROOFING PLANT, SHOWING CYLINDER HEADS AND COVERS.

Turning now to the process which is employed for fireproofing wood for United States war vessels, it can be described in a general way as resembling very much the process of creosoting timber to preserve it from decay. The timber to be treated is placed in an air-tight cylinder and enveloped in an atmosphere surcharged with aqueous vapor at a temperature of from 110° to 200° F., until its pores or cells are opened. The moisture is then evaporated from the wood by creating a vacuum in the cylinder. When the evaporation is completed the cylinder is filled with the fireproofing solution consisting of phosphate of ammonia and sulphate of ammonia, with, in some cases, other chemicals, and pressure is applied to force the solution into the pores of the wood. After this saturation the wood is thoroughly kiln-dried at a temperature of from 85° to 125° F., which solidifies the chemicals contained in the pores. More complete details of the process and of the plant used to conduct it will be given further on, but right here it will make some features of the work more clear if we consider another phase.

The end which is sought in fireproofing wood is not merely to render it non-inflammable, but to do this without injuring its structural and decorative qualities. To preserve the strength, elasticity and life of the wood its cellular structure must not be broken down or injured in the process of filling the cells or pores with the fireproofing liquid. This requires a thorough knowledge of the age, texture, condition, etc., of each kind of wood treated, for all of these things affect the strength and toughness of the fibers, and, therefore, their resistance to injury. To fill the pores of a crooked-grained, gnarled piece of oak with the fireproofing solution is an entirely different task, for example, than filling pores of a straight-grained stick of white pine; the quantity of solution required is different, the pressure necessary to force it into the wood is different, and the preliminary processes of saturation and evaporation likewise differ.

The first work in the process of fireproofing wood, therefore, is to sort the timber according to its various natural and acquired characteristics. This being done, it is put through the successive treatments of saturation, evaporation, impregnation and kiln-drying with such particular characteristics of manipulation as previous experiment and experience have determined to be necessary to secure the best results for wood of its kind and condition. It will be seen at once that the success of fireproofing wood depends largely upon the intimate knowledge of woods and experience in their treatment which the operator possesses.

The plant at which the fireproofing of wood for the new battleships is being done is located on the East River front, between 19th and 20th Sts., in New York city, and is owned by the Electric Fireproofing Co., which controls the process. Figs. 1, 2 and 3 are views of the plant. Fig. 1 shows the yard for the storage and shipment of lumber, with a number of charges of treated and untreated material loaded on the cars ready for further processes; Fig. 2 is a view inside the plant showing one of the cylinders, the solution tank above it, the steam and other piping, and other apparatus, and Fig. 3 is a nearer view of the front ends of the two cylinders showing the construction of the covers or doors.

The cylinders are 105 ft. long and about 7 ft. in diameter, and hold when filled about 15,000 ft. B. M. of timber. The material of the cylinders is steel ¾-in. thick. Referring to Fig. 4, a, a, are rails upon which the cars loaded with lumber are run into the cylinders. Below the trucks and the bodies of the cars when they are in the cylinder is the steam coil d, d, which runs the whole length of the cylinder. Adjacent to these coil pipes is an apertured pipe e also running the full length of the cylinder. This pipe e brings steam to the cylinder and the apertures in it increase in size from the points of entrance of the steam so as to deliver the same quantity of fluid at all points. The pipe e connects with a pipe f, which leads outside of the cylinder to a T-coupling g, to which a pipe h is connected on one side. This pipe h leads from the pressure pump and serves to bring liquid to the cylinder from the pump. A pipe i connects to the opposite side of the T and serves to admit steam to the cylinder through pipes f and e at the appropriate time and to exhaust the same therefrom. This pipe has a number of branch pipes k, l, the source of the steam supply being connected to l and k being the exhaust pipe.

The mud drum B of the cylinder is connected to the cross coupling C by the arm m, the opposite arm n being a vent to clear the mud drum. Connected to the arm m' of the cross coupling is a pipe D, which is provided with a valve d' and leads to the bottom of the tank containing the fireproofing solution, and connected to the opposite arm n' is the pipe F which serves to return the unused liquid from the cylinder to the supply tank. Along the top of the cylinder are a number of pressers G, which, when screwed down upon the top of the lumber, hold it firmly in place.

The method of operation is then as follows: the lumber being in the cylinder and the cover firmly closed, a depth of 3 ins. to 6 ins. of water is introduced; all the valves except those in the steam pipe are closed, and steam at low pressure is introduced by means of the pipes l, i, g, f and e and through the water into the cylinder. This process continues for from one to eight hours, the temperature being maintained from 110° to 200° F., depending upon the kind of wood being treated and is very important, its purpose being to open the pores of the wood and fill them with moisture. Aqueous vapor at a low temperature is employed. If live or dry steam at a high temperature is used it has been found that the wood is discolored, and its elasticity and tensile strength are reduced. Moreover, the action of the heat is to seal rather than to open the pores of the wood, forming an impenetrable outer shell to the timber, and preventing the introduction of the fireproofing fluid. The mild action of the aqueous vapor, on the contrary, opens up the pores of the wood like a sponge.

The process of saturation being completed, that of evaporation is begun by gradually inducing a vacuum in the cylinder to exhaust the moisture from the pores of the wood, and leave them open for the entrance of the fireproofing fluid. This vacuum is broken about every three hours to allow the accumulated moisture to be drawn off from the cylinder, and it is kept up until the lumber is dried. When the work of evaporation is finished a final vacuum of from 20 ins. to 28 ins. is induced in the cylinder, and the fireproofing solution is then admitted to the cylinder from the tank above it. Care is taken to have the temperatures of the timber and of the solution the same, as this facilitates the impregnation. The fluid is allowed to fill the cylinder completely, and at first the pressure is only that due to the head of the liquid and to the vacuum. Finally, however, the liquid is shut off from the tank, and the pressure pump is started, forcing liquid into the cylinder through the pipe k. Gradually the wood takes up the fireproofing solution, and when the gages show that it has absorbed all it can hold, the remaining liquid is drawn off.

The final step is to kiln dry the treated timber. This is done slowly at a low temperature, not more than 125° F. Particular importance is claimed for this low temperature process of drying. Greater heat, it is asserted, tends to make the wood brittle and to discolor it, while temperatures of from 85° to 125° F. preserves all the elasticity and life of the natural material. Except for the low temperatures employed, the process of kiln drying presents no differences from the process ordinarily used.

The process of fireproofing wood as conducted by the Electric Fireproofing Co. is perhaps sufficiently described in the preceding paragraphs. At the present time the company is treating regularly the following timbers: Mahogany, cherry, butternut, walnut, red oak, sycamore, maple, birch, pine, ash, spruce, elm and white wood. The charge of fireproofing is the same for all kinds of wood, $50 per M. ft. B. M., exclusive of the final kiln drying. The company either furnishes the wood fireproofed at the usual market price plus $50 per 1,000 ft., or will fireproof wood furnished by others to order.

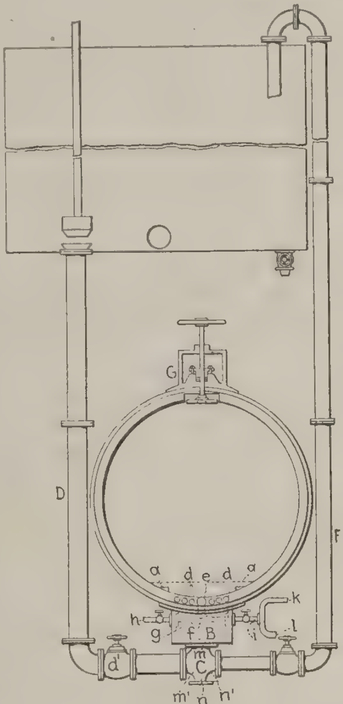

Fig. 4.—Diagram Cross-Section of Cylinder and Solution Tank Illustrating Operation.

Although generally spoken of as fireproof, wood which has undergone the process described is more correctly described as non-inflammable. When exposed to flame the wood chars, and will, if the flame be continued, be completely carbonized. Non-inflammable, however, is pretty certainly obtained. Shavings and splinters of the treated wood held in an alcohol flame will char, but will not catch fire nor retain the flame when removed; in fact, the glowing coal on the charred wood almost immediately goes out upon removing the source of heat. Small test buildings built of the treated wood and having kindling saturated with oil piled inside and around them, have been fired in New York (Eng. News, Aug. 29, 1895) and in London, and have shown almost as perfect non-inflammability. The standard for fireproof wood adapted by the United States Navy Department, and to which all the treated wood supplied for the new battleships conforms, is that, "when dry and subjected to heat of 600° F., it will remain non-inflammable and absolutely safe against spread of fire from point of contact."

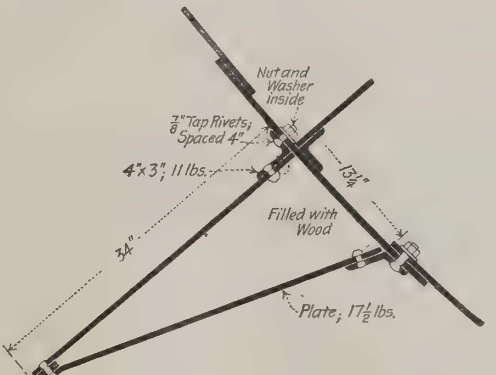
The fireproofing material contained in the wood is solid and non-volatile, and the fireproof quality of the wood is, therefore, claimed to be permanent. Even by long continued soaking, it is stated, the fireproofing material is not injured or withdrawn. The material is also claimed to have no injurious action upon paint or varnish, or upon nails driven into or hardware attached to the woods, provided it is thoroughly dried. It, however, makes the treated wood slightly darker than its natural color. The treated wood is also harder and somewhat heavier, and as a consequence is harder to work, but by a proper tempering of the tools this difficulty is easily overcome. In respect to the strength of wood which has been fireproofed, we find records of tests made in the laboratory of Stevens Institute, Hoboken, N. J., and at the Watertown Arsenal. In the Stevens Institute tests of both Oregon pine and yellow pine showed a loss of from 2.4% to 12.6% in transverse strength by being fireproofed. White pine, however, showed an increase of 7% by being fireproofed. In compressive strength both white and yellow pine showed a loss due to fireproofing of from 6.4% to 9.2%. In tension, however, white pine and yellow pine showed gains in strength of 19.6% and 24.2%, respectively. In tests made at the Watertown Arsenal for transverse strength both white pine and white wood showed a gain from fireproofing. These results do not agree very well, because, it is stated, of the difference in degree of heat applied in the kiln drying, which is a matter easily corrected, but they show generally that the wood is rendered somewhat more brittle by the fireproofing treatment. It is pointed out that these tests were made some time ago, and it is stated that the recent improvements in the process of fireproofing have corrected many of the former objections.

In conclusion it may be stated that so far as we have been able to ascertain, the Electric Fireproofing Co., illustrations of whose plant we present herewith, and its offspring the British Non-Inflammable Wood Co., are the only concerns which now manufacture non-inflammable wood on a marketable scale.

BILGE KEELS AND ROLLING EXPERIMENTS.

At the sixth general meeting of the Society of Naval Architects and Engineers, held in New York last week, Asst. Naval Constructor Lawrence Spear, U. S. N., presented a paper with the above title. He stated that the original designs for the battleships "Oregon," "Indiana" and "Massachusetts" called for bilge keels about 30 ins. deep; but to facilitate docking these keels were omitted in building. This omission was at the time in line with the best foreign practice, and theoretical considerations led to an underestimation of the steadying effect of bilge keels of any practical dimensions as applied to slow-moving ships of large displacement and inertia.

But while these ships were nearing completion foreign practice, and, especially, that of England, underwent a change, as the result of comparisons of sister battleships with and without keels. Experience with the "Oregon" class at sea showed that some steadying influence was necessary; though the maximum inclination of the "Oregon" herself never exceeded about 22°, under a long, low swell. Bilge keels were put on the "Oregon" in January, 1898. These keels had a maximum depth of 34 ins. near the ends, tapering to 14 ins. amidships. The comparison in rolling effect, with and without keels, is shown in the following table:



Section of Bilge Keel Fitted to U. S. Battleship "Oregon."

	Keels, Without.	Keels, With.
Date of trial	Dec. 30, 1897.	Feb. 17, '98.
Draft, forward	22 ft. 9½ ins.	22 ft. 9 ins.
" aft	23 " 8½ "	23 " 8 "
" mean	23 " 3 "	23 " 2½"
Displacement, tons	9,810	9,790
Metacentric height, feet	3	3
Mean period, single swing, secs.	7.6	7.83
Weight of coal, tons	115	50
Weight of ammunition, tons	26.7	26.7
Bilge keels, number	0	2
Length		207 ft. 6 ins.
Greatest depth		34 "
Least depth		14 "
Total area		830 sq. ft.
Effective radius,		34.4 ft.

Except as above stated, conditions were alike in both cases. At slack water, and practically no current, with ship moored and without keels, 350 men running across the deck caused an inclinaton of about 7° from the vertical; with 200 men acting in conjunction with the 8-in. turrets, an inclination of nearly 6° was reached. Without bilge keels the rolling was practically isochronous within the range of experiments. With bilge keels, the period for single swing decreased slightly with the amplitude of roll. As measured by the radius of gyration, the period without keels was 7.6, and that with keels, 7.83, a difference of a little over 3%.

The results of the observations were plotted as "curves of declining angles" and "curves of extinction," and these were compared with corresponding curves for the first-class English battleship "Revenge," in light condition. It is noted that the "Oregon," starting at an inclination of 6°, required, without keels, 60 swings to reduce this inclination to 2°; while with keels the corresponding extinction required only 10 swings. For the "Revenge" the corresponding figures were 45 and 8. Taking the extinction value of the "Oregon," without bilge keels, as unity, the curves gave the following results at an inclination of 5° from the vertical:

"Oregon," light, no keels	1.0
"Revenge," light, no keels	1.32
"Oregon," light, with keels	7.36
"Revenge," light, with keels	8.18

The "Oregon's" loss of range per swing with this inclination is thus over seven times greater with keels than without; and this figure holds approximately true for any other angle within the range of experiments. In the case of the "Oregon," the same forces that would produce an unresisted roll of 20° would only produce one of 6° with the keels in place. In the case of the "Revenge" these figures were about 18° and 6°; or, broadly speaking, the roll, with keels, under identical conditions, would only be one-third as great as without them.

Generally speaking, it appears to be pretty well established that the entinction work done by keels may be divided under these three main heads: (1) Increased wave-making resistance; (2) disturbance of natural stream line motions about the ship; (3) direct resistance of plain surfaces of keels. As yet we have no data on which to base a quantitative division of the total resistance under these three heads; but it can be easily shown that the third is a comparatively small factor. Constructor Spear then mathematically stated, on the assumption of the late Mr. Froude, that 1.6 lbs. per sq. ft. is the resistance of the keel harmonically oscillating at a mean speed of 1 ft. per second, that the direct resistance of the keel is responsible for but a small part of the work done in steadying the vessel. As the third effect is practically unsolvable, with the data at hand, it is recommended that tank experiments be made so that naval architects may later obtain some emperical formulae sufficiently accurate for general design.

While service conditions prevented fuller trials of the "Oregon," the English experiments proved, what was to be expected, that the bilge keels had an increased effect when the ship was under way, and that the steering qualities were improved and tactical dimensions were decreased by the addition of keels.

STANDARDIZED CAST-IRON DRILLINGS FOR ANALYSIS.

The Committee appointed by the American Foundrymen's Association to establish a Bureau for the distribution of uniform standardized drillings, has issued a circular saying that it is now able to distribute a range of samples that it is felt will meet the indorsement of managers and chemists employed in all branches of the iron industry, pertaining to the making or use of pig iron.

The standardized samples now ready for distribution cover the following determinations: Silicon, sulphur, manganese and phosphorus, one each of a low, medium and high range; total carbon and graphite, one determination each; titanium, three determinations; in all, 17 determinations, made on four samples.

The samples are designated as A, B, C and D. Sample A, which has been ground to pass a 40-mesh sieve, gives one total carbon and one graphite. Sample B gives a low silicon, a medium sulphur, a low manganese, a phosphorus within the Bessemer limit, and a titanium. This has been passed through a 20-mesh sieve. Sample C gives a medium silicon, high sulphur, medium manganese, medium phosphorus and a titanium. This has also passed a 20-mesh sieve. Sample D gives a high silicon, low sulphur, high manganese, high phosphorus, and a titanium, and has passed through a 40-mesh sieve.

The drillings were obtained from castings made after the plan described by Mr. West in his paper before the Pittsburg Foundrymen's Association, June, 1898. The drillings were prepared under the supervision of Prof. C. H. Benjamin, and the standardizing under that of Prof. A. W. Smith, both of the Case School of Applied Science, Cleveland. The chemists engaged in standardizing the four samples are Messrs. Booth, Garrett & Blair, Philadelphia; Prof. A. W. Smith, and Cremer & Bicknell, Cleveland, O., and Andrew S McCreath, Harrisburg, Pa.

The standards are sold at the price of $5.00 per lb., and in no instance will less than 1 lb. be sold. The samples are packed in bottles, holding one-third of a pound and delivered in cases holding three or four bottles, according to the desires of a subscriber. One pound of the samples should furnish enough material for 36 complete analyses, or at least 200 separate determinations. The analyses of the samples, A, B, C and D will be sent separately by mail, so that they may be placed upon bottles or kept private, as desired by the subscriber.

About 35 leading laboratories have already subscribed for samples. Orders for samples may be sent to any member of the following committee: Thos. D. West, Chairman, Sharpsville, Pa.; Dr. R. Moldenke, 48th St. and A. V. Ry., Pittsburg, Pa.; James Scott, Lucy Furnace, Pittsburg, Pa.; P. W. Gates, Gates Iron Works, Chicago, Ill.; E. H. Putnam, "The Foundry," Detroit, Mich.

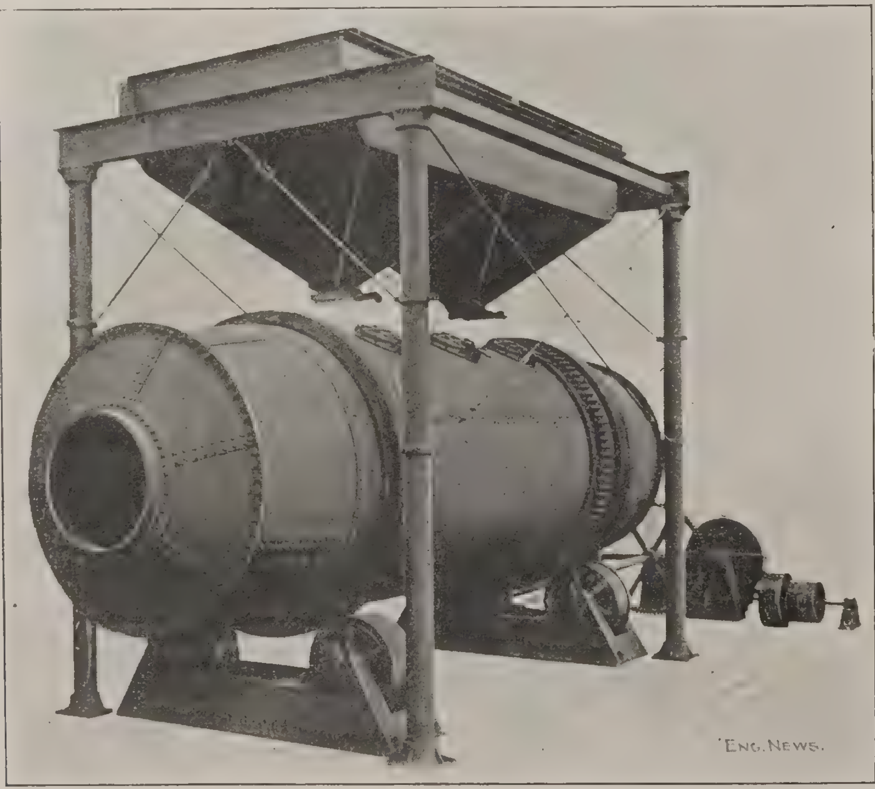
ROTARY FURNACES FOR ROASTING ORES.

The accompanying cut represents one of six large Bruckner rotary furnaces for treating ore, which are probably the largest ever built. Each furnace is 28 ft. long and 8 ft. 6 ins. diameter, with an end opening of 3 ft. 4 ins. diameter. Its capacity is about 20 tons of ore. Around the shell are two circular bearings or roller paths, which rest upon four 34-in. rollers in the bed-plates. Lateral motion is prevented by having one pair of the rollers made with double flanges. The total weight, including the charge, which is carried by the rollers, is 101,000 lbs. An iron frame supports two hoppers, and the furnace has three doors in the shell. Two of these are for receiving the charge from the hoppers, while the third is to facilitate the discharge of the roasted ore.



20-TON ROTARY ROASTING FURNACE. Gates Iron Works, Builders, Chicago, Ill.

The furnace is revolved by a pinion gearing with a circular rack attached to the shell. The pinion is carried by one of the bed-plates and is driven by a spur gear and worm-wheel and worm-shaft, the latter being on the shaft of the belt pulleys. Two belts are used, one for high speed and the other for low speed. The furnace makes about one revolution per hour while roasting and six per hour when discharging. Six of these furnaces have recently been built for the Canadian Smelting Works, at Trail, B. C., by the Gates Iron Works, of Chicago, and we are indebted to the builders for the above information respecting them.

ELECTRIC POWER IN THE NEW PRINTING PLANT OF THE W. B. CONKEY CO., HAMMOND, IND.

The recent removal of the large printing plant of the W. B. Conkey Co., from Chicago, Ill., and its re-establishment in new buildings at Hammond, Ind., has given the opportunity for one of the most comprehensive applications in this country of electricity to the work of a printing house. This new plant is fully described in a paper read before the Chicago Electrical Association, on Nov. 4, 1898, by Mr. Geo. A. Damon, and we abstract from that paper the following facts of general interest.

The reasons which first of all led to the removal of the firm's plant from the city to the suburbs was the saving which it was found could be effected in many ways. In the city taxes were necessarily high, and the insurance rates large on such property. Another great disadvantage of the city plant was the cost and delay of cartage through the congested city streets to and from the railway depots. The necessity of artificial lighting, and, also, the fact that the power transmission as established was expensive, were also important factors in deciding the change of location. To secure adequate natural light, in fact, especial attention was given to the design of the new building.

The plant at Hammond, as finally erected, consists of a single story building, 520 x 450 ft. The roof is of the weaving shed or saw tooth type, and all its windows are glazed with frosted glass and are placed at an angle looking toward the north. Every 29 ft. of roof space provides 11 ft. of light. Owing to the angle of the roof the direct rays of sun are kept out of the building, which is thus lighted by the soft reflected rays from the northern sky. The entire roof is built up of light structural steelwork resting upon cast-iron columns spaced 29 ft. c. to c. one way, and 16 ft. c. to c. in the other direction. The height of the trusses above the floor is 12 ft.

The generator plant consists of two engines and three 100 K-W. 225-volt generators connected on the Arnold system, described in Engineering News of Jan. 26 and Aug. 28, 1898. The power is conveyed to 95 motors distributed as follows:

		HP.
	Electrotype Foundry.	
17	Motors, belted or geared to dovetailing machine, trimmers, planers, roughers, saws, routers, black leaders, molding machines, beveling machines, blowers and jig saws	21
1	Direct-connected to electroplating dynamo	10
	Bindery.	
15	Belted to shafting driving folders, book-covering machines, trimmers, sewers, wire-stitchers, sewing machines, case makers, embossers, rounding and backing machines	52
2	Direct-connected to shafting driving cutters and smashers	10
8	Individual motors belted to knife-grinders, tying machines and gluing machines	18.5
	Stock Room.	
2	Belted to shafting driving cutting machines, rotary board cutters, grinding machines, sizing machines and bevelers	6
	Heating Apparatus.	
1	Belted to blower fan to heat office	12
	Machine Shop.	
1	Belted to line-shaft driving machine tools	10
	Composing Room.	
1	Belted to shaft driving type-setting and distributing machines	3
	Press Room.	
6	Belted to job presses, ink grinders and bronzing machines	5.5
41	Directly attached to presses	173
	Total horse-power of motors installed	321

The motors are of the Lundell type. Each motor is made with one field coil, which is entirely protected by the form of the field casting. The armature is of the ironclad type with removable form-wound coils. The motors have a steady neutral point of commutation, and do not spark under sudden changes of load. The motors directly attached to the presses and shafting are multipolar, narrow in width, with a relatively large circumference of field frames. The commutator, like the armature, is narrow and of large diameter, with a large number of bars.

Besides the improvement in lighting, ventilation and cleanliness, and the advantages of a more perfect control of the various machines, the new plant has exhibited a notable saving in fuel. Mr. Damon in his paper states that the result of the operation of the new plant is that only about one-third of the amount of coal is burned that was required before the move was made. A part of this saving, he says, however, must be attributed to the design of the power plant, with its modern equipment, so that just how much economy has been gained by the operation of the purely electrical part of the plant cannot be definitely determined.

The Corliss engine was furnished by the Atlas Engine Co.; the motors, by the Sprague Electric Co.; the motor, controllers and starting boxes by the Cutler-Hammer Mfg. Co., and the switchboard and wiring by the Western Electric Co. Mr. George C. Nimmons was the architect of the building, and Mr. Bion J. Arnold, M. Inst. C. E., was Consulting Electrical and Mechanical Engineer.

TEST OF THE BULKHEAD SEPARATING THE ENGINE ROOMS OF THE BATTLESHIP "ILLINOIS."*

By J. J. Woodward, M. Soc. N. A. & M. E.†

The specifications for the U. S. battleships "Kearsarge," "Kentucky," and "Illinois" require all watertight compartments to be tested by filling the compartments with water under a head; and the most important bulkheads, whose strength it was desired to test in this manner by actual water pressure, were the center-line longitudinal bulkheads existing between the engine rooms and fire rooms on the vessels in question. These bulkheads were all of large size, and the head of water directed to be used for the test was 5 ft. greater than the normal load water-line of the ship. This corresponded to a water level during test of 28 ft. 6 ins. above the keel. The bulkheads were all of approximately the same depth, namely, 23 ft. 5⅞ ins., and they were very strongly supported on all sides, being limited at their bottom by the inner bottom of the ship, and at their top by a heavy protective deck, which was formed by two thicknesses of ½-in. steel plating and an upper thickness of 1¾ ins., all three riveted together in an efficient manner. The ends of the bulkheads were also well supported by complete transverse bulkheads extending across the ship.

---

*Abstract of paper read at the sixth general meeting of the Society of Naval Architects and Marine Engineers, held in New York, Nov. 10 and 11, 1898.

†Naval Constructor, U. S. N., Newport News, Va.

As all the work had been carefully inspected during construction for general workmanship (which was found to be entirely satisfactory), and the principal point it was desired to determine was whether the scantlings of the bulkheads, as built, were ample for the work they had to perform, it was considered that if one bulkhead was tested and shown to be entirely satisfactory, that the other bulkheads would be considered as satisfactory, subject to passing a test with hose, for local defects in calking. As the length of the bulkheads separating the engine rooms was greater than those separating the fire rooms, and were consequently of the greatest area, since all of them had the same depth, the bulkhead separating the two engine rooms on the "Illinois" was chosen for the test for strength.

The volume of one engine room being such that to have filled it with water would have resulted in a possible injury to the general structure of the vessel which, at that time, was on the blocks of the building slip, it was decided to make the test by building in the port engine room a wooden cofferdam, placed about 3 ft. 9 ins. from the center-line bulkhead under test, the cofferdam being made of 5-in. plank. In this manner the weight of water necessary for the test was reduced to a very moderate amount, and it may be remarked in passing, there was no difficulty (with the exception of a slight amount of leakage, which occurred during the first test, on account of a defect in calking the plank), keeping up the pressure desired for the tests. It should be stated further that the water level of 28 ft. 6 ins. above the keel, required for the full test, was obtained by means of a small stand-pipe connecting with the water space within the cofferdam, through a circular hole in the protective deck. The bulkhead was subjected to three series of tests by filling the space between the cofferdam and the bulkhead with water, and carefully measuring the deflection on all stiffeners corresponding to different heads of water.

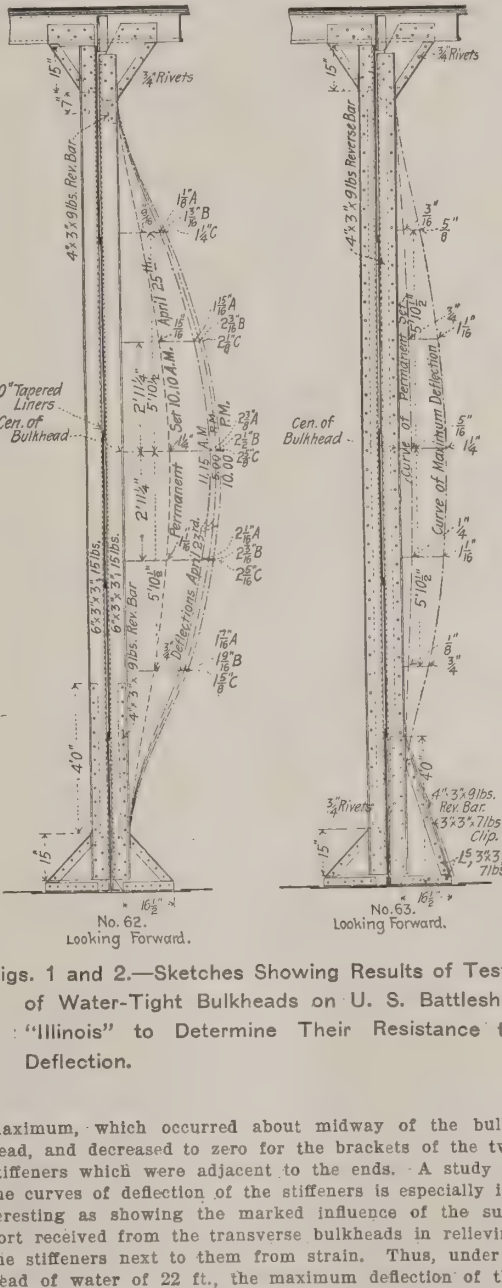
First Test.—Before the test, the actual shape of the bulkhead was carefully determined by measuring on each stiffener the distance from a vertical reference plan parallel to the center-line of the ship, these measurements being taken at three points, respectively, 5 ft. 10 ins., 11 ft. 8 ins., and 17 ft. 6 ins. above the top of the inner bottom plating, the measurements being taken on the side opposite the cofferdam, so that corresponding measurements could be made after the space between the cofferdam and the bulkhead was filled to different water levels

On beginning to fill the cofferdam space with water, no appreciable deflection could be noticed until the head of water had reached a height of 8 ft. above the inner bottom plating. At that height, however, a slight deflection was measured, and the filling of the cofferdam space then proceeded with, the water levels being maintained constant for heads of water corresponding to the heights of 12 ft. 9 ins., 16 ft., 18 ft., 20 ft. and 22 ft. above the inner bottom, measured as described, for such lengths of time as permitted the three measurements on each stiffener to be taken for the deflection corresponding to such heads of water. These intermediate water levels correspond, approximately, if we add the depth of the inner bottom space, to the 15 ft., 19 ft. 3 ins., 23 ft. 3 ins, and 25 ft. 3 ins. water-lines of the ship.

A careful examination of the behavior of the bulkhead while under test, showed that up to a head of 18 ft. the deflection increased very regularly, and, as well as could be judged, the material forming the center-line bulkhead had not, up to the head of 18 ft., been strained beyond its elastic limit. Between the heads of water of 18 and 20 ft. the deflections increased much more rapidly, and, as well as could be judged, the elastic limit of the material was passed somewhere between these two points. Between heads of water of 20 and 22 ft., the deflections of the stiffeners increased very rapidly indeed, though up to the latter head no leak showed at any of the butts or seams, although a few drops of water went through four or five rivets. Just as the water level reached the head of 22 ft., the lower brackets of the Z-bar stiffeners connecting them to the inner bottom plating buckled badly, as did also the brackets at the upper end of the stiffeners, where connected to the beams of the protective deck. The buckling of both upper and lower bracket plates decreased rapidly for the stiffeners near the ends of the bulkhead. At this head also the local deflection of the plating between the stiffeners was observed, and found to be very small, the maximum deflection in 4 ft. being ¼-in.; it, of course, being understood that the deflection referred to is that caused by the bellying of the plate between the Z-bar stiffeners, and is therefore more properly defined as the difference in the total deflection of the plating at such points situated midway between stiffeners and the corresponding deflection of the stiffeners themselves.

On attempting to increase the head of water above 22 ft., it was found that on reaching a head of 22 ft. 4 ins. the maximum deflection of the stiffeners increased very rapidly; the increase due to the 4 ins. additional head of water, and also the time element of the test, had resulted in an increase of maximum deflection from 2 13-16 ins. to 3⅝ ins. Under these circumstances and in view of the buckling of the lower brackets of the stiffeners, the test of the bulkhead was discontinued at this point, it being manifest that it could not stand a pressure due to the full head of water required by the specifications.

After the water had been entirely run out of the cofferdam, the deflections of the various stiffeners of the bulkhead were measured, and the stiffeners and brackets on the opposite side of the bulkhead, which had been in the cofferdam space and so could not be examined during the progress of the test, were then carefully inspected, and it was found that no rivets had been sheared, and the bracket plates remained perfectly plane, and, as far as could be determined, had not been permanently deformed. The heel, however, of the 3 ins. × 3 ins., 7-lb. angle clips connecting these brackets to the inner bottom plating were drawn away from the plating at the outboard ends of the clips to the extent of nearly 3-16-in. at the maximum, which occurred about midway of the bulkhead, and decreased to zero for the brackets of the two stiffeners which were adjacent to the ends. A study of the curves of deflection of the stiffeners is especially interesting as showing the marked influence of the support received from the transverse bulkheads in relieving the stiffeners next to them from strain. Thus, under a head of water of 22 ft., the maximum deflection of the forward end stiffener is approximately 1 3-16 ins., and the after end stiffener deflected 1½ ins., whereas the stiffeners in the central portion of the bulkhead deflected 2 11-16 ins.



Figs. 1 and 2.—Sketches Showing Results of Tests of Water-Tight Bulkheads on U. S. Battleship "Illinois" to Determine Their Resistance to Deflection.

Second Test.—In the second test the bulkhead was stiffened by re-enforcing the bracket plates at the upper and lower ends of the stiffeners with a 4-in. × 3-in., 9-lb. reverse-bar on the opposite side of the outer flange of the Z-bar stiffener (Fig. 1). The object of this test was clearly to demonstrate that the cause of the first failure of the bulkhead had been the want of strength of the stiffeners themselves, and not that of the brackets connecting the Z-bars to the inner bottom plating and the protective deck. The failure of the lower brackets had undoubtedly been the determining cause of the rapidly increasing deflection of the bulkhead at the time the testing was suspended during the first test, and it was desired to establish beyond doubt that additional strength was required for the stiffeners themselves, and that satisfactory strength of bulkhead could not be obtained by simply increasing the strength of the gussets themselves. The ship's main drain and other piping prevented the size of the brackets being increased at all on the starboard side of the vessel and, for this test, they were kept of the same size as in the previous test, but stiffened as described. The general method of conducting the test was similar to that previously followed, except that deflections of the stiffeners were measured at five points in the height of every stiffener.

Up to a head of 8 ft. above the inner bottom, the deflections were inappreciable. After that head, deflections were recorded with heads of 12 ft. 9 ins., 16 ft., 18 ft., 20 ft., 22 ft., 22 ft. 6 ins., 23 ft., 23 ft. 5⅞ ins., 24 ft., 24 ft. 6 ins., and 25 ft. 2⅝ ins., the latter height corresponding to a head of 5 ft. above the normal load water-line. At the latter head of water three records of the deflections of the bulkhead were taken; the first of these records was taken as soon as this head of water was reached, at 11.15 a. m.; the second one at 5 p. m., and the third at 10 p. m. Forty-five hours after the bulkhead was relieved from water pressure, a record of its permanent set was taken.

An examination of the records of this test shows the same general conditions as in the first test, in so far as concerns the influence of the transverse bulkheads upon the deflection of the stiffeners at the ends of the bulkhead under test, but that the additional stiffening given the brackets had been sufficient to prevent their buckling during the test; moreover, when the brackets in the port engine room were examined it was found that there was no measurable deformation of either bracket plates or angles as had previously been the case. In view, however, of the fact that under the pressure required by the specifications, namely, of a head of water of 5 ft. above the normal load water-line, the deflection of the bulkhead constantly increased with the length of time it was under test, it was evident that the stiffeners were strained beyond their elastic limit, and it was therefore decided materially to increase their strength. This was done by carrying a 4-in. × 3-in., 9-lb. reverse-bar for the full length of the stiffener, and of the brackets at both head and heel; and, in addition, by adding for the lower bracket a second clip for securing the bracket plate to the inner bottom plating, also a short reverse clip on the edge of the bracket plates, so that the strength of the new end connections would be proportioned to the strength of the reinforced stiffener.

Third Test.—The test was conducted in the same manner as the previous series. Up to a head of 12 ft. 9 ins. no deflections were observed. Above that head, deflections were recorded for 16 ft., 18 ft., 20 ft., 22 ft., 24 ft., and 25 ft. 2⅝ ins. At the maximum head of 25 ft. 2⅝ ins., or 5 ft. above the normal load water-line, three sets of measurements of deflections of the stiffeners were taken; the first of these records was taken as soon as the maximum head of water was reached at 1 p. m.; the second at 5.30 p. m., and the third at 10 p. m., the maximum head of water being maintained continuously until the last measurement was taken. Each of these records gave the same deflection for the stiffeners; in other words, the deflection of the bulkhead did not increase at all in nine hours, while under the test head of water called for by the specifications. The results of this final test may, therefore, be summarized as follows:

(1) There was no appreciable increase of deflection under the maximum head of 25 ft. 2⅝ ins. with a lapse of time of nine hours.

(2) The maximum deflection observed on any stiffener was 1¼ ins., and the maximum permanent set, measured twelve hours after the bulkhead was relieved of water pressure, was 5-16 of an inch.

(3) The maximum deflection of the bulkhead plating between stiffeners, observed during the test, was ⅝ of an inch, and after the test there was a corresponding permanent set of about ⅛ of an inch.

(4) The stiffener brackets in the starboard engine room showed no signs of buckling during the test. After the water had been pumped out of the cofferdam space, the brackets in the port engine room were examined and were found to be in perfect condition, no permanent deformation of any kind having occurred for either the bracket plates or the angles.

It was therefore decided that the strength of the bulkhead, as finally stiffened (Fig. 2), was thoroughly satisfactory, and the remaining nine similar bulkheads on the "Kearsarge," "Kentucky" and "Illinois" were reinforced in a similar manner.

The observation of the actual test, together with other similar experience, leads me to express my belief, first, that for bulkheads in which general strength to prevent collapse and not absolute water-tightness, is required, a wider spacing than the usual 30 ins. spacing is permissible, and that this increase may extend to as much as 4 ft., it being, of course, understood that the strength of the stiffener bars ars suitably increased; secondly, that in bulkheads in which the length is great relative to the depth, if subjected to considerable heads of water pressure, better results will be obtained if one or more deep belt stiffeners are worked in connection with intermediate stiffeners of moderate weight, rather than that all the stiffeners should be uniform depth and strength; it being, of course, understood that the spacing of all stiffeners here referred to may be as much as 4 ft. between any two of them. Such a general arrangement of stiffeners can be made lighter for a given strength than with a uniform spacing and weight of stiffeners, such as exists in the center-line bulkhead whose tests have been described.

SINGLE COPIES of any number in current year,* 15 *cents.*

In ordering changes of mailing addresses, state BOTH old and new addresses; notice of change should reach us by Tuesday to be effective for the issue of the current week. The number on the address label of each paper indicates when subscription expires, the last figure indicating the year and the one or two preceding figures the week of that year; for instance, the number 328 *means that subscription is paid to the* 32d *week (that is the issue of Aug.* 11) *of the year* 1898; *the change of these figures is the only receipt sent, unless by special request.*

ADVERTISING RATES: 20 *cents per line. Want noticees, special rates, see page* 18. *Rates for standing advertisements sent on request. Changes in standing advertisements must be received by Monday afternoon; new advertisements, Tuesday afternoon; transient advertisements, by Wednesday noon.*

The Navy Department has done well in revising and improving the plans for the four new monitors ordered at the last session of Congress. It would do still better if it should induce Congress to repeal this appropriation and allow the $5,000,000 to be used for some type of vessels which would be a real addition to our naval strength. The fact is that the monitor is an obsolete type of warship; and it is ridiculous for the United States to continue their construction. In the appropriation bill by which their construction was authorized, they were referred to as "harbor-defence vessels"; and it is conceivable that in the smooth waters of a harbor, a monitor might give a good account of itself in a naval engagement. But naval battles are no longer fought in harbors and are little likely to be in the future. There was a period when the construction of harbor-defence vessels was appropriate. That was when the range of naval ordnance was so small that the defences of a harbor were placed in the harbor itself. At a later date, too, the rapid advance in the power of guns made all the old-time masonry forts obsolete, and it was necessary to meet ship with ship for purposes of defence. Now, however, the invention of the high-powered rifled mortar and the disappearing gun carriage and the perfection of systems of submarine mines have entirely revolutionized the science of naval attack. Nearly all the important harbors of the world are to-day absolutely impregnable. Modern naval vessels are powerless against modern land fortifications. Warships are designed, therefore, only to attack the vessels of an enemy, and that attack must be made in the open sea, not in the smooth waters of a harbor.

Of what use, then, is the monitor? Our naval officers found by experience in the recent war —what they knew before—that the monitors were worse than useless to take part in fleet actions. On the long voyage of Sampson's squadron to Porto Rico and back, the monitors of the fleet held the other vessels back, and were generally more of a nuisance than all the rest of the fleet combined. The only thing left for the monitor to do, then, is to operate independently; but in this field, too, it is equally ineffective. It can neither catch any vessel which it can whip or run away from any of superior force. It offers a shining mark for torpedo boats, since it has too little secondary battery to make the attack of such vessels dangerous, and its slow speed makes it a good mark. Finally, it is so unsteady that good shooting from its guns is practically impossible in a seaway; its low free-board and quick roll subject it to peril at every storm, and life upon it at sea is constant misery for officers and crew. In view of all these well-known facts, it ought to be possible to secure a repeal of the law ordering the construction of these vessels. The taxpayers of the country will have no objection to seeing $5,000,000 come back to the treasury; or, if it is desired to use it for the increase of the navy, let us at least build vessels of modern type, instead of vessels which are obsolete before they are begun.

The present agitation over the effect of the Chicago drainage canal upon the water supply of St. Louis would be more impressive if there were not reasons for believing that it is prompted, to some extent, by other than sanitary considerations, and if those city officials most directly responsible for the purity of the water supply and the welfare of the city were not either silent or very convervative in their comments on the subject. It seems rather late in the day to demand a national investigation of this matter, now that so many millions have been spent and the work is so nearly done. There have been similar attempts before, but they came to nothing.

Whatever the real merits of the case, it is certain that Chicago is only one of many cities already polluting the water flowing by St. Louis, and that the latter city does not call in question its own conduct in discharging its sewage into the same stream, for the benefit of Memphis, New Orleans and other cities below. The new drainage canal will undoubtedly result in sending more of the Chicago sewage towards St. Louis than now goes in that direction, but it will greatly increase the dilution. The law requires a flow of 20,000 cu ft. of water per minute in the canal for every 100,000 population, or over 1,800 gallons per capita per day, so the sewage starts out more than 300 miles above St. Louis with much dilution. This dilution is gradually increased as Illinois is traversed. Before St. Louis is reached the Mississippi and Missouri dwarf the original volume of sewage to insignificant proportions.

But for all this it is perfectly proper for St. Louis to inquire how much its water supply is going to be endangered by any disease germs that may survive the conflict for life during the long journey from Chicago. The reduction in the original number of disease germs will be immense, since they die, rather than multiply, out of their natural element, and will be deposited along the bed and banks of the stream for more than 300 miles; there, too, to succumb to adverse influences. The number that may finally reach the St. Louis intake will be scattered through hundreds of times the original volume of the water that conveys them. It is quite probable, though we do not pretend to have definite information, that towns of comparatively insignificant size, not far above St. Louis, will endanger its water supply more than the discharge of the Chicago drainage canal, while if the latter is to be feared far greater danger has existed for years from the sewage of Chicago, St. Paul, Minneapolis, Omaha, Kansas City, and scores of smaller places in the Mississippi drainage area.

Settling basins and filter beds were recommended for St. Louis by the late Mr. Jas. Kirkwood, some thirty years ago. Certainly, if they were needed then they would be of far greater value now. The settling basins were provided and they have been included, on a larger scale, in the new works for St. Louis. Studies for filtration have also been prosecuted there for some years past, and doubtless a filter plant will be installed inside of five or ten years. In any event, St. Louis should not rely too much on national action, which is likely to be slow, at best, so great is the inertia to be overcome in all attempts at national sanitary legislation. When they feel that the proper time has arrived, we believe the city officials of St. Louis will come forward with plans to fully protect the water supply. To many outsiders it seems as though the time had already arrived.

Elsewhere in this issue is given a brief abstract of a paper describing a recent application of electricity to factory operation which clearly shows some of the advantages to be derived by substituting individual electric motors for the usual array of shafts, pulleys and dust-disturbing belts.

The plant in question is that of a large Chicago printing establishment, which has recently been moved to Hammond, Ind., where an entirely new plant has been erected. This was built from plans which, with one important exception, seem to have been prepared with unusual care, so far as we can judge from a somewhat cursory examination. The one exception referred to is the placing in one enormous building, under a single roof covering a space of about 218,000 sq. ft., all the departments of a great manufacturing plant. So far as we can ascertain from the published descriptions and illustrations of this building, there is nothing whatever to prevent a fire starting in any part of this great room from sweeping over every part of it, destroying the entire plant and very likely proceeding with such rapidity as to give many of the operatives no time to escape.

We call attention to this, not for the purpose of criticising this particular manufactory, which may, perhaps, have safeguards against the spread of fire of which we are not informed, as to emphasize the fact that very few factory buildings are planned with equal attention to all the different details that should be considered in the design. The chances are that the proprietor has one particular thing into his mind as the thing of all importance, and other matters receive minor consideration. For example, in the W. B. Conkey plant, referred to above, the matter of securing the best possible light seems to have been the controlling consideration. To obtain this, the saw-tooth or weaving shed roof has been adopted, notwithstanding the well-known objections to it in a climate of heavy showfalls; and the entire plant has been placed on the ground floor, and in a single building. The fire risk that is involved in this we have already alluded to; and it is also apparent that the maintenance account for keeping in repair this great area of roof will amount in a few years to a large figure. By making the structures two stories instead of one story in height, and placing the various departments in separate buildings connected by covered runways, the roof area and the ground floor area subject to rapid decay would have been nearly halved, the lighting might have been made almost equally good, communication between different departments might have been made equally easy, and the danger of a total fire loss of the whole plant might have been greatly reduced.

The textile manufactories are almost the only ones in the country which have come to fully appreciate the fact that in the matter of fire protection an ounce of prevention is worth a pound of cure, and that the time to prevent the destruction of a plant by conflagration is when it is first laid down on the drawing board. In other manufacturing industries far too little attention is paid to planning for fire protection, the owner or superintendent generally sees to it that the arrangements for communication and transport throughout the plant suit his ideas and leaves the rest to the architect. In nine cases out of ten the architect is a local man, who has never made any special study of the requirements for heating lighting, fire protection, etc., in factory buildings. Under these circumstances it is not strange that money is wasted in some directions and squandered in others, and that poor light, defective and uneconomical heating facilities and standing invitations for the spread of fire are far too common, even among those modern factory plants which are pointed to with pride by their owners as models of good construction.

The excellent form of annual report of waterworks systems adopted years ago by the New England Water-Works Association, and used by quite a number of works in and out of New England ever since, seems to have been overlooked

in the discussion of forms for such reports at the recent meeting of the American Society of Municipal Improvements. The proposed new form appears to be a good one. Perhaps it contains some valuable features not included in the old one, but probably more would have been gained by bringing the old one to the attention of the association and recommending its adoption. Without an actual count of items it appears that the new form is longer than the old one. Many of the water-works using the New England form do so only after abbreviation. Until the compilation of municipal statistics under a uniform system is made compulsory, and entrusted to competent central administration, all attempts at uniformity should proceed along simple and easy lines, and the aim should be to increase the use of such existing forms, as are meritorious and well-established, rather than to secure the adoption of new ones.

◆

THE NEW RAILWAY CONSTRUCTION OF 1898.

The steady decrease in railway construction in the United States which followed the "boom" years of 1886 to 1888, seems to have reached its lowest point in the figures of 1895, and to be now turning into a slow and healthy increase. The best available information indicates that the mileage of new railway line completed during the twelve months of the calendar year now drawing to a close will not fall far short of 3,000 miles. In 1895, according to Poor's Manual, 1,603 miles of new railway were built; in 1896, 1,668 miles, and in 1897, the greatly increased total of 2,094 miles. With 3,000 miles of new road, the year 1898 will present the largest figures of new construction since 1892, when 4,419 miles were built.

A general survey of the new work of 1898, shows the South and Southwest to have been the fields of greatest activity, while in the New England states, with one exception, construction has been almost nil. Important individual lines have been built in Maine, Pennsylvania, North Carolina and California, but it is the states of Alabama, Texas, Louisiana, Arkansas, Oklahoma, Missouri and Minnesota, all essentially Southern and Southwestern states, with one exception, which exhibit the longest lines and the greatest aggregate mileage of new road. Canada and Mexico have both added somewhat to their railway mileage during the year. Most of the new Canadian work has been done in the far western provinces, and the most notable single line is doubtless the new extension of the Canadian Pacific Ry. through the Crow's Nest Pass of the Rocky Mountains (Eng. News, March 10, 1898), to reach the rich Kootenay mining districts. The wilderness opened up by this line is exceeded only by that penetrated by the new narrow gage line to the Klondike, by which Alaska for the first time adds her quota to the new railway construction of the United States.
